A significant abundance of bacterial-mediated carbonate-bearing fluorapatite (CFA) nodules in the lacustrine shale of the Dongying Depression in Bohai Bay basin was found with variable occurrence on drilled core samples. However, there is no systematic description and analysis, and the lack of mineralogical and geochemical studies limits specific understanding of the formation process and environmental instruction of the nodular CFA. In this study, CFA nodules obtained from three boreholes were analyzed to specify their petrology and chemical composition of trace elements (TEs), Rare earth elements and yttrium (REY). An integrated approach, including Scanning Electron Microscope (SEM), Cathode luminescence (CL), Micro Fourier Transform infrared spectroscopy (Micro-FTIR), electron microprobe analyzer (EPMA), and Laser ablation-inductively coupled plasma-mass spectrometry (LA-ICP-MS), were carried out. The result suggests that Ca (25.85 to 39.95 wt.%), P (17.19 to 29.35 wt.%) and F (0.71 to 2.99 wt.%) are the dominant components of the CFA nodules, with very low Mn/Fe ratios and few incorporations of CO32-. They always present as black nodular shape, and lie within both the micritic calcite lamina (Type A nodules) and clay and organic-rich lamina (Type B nodules) of the laminated shale. Electron microscopic observation of a porous nanostructure corresponding to substantial nanoscale micro-crystals and occasionally pellet (1 to 3 μm in diameter) for the CFA, probably related to the bacterial activities. REY concentration was normalized against the Post-Archean Average Shale (PAAS), showing weak negative Ce anomalies, obvious negative Y anomalies and typical “hat-shape” patterns, in which type B nodules obtain strong depletion of HREE. Contents of typical transitional elements such as Co, Ni, Cu, V and Zn are extremely low compared with the marine CFA nodules, while Sc, Sr, Zr, Ba, Th and U are relatively enriched. All of the petrology and geochemical compositions suggest that the formation of the CFA nodules is correlated with the terrigenous inputs of hydrogenetic ferromanganese oxide, especially for the Fe-oxides, which prefer absorption of the REY components with low Y/Ho ratios (18.4 to 28.9, average of 23.9) in the water column before deposits. Once the Fe-rich oxide components settled within the oxic/suboxic interface, dissolution of the Fe-oxides occurred with the release of magnitude P and REY with MREE enrichment to pore waters. It seems to be the significant process that resulted in the recapture of the inherited P and REY due to favorable precipitation of carbonate-bearing fluorapatite. The circumferential pellet of the microcrystals of the CFA reveals the bacterial activities, mostly like the sulfate-reducing microorganism that framboidal pyrite was also observed within the CFA nodules. Our data points to the fact that the nodular CFA in lacustrine shale in Shahejie Format of the Dongying Depression probably formed during the early-stage diagenesis beneath the suboxic zone with bacterial mediated, and utilize of the weak Ce negative anomalies and “hat-shaped” REY patterns should be cautious for lake ecology study.

Widespread Putrefaction After the Marinoan-Nantuo Snowball-Earth Glaciation

Dominic Papineau[1,2,3,4*], Zhenbing She[1], Liangxuan Jiao[1], Shuzhan Liu[1], Gary Tarbuck[2], Deng Liu[1], Genming Luo[1], Chao Li[1]

Keywords: phosphorite, botryoid, granule, fossil, Neoproterozoic, Raman

The Neoproterozoic Nantuo glaciation was followed by atmospheric oxygenation, phosphogenic events and the rise of animals, all well-recorded in South China. While the origin of ^{13}C-depleted carbonate in these rock formations suggests the oxidation of organic matter, there lacks a sedimentological connection with the Neoproterozoic Oxygenation Event. Here we show that various self-similar patterns occur in diagenetic spheroids such as botryoids, rosettes, granules, and concretions, which are widespread in the Ediacaran Doushantuo Formation. The distinct radial and circularly concentric geometry in diagenetic spheroids spans several orders of dimension size, as do fractal patterns. These rounded mineralised self-similar objects are also composed of mineral assemblages variably including quartz, apatite, carbonates, oxides, sulphates and sulphides. Cations and anions in these compounds are suggested to represent redox-sensitive analogues to reactants, intermediates, and products in chemically oscillating reactions. In addition, diagenetic spheroids are associated with structurally highly variable forms of organic matter, suggesting out-of-equilibrium conditions during diagenesis and sub-greenschist metamorphism, consistent with chemically-oscillating reactions soon after deposition. The new observations and model lead to the suggestion that post-snowball oxygenation caused widespread oxidation of biomass, and that this produced diagenetic spheroids through the oxidation of biomass and preserved through a combination of putrefaction and later diagenetic fluids enriched with residual phosphate, carbonate, halogens and sulfide. The role of TiO_2, as commonly detected in anatase and rutile inside diagenetic spheroids remains uncertain, but appears linked to the degradation of organic matter. We conclude that diagenetic spheroids link sedimentology and organic geochemistry, and in turn, elegantly but imperfectly explain post-snowball perturbations in biogeochemical cycles and the exceptional preservation of fossils

Lower-Permian Lacustrine Microbial Buildups in a Cyclostratigraphic Context from Bogda Mountains, NW China

Yiran Lu[1], Wan Yang[1*]
1. Geology and Geophysics, Missouri University of Science and Technology, Rolla, Missouri, UNITED STATES
E-mail: yangwa@mst.edu

Keywords: Microbial buildups, Lacustrine Microbialite, NW China

Microbial buildups in lake deposits of lower Permian Lucaogou low-order cycle in Zhaobishan, Bogda Mtn., NW China, occur in 12 high-order cycles (HC) in a 20-m succession. They overlie transgressive oolite or conglomerate and underlie regressive deltaic sandstone. They are mound-shaped and coalesced, 10s of cm wide and 10-50 cm high. Data from 40 thin sections show that mounds contain thrombolite, stromatolite, wackestone, and packstone. Thrombolites consist of lumps separated by cements and sediments. Lumps comprise clustered clots and calcite cements, are 1-4 cm in size, and show upward and lateral growth patterns. Clots are 10-100 microns in size and equant. Sediments between lumps include micrite, extra- and intraclasts, and patches of clots without a growth pattern. Stromatolites are laminated or digitated, domal or wavy. Wackestone is mud rich and contains extra- and intraclasts and clots. Packstone contains oncoids and extraclasts, lumpy micritic matrix, and calcite cement. Oncoids are mm in size, have uneven cortices of clotted micrite and rare sparry calcite with a wrinkly surface. Micro-analysis shows that generally all lithofacies contain copious nano-globules (50-200 nm) and muscus-like films. Globules assemblage to form micrite crystals in micritic matrix, thrombolitic clots, and coating of oncoids. Stromatolites also have voids (1-5 μm in diameter) in laminations. In a mound, thrombolite is dominant; stromatolite and wackestone are mainly in the lower part; and packstone in the top part. Upward in the lower part of the succession, mounds become larger and higher in relief; the amount of extraclasts decreases. In the upper part, the trend reverses and the amount of oncoids increases upward. The nano-globules and muscus-like films have similar texture of microbially-induced carbonate precipitation in modern and ancient analogues. The voids in stromatolitic laminae are similar to relicts of carbonate-replaced EPS alveolar structure. These suggest that basically all lithofacies in buildups are closely related to on microbial-induced carbonate. The thrombolites formed in quiet shallow lake; and episodic storm agitation and clastic influx and water depth change produced stromatolite and wackestone. The presence of clastic nuclei, agitated water, and fast micritic precipitation induced by microbial activities formed oncoids. Lake water was likely rich in Ca to provide nutrients for microbes and precipitate calcite. The mounds occur in the maximum-transgressive interval of HCs when the lake was deepest and clastic influx smallest. The thickness of buildups is inversely related to that of overlying deltaic deposits in HCs. The increased flux of freshwater and clastics during delta formation reduced the Ca concentration and hampered calcite precipitation and microbial activities. Thus, climate was relatively arid during transgression and humid during regression during the formation of both the lower and upper parts of the succession.

Microbial Origin of botryoidal dolostones in the Dengying Formation, Sichuan Basin

Xiufen Zhai[1*], Songtao Wu[1], Hua Jiang[1], Ping Luo[1], Zhidong Gu[1], Guixia Liu[1]
1. Petroleum Geology Department, Research Institute of Petroleum Exploration & Development, PetroChina, Beijing, CHINA
E-mail: zhaixiufen@petrochina.com.cn

Keywords: Botryoidal, Dengying, Filament, Extracellular polymeric substances (EPS), Microbialite, Sichuan Basin

Microbialites are abundant in the upper Sinian Dengying Formation of the Sichuan Basin, SW China; and are important exploration objects for deep oil and gas. Although they have been extensively discussed because of the old strata, deep burial and complex evolution history. However, there is no consensus on the microbial impact on their deposition and reservoir origin mechanism. This study focuses on botryoidal dolostones in the Dengying Formation from typical outcrops and wells of the Sichuan Basin. The botryoidal dolostones in Dengying Formation are classified and evaluated by means of core-outcrop observation, thin section identification, cathodoluminescence (CL) and field emission scanning electron microscopy (SEM). The mechanism of microbial coating and its influence on reservoir quality are discussed. The main understandings are as follows: (1) There are three macroscopic morphological types of botryoidal lamination: stromatoid lamination, cavity-lining lamination, and spherical-encrusting lamination. They are all composed of interbedding bright-dark lamina. The deposition mechanisms can be divided into two categories: microbial mat and biofilm growth. The botryoidal lace structure was mainly formed by biofilms. (2) Evidences of microbial origin, including tubular sheath bodies and forms of EPS, are observed under the high resolution SEM. Three mineralization methods, microbial controlled, microbial induced and microbial influenced are classified according to the occurrence and morphology of microbial activities evidence. (3) Mineralization of sulfate reducing bacteria is divided into three evolution processes. Phase 1 with less than 1 μm micro dumbbell shaped ball attached to cleavage plane; the second phase mainly 5~25 microns' dumbbell and single ball attached to dolomite crystal plane; the third phase with diameter greater than 25 microns of ball aggregation growth within the pore space. (4) The microbial mineralization mechanism determined the dolomite crystal distribution and primary pore structure, and influenced the subsequent diagenetic transformation. From the perspective of reservoir formation mechanism, microbial coating formed rock skeleton resistant to compaction and beneficial to the subsequent karst. (5) The microbial coating formed different reservoir rocks. Reservoir space in cavity-lining lamination and spherical-encrusting rocks are dominated by cavity dissolved pores, mold pores and intergranular pores, while the reservoir space of stromatoid lamination is dominated by fenestral pores and bird's eye pores. In general, the cavity-lining lamination and stromatoid lamination formed better reservoir rocks than spherical encrusting. The results are useful in understanding the origin and formation mechanisms of the Neoproterozoic microbialites. The new findings may also shed new light on the occurrence and evolution of early life on Earth in the Precambrian Era.

E-mail: mathilde.mercuzot@outlook.com

Keywords: microbial deposits, Paleozoic, non-marine, carbonate precipitation, eastern Pangea

Western Europe continental basins of the late Carboniferous–Permian period formed in Eastern Equatorial Pangea during a major climate and geodynamic changes: the icehouse–greenhouse transition corresponding to the demise of the long-life Late Paleozoic Ice Age, and the dismantling of the Variscan belt. Siliciclastic sedimentary successions corresponding to fluvial, deltaic and lacustrine deposits are increasingly studied to understand their environmental response to climate and geodynamics at low paleolatitudes.

These basins are punctuated by scarce periods of carbonate sedimentation, potentially induced by microbial development; however, the origin of these deposits is still poorly addressed to that day, while it implies very peculiar environmental and climate conditions. We selected such carbonate deposits from four French Late Paleozoic basins (Autun, Aumance, Decize–La Machine and Brive basins) to address two main questions, regarding (i) their biogenicity, still unclear for these specific deposits because of the diagenetic overprint, and (ii) the driving factors of such deposits, formed in a carbonate-free continental setting.

At the scales of the macrofabric (crusts, domes, cauliflowers and flat-to-wavy structures) and the mesofabric (laminated, clotted, structureless, columnar and branching), microbial-related structures appear clearly, but at the microfabric scale, an intense recrystallization (dolomite or silica) prevents the observation of direct biological evidence. Features such as oncoids and irregular peloids, combined with the observation of a lateral replacement of irregular micritic laminea by diagenetic cements, are in line with a biotic origin, whereas shrubs and spherulites are more indicative abiotic processes. Therefore, these structures seem to result from a biotic-abiotic continuum.

We suggest that the high regional volcanic and hydrothermal activities, attested by contemporaneous volcanogenic rocks and specific mineralizations, as well as high-resolution climate modifications (e.g., humidity-aridity variations), have triggered episodic physical and chemical modifications in the lake, favoring the carbonate precipitation and the mineralization of microbial mats.

Beyond understanding Eastern Equatorial Pangea environments and climate, these deposits also address questions largely debated in the microbialite scientific community for deep-time non-marine carbonate precipitation.

E-mail: qdxhong@163.com

Keywords: Xisha Islands, Reef building of plants, Red algal reef framework rock, Chlorella and raeanum nodule schist, Algal reef dolomite

This paper reviews 49 years of exploration and discovery, 39 years of exploration and 30 years of algal reef research in the South China Sea, focusing on the frontier, hot spots and weak links of basic research. It is pointed out that China has already formed the algae research enthusiasm of family exploration Wells in Xisha Islands, and obtained the main discoveries of three family exploration Wells in two major atolls and the identification of algae species and comprehensive research understanding of core samples. The characteristics of the fossil types of phytoalgal reefs are clarified, and the observation of one hole forms the observation of three holes. A variety of reef-building calcareous algae and their fossil types were identified, and they formed different structures and rock types of calcareous algae. This paper compares the results of algae reef, algae reef-building and case studies at home and abroad, and points out that the relevant theories have been established and reached the first class level since the formation of the Miocene reef in Xisha Islands, the formation of the early Miocene red algae coral reef, the formation of the late Neogene green Halimeda sp algae reef, and the formation of the algae reef dolomite since the formation of the reef.

Sedimentary evolution and control factors of beach bar sand body of the Upper Ganchaigou Formation in Zhahaquan area, western Qaidam Basin

1*

1. , , , , CHINA
E-mail: dingyh_04@163.com

Keywords: Beach bar,Paleogeomorphology , Upper Ganchaigou Formation,Neogene,Zhahaquan slope,Qaidam Basin

In order to further evaluate the oil and gas exploration prospect of the beach bar of the Upper Ganchaigou Formation in Neogene in Zhahaquan area, western Qaidam Basin, and predict the favorable exploration zone and exploration target, based on the comprehensive analysis of core observation and drilling / logging data, combined with the analysis results of rock slice, cumulative grain size probability curve, mud-land ratio of dark mudstone and sand-land ratio sensitive parameters, this paper carried out a detailed study on the development and evolution characteristics of beach bar of the Upper Ganchaigou Formation in this area. It is believed that the development and evolution of beach bar in Zhahaquan area is mainly controlled by the development and evolution of paleogeomorphology. The results show that : The braided delta-shallow lake sedimentary system was developed in the Upper Ganchaigou Formation in Zhahaquan area. The beach bar was developed, and the lithology was mainly lithic feldspar fine sandstone-ultrafine sandstone. The composition maturity was medium-poor, and the sorting roundness was medium-good. The particle size probability curve was mainly composed of two-stage jump and suspension reflecting wave action. Sedimentary structure types are diverse, mainly developed wave sand ripple cross bedding, wavy bedding, hilly cross bedding and lenticular bedding. During the sedimentary period of the Upper Ganchaigou Formation, the development scale of beach bar in the study area first increased and then decreased. From the early to the middle period, the development scale of beach bar continued to increase. Among them, the nearshore bar mainly expanded in the south and east directions, and distributed in the north-west direction. The farshore bar mainly expanded in the north-south direction, and distributed in the northwest-southeast direction. From the middle stage to the late stage, the development scale of beach bar decreases continuously. Among them, the nearshore bar mainly shrinks in the north-south direction and extends eastward, and the distribution direction changes from southeast to northeast. The farshore bar mainly shrinks in the north-south direction.During the deposition period of the Upper Ganchaigou Formation, the study area paleogeographic background of high in the west and low in the east, low in the north and low in the south, and high in the middle part. From the early to the middle, the paleogeomorphology highs in the middle of the study area continued to expand significantly to the east and southeast, and the scope was expanding. From the middle stage to the late stage, the range of paleogeomorphology high points continued to shrink in the north and northwest directions, and the range of paleogeomorphology high points in the southeast corner of the study area continued to expand northward. Comprehensive analysis shows that the development and evolution of beach bar of the Upper Ganchaigou Formation in Zhahaquan area is controlled by the source scale and the development and evolution of micropaleogeomorphology. Among them, the development and evolution of micropaleogeomorphology is the main control factor of the development and evolution of beach bar .

Sedimentation and sedimentary model of Fine-Grained Gravity flow Deposits within Lower Permian Fengcheng Formation, Mahu depression, Junggar Basin, Northwestern China

Youliang Feng[1*], Yang Zhi[1]
1. Department of Petroleum & Nature Gas Geology, Petrochina Research Institute of Petroleum Exploration and Development, Beijing, CHINA
E-mail: fyouliang@petrochina.com.cn

Keywords: Fine-grained gravity flow deposits, episodic rifting, rise and fall of lake-level, salinized rifted lacustrine Basin, Fengcheng Formation (P1f), Junggar Basin.

Mahu depression in Junggar Basin is an early Permian salinized rifted lacustrine Basin. Three third–order sequences are identified in lower Permian Fengcheng Formation (P1f). There are plenty of fine-grained gravity flow deposits in pro-delta to deep lake within the three sequences. Research on the fine-grained gravity flow deposits in Fengcheng Formation (P1f) has broad application for understanding the sedimentary processes and pattern of the fine-grained gravity flow systems, predicting the presence of “sweet spot” reservoirs in rifted lacustrine Basins for shale oil. The six kinds of fine-grained gravity flow deposits are identified by this research. They are concentrated density flow deposits characterized by normally graded bedded coarse-grained siltstone with mud-clasts; debris flow deposits characterized by deformed lumps of light grey siltstone, and silty clasts surrounded by laminated, or veined mudstone, soft sediment deformation structures, silty injectites, dykes and liquefied structures; mud flow deposits characterized by irregular, angular, and rotated silt clasts in the dark grey mudstone and the silt clasts contain small mud clasts as well; turbidity surge-like flow deposits characterized by normally graded bedded siltstones with scour surface; transitional flow deposits characterized by high frequency interbedding of laminated thin siltstone and mudstone; hyperpycnal current deposits characterized by a coarsening-upward interval and a fining upwardinterval couplet. The fine-grained gravity flow deposits in slope fan fringe show eight kinds of sedimentary associations: concentrated density flow deposits via transitional flow deposits to debris flow deposits; hyperpycnal current deposits; concentrated density flow deposits to debris flow deposits; turbidity surge-like flow deposits via transitional flow deposits to deep lake fallout deposits; transitional flow deposits to debris flow deposits, debris flow deposits to mud flow deposits; debris flow deposits to turbidity flow wake deposits; transitional flow deposits. Each sedimentary association represents a specific depositional process and transition of gravity flow rheology. There are many dolomite and calcite aggregates within the fine-grained deposits too. The research results indicate that the intensive episodic rifting of border faults and stretching of basement of Mahu depression during Early Permian Fengcheng period (P1f) , and climatic changes resulted in rise and fall of lake-level, volcanic eruption and deep-seated hot brine rising along faults. The tuff and the hot brine were mixed into the lake to salinize the lake. The fine-grained gravity flow deposits caused by the fall of lake-level and structural movements are “sweet spot” for shale oil, and deep lake mudstone with organic matter and turbidites deposited during rise of lake-level are good source rock and “sweet spot” reservoirs for shale oil.

Sedimentary characteristics and main controlling factors of thick sublacustrine fans in Dongying Formation, Bohai Sea

xiaojun pang[1,2*], guanmin wang[1], xiaofeng du[2], qingbin wang[2], liming dai[2]
1. School of Geosciences, China University of Petroleum, Qingdao, Shandong, CHINA
2. Bohai Petroleum Research Institute, Tianjin Branch of China National Offshore Oil Corporation Limited, Tianjin, CHINA
E-mail: pangxiaojunupc@163.com

Keywords: sublacustrine fan, delta front, slump deformation, sand-richness, Dongying Formation, Bohai Sea

During the depositional period of the Dongying Formation in the Bohai Sea, a large number of sublacustrine fan deposits developed. In recent years, a large amount of oil and gas has been discovered in the sublacustrine fan sandstone. Compared with thin sublacustrine fans, more hydrocarbons with commercial value are found in thick sublacustrine fan sandstones. Through casting thin section, scanning electron microscope and physical property analysis, it is found that thick sandstone is more conducive to the preservation of primary pores and the development of dissolved pores. Therefore, finding thick sublacustrine fan sandstone is the main problem to be solved in the future oil and gas exploration of Dongying Formation sublacustrine fan in the Bohai Sea. On the basis of 3D seismic comprehensive interpretation, using drilling data and seismic sedimentology, the sedimentary characteristics, distribution characteristics, triggering mechanism and sand-richness of sublacustrine fans are comprehensively studied. The following conclusions are obtained: (1) On the seismic profile, large-scale delta deposits with foreset reflection structures developed during the depositional period of the Dongying Formation in the Bohai Sea. A series of worm-like or lenticular sedimentary bodies developed in the deep lakes at the front of the delta. (2) Core observation shows that these sedimentary bodies are mainly composed of fine-coarse sandstone and a small amount of siltstone and gravel-bearing sandstone. It generally contains brown-dark gray mud-gravel and mudstone torn debris, and develops massive and graded bedding. Among them, the size and shape of the gravel are different, often elongated, sausage-shaped, intermittent, and potato-shaped. Some mud-gravel are rounded to a certain extent, and mud-gravel often develops on the top of positive-grained graded bedding. Mudstone tearing debris developed. The wrap deformation structure can be seen. It has Bowmar sequence and obvious slump deformation structure. Sublacustrine fan deposits are mainly caused by slump gravity flow. (3) Normal faults, strike-slip faults or abruptly steep terrains often develop between large deltas and sublacustrine fans. As the large delta continues to accumulate towards the lake basin, an unstable slope is formed in front of the delta front. Under the action of flood or earthquake, the unstable sandstone of the delta front slides towards the lake basin along the front slope. When encountering faults or suddenly steep terrain, it will continue to transport towards the lake basin. These sliding sandstones do not stop transporting until they encounter the blocking action of depressions or local uplifts, and accumulate in depressions or local uplifts to form slump-type sublacustrine fan deposits. The sandstone thickness of the sublacustrine fan is mainly controlled by the sand-richness of the delta front and the scale of the transported sandstone. The results can provide a basis for the prediction of sand-richness of sublacustrine fans in lithologic exploration.

Sedimentary Facies and Insights on Architectural Elements of the Deep-Lacustrine Chang 7, Ordos Basin, at TongChuan Area, China

Zhanlong Yang[1*]
1. Sub-Institute of Petroleum Strategy Planning , Northwest branchReswarch institue of Petroleum E&P, Petrochina, Lanzhou, Gansu, CHINA
E-mail: yang_zl@petrochina.com.cn

Keywords: Ordos Basin, Yanchang Formation, Chang 7, slope channel-levee, terminal splays, turbidity currents

As part of an effort to identify deep-lacustrine facies and architectural elements of the prolific Upper Triassic Yanchang Formation, Ordos Basin, China and provide some theoretical guidance about deep-water gravity flow deposit and conventional and unconventional oil and gas field exploration and development in the Ordos basin, seven outcrops in the Tongchuan area have been observed in detailed. The Yanchang Fm. is loosely subdivided into 10 oil bearing horizons, from 1 to 10 youngest to oldest respectively, and the focus of this research is the Chang 7, with some outcrops comprising portions of the underlying Chang 8, and the overlying Chang 6. Amongst the deposits, 10 lithofacies have been interpreted based on their lithology, grain size, bed thickness, presence of sedimentary structures, beds associations, and interpreted flow mechanisms. The dominant transport mechanism is interpreted as high- and low-density turbidity currents, with subordinate debris flow. Large sandstone deposits, previously described as massive sandstones and interpreted as sandy debrites, have been re-evaluated in detail and re-interpreted as amalgamated sandstones deposited by high energy high-density turbidity currents, mostly related to lacustrine slope channels. Inverse- to normal-graded deposits, potentially related to hyperpycnal flow deposits, have not been observed and though hyperpycnal flows might have triggered, they have been interpreted as indistinguishable from turbidity current deposits. Two outcrops Jiaquhe and Yanquhe sections dominated by interbedded deposits of disturbed and not disturbed graded sandstone to mudstones, ranging from few to tens of centimetres, interbedded with 1 to 3 metres thick amalgamated sandstones, forming intervals ranging from 6 to 20 metres thick, and laterally ranging from 600 to 1200 metres, have been interpreted as lacustrine slope channels. These deposits seem to decrease in thickness and amalgamation away from an axial area, until complete pinchout, forming U-shaped sandstone-rich geobodies. Deposits composed dominantly by interbedded thin-bedded graded sandstone to mudstone, with common occurrence of cross-ripple lamination 70-90% of the beds, interbedded with sporadic medium to thick sandstones, have been interpreted as levee deposits. Interbedded thin- to medium-bedded graded sandstones to mudstones, neither related to a confining surface nor adjacent to a slope channel, have been interpreted as terminal splays. The remaining fine-grained dominated deposits have been interpreted as slope to basin floor deposits.

Lacustrine and marine slope channels have similar characteristics, especially geomorphologically. However, they are substantially different in scale and in their architectural fill, with marine systems' fill highly depending on different orders of sea-level changes, and lacustrine systems probably more susceptible to positioning on slope and accommodation space changes.

Sedimentary characteristics of tuffaceous laminae in high gamma shale in Chang 7 Member of Yanchang Formation, Ordos Basin, China

Fuliang You[1], Guangdi Liu[1*], Mingliang Sun[1]
1. College of Geosciences, China University of Petroleum (Beijing), Beijing, CHINA
E-mail: guangdiliucupb@gmail.com

Keywords: Tuffaceous laminae, High gamma shale, Yanchang Formation, Ordos Basin

A large number of tuffaceous laminae have been found in the high-gamma shale in the Chang 7 Member of the Yanchang Formation in the Ordos Basin. The thickness of these tuffaceous laminae is mainly in the order of millimeters, and the thickness is mainly distributed between 1 and 5 mm. Through the observation of rock slices, it is found that three types of tuffaceous laminae are mainly developed in the high-gamma shale of Chang 7 Member. The three types of tuffaceous laminae are wavy laminae dominated by volcanic dust, horizontal lamina dominated by angular volcanic vitreous debris, and horizontal lamina dominated by volcanic crystal debris. Multi-stage reverse-order bedding can be seen in the horizontal laminae with volcanic crystal debris as the main component, indicating that its formation is related to gravity flow deposition. Under the condition of oil immersion blue fluorescence, the light oil flow with green fluorescence is enriched in the crystal particles, indicating that its storage properties are good. The total organic carbon content of the adjacent high-gamma shale can be greater than 20%, but the analysis of main and trace elements and the analysis of pyrite particle size show that its depositional environment is a sub-oxidative to sub-reducing environment (Yuan et al., 2017; Chen et al., 2020), but the traditional view is that organic-rich shale deposited in a reducing environment Fluorescence observation shows that the macerals in the organic-rich shale laminae are mainly stratiform algae. However, if the depositional environment is under absolute reducing conditions, it is impossible for so many stratiform algae to grow and reproduce in situ. Based on this, we believe that gravity flow deposition not only brought volcanic tuff rich in nutrients, but also brought an appropriate amount of oxygen, which ultimately promoted the development of stratiform algae in the shale of the high gamma section. Studying the sedimentary characteristics of organic-rich laminae and tuffaceous laminae is not only of great significance to the study of the depositional environment, but also of tuffaceous laminae can provide favorable storage space for shale oil.

New discovery of sandy clastic flow sand body and its significance of oil and gas exploration in Junggar basin, NW China

Hou Gangfu[1*]
1. experiment institute, Petrochina Hangzhou Research Institute of Geology, Hangzhou, Zhejiang, CHINA
E-mail: hougf_hz@petrochina.com.cn

Keywords: Junggar basin, Sangonghe formation, sandy debris flow, lithologic trap, Oil and gas exploration

Jurassic which shallower buried was the most important field to find high-efficiency oil and gas reservoirs in the hinterland of Junggar basin. After the breakthrough of lithologic reservoir exploration of well SN31 in 2004, a number of exploration wells were deployed according to the lithologic trap pattern of well SN31, all of which were declared to be unsuccessful1. At present, there had been no major breakthrough in the exploration of oil-gas in the abdomen in the past 15 years. The key problem restricting the breakthrough in the exploration of oil-gas was that the lateral shielding conditions of sandbodies are not implemented, and the lithologic traps were not implemented. According to the current situation of oil-gas exploration in the abdomen, the exploration degree of low convex was higher than that of depression area. Were effective sand bodies developed in the depression? Does the sandbody had lateral shielding conditions? Was lithologic trap implemented? These key problems restricted the next step of exploration. Therefore, it was urgent to reorganize the genetic types and lithologic trap conditions of the sand bodies in the southern depression, established a new lithologic trap model, and found a new replacement field. On the basis of fully absorbing the previous research results, through core observation, heavy mineral analysis, reservoir characterization and seismic reflection characteristics analysis, the paleogeomorphology, sedimentary microfacies, reservoir properties and oil-gas properties of the second member of Sangonghe Formation in the western Pen-1 depression were analyzed, and the typical sandy clastic flow sand bodies, top, bottom and side, were proposed The directional blocking condition was better, and the lithologic trap condition was superior. The results showed that the second member of Sangonghe formation around the western Pen-1 depression develops multi-stage ring-shaped slope break, the sand body of delta front was developed above the slope break, and under the trigger of Yanshanian tectonic activity, the sand clastic flow sand body was formed under the slope break. Compared with other basins at home and abroad, the identification mark of sandy clastic flow sand body retained the reservoir physical properties and oil-gas properties of the front facies sand body, which was the most favorable exploration field for the next oil-gas exploration. This recognition had been applied to the well location deployment of oil field and achieved good application results. According to this understanding, well QS2 was deployed for the sandy clastic flow sand body under the slope break in the oilfield, and a major breakthrough was made after drilling. The breakthrough of well QS2 broke the deadlock of exploration for lithologic reservoir in the abdomen, opened up a new scene of exploration for large-scale lithologic reservoir in the depression, and confirmed that the sandy clastic flow sand body under the slope break had the conditions for forming large-scale lithologic reservoir.

Sedimentary response of transitional flow transformation revealed in shallow lacustrine hyperpycnites

Luxing Dou[1*]
1. College of Resources and Environment, Yangtze University, wuhan, hubei, CHINA
E-mail: douluxing@hotmail.com

Keywords: hyperpycnal flow,transitional flow,sedimentary response,flow transformation

In recent years, hyperpycnal flow has become a hot topic in gravity flow sedimentology research. Most past work concerning sedimentary dynamics interpretation has been founded on concepts based on fully turbulent flows. In recent years, flume tank research has revealed that hyperpycnal flow can transform from turbulent flow to laminar flow influenced by clay minerals. However, interpretation of transitional flows in ancient sedimentary rocks is still a question to be answered. In this study, lacustrine hyperpycnal flow generated channel-lobe deposits were interpreted in the Cretaceous Nenjiang Formation in the southern Songliao basin. The sand-mud mixed deposits are formed under river flood events which reflect waxing and waning sedimentary process. Typical transitional flow related sedimentary structure are also found in those channel-lobe deposits. Using cores and well log data, sedimentary interpretation is conducted to reveal the controlling mechanism of flow transformation in lacustrine hyperpycnal flow deposits. The flow transformation could be related to the erosion process which bring mud deposits to the hyperpycnal flows. The yield strength of the flows is modulated with the flow types of the transitional flows in the depositional process. At last, flow transformation process model and controlling factors in hyperpycnites will be proposed based on the lacustrine sedimentary records.

4. Geological Department, Northwest University, Xi'an, ShannXi, CHINA
E-mail: jgpang@xsyu.edu.cn

Keywords: Architectural elements,Lithofacies associations,Turbidite channels and lobes,Deep-lacustrine fans,Ordos Basin,China

Turbidity currents are the main process responsible for the delivery of sediment to deep marine and lacustrine environments. Turbidite sandstones form favorable petroleum reservoirs worldwide, commonly in marine successions, but in some cases also in lacustrine successions. Compared to marine environments, lacustrine systems differ significantly in terms of processes and sequence stratigraphy. The frequency, rate and magnitude of lake level fluctuations may be higher, and water salinity can be considerably different than in marine settings. As such, the main characteristics of turbidites in lacustrine environment may differ from those of their marine counterparts. The recognition and analysis of turbidites in deep-lacustrine fans from the Triassic Yanchang Formation (Ordos Basin, China) can guide the establishment of an effective criteria for understanding turbidity current deposition in lacustrine basins. These criteria can aid palaeogeographic restorations, which are critical for guiding subsurface exploration and exploitation of hydrocarbons.

During the late Triassic, the Ordos Basin was occupied by a huge lake. The rapid subsidence in the southern part of the Ordos Basin (foreland basin) was a consequence of the rapid uplift of the Qinling Mountain. The Yanchang Formation is dominantly composed of fluvial-deltaic-lacustrine deposits, and is internally subdivided into 10 Members. Deep-lake turbidites are mostly found in members Ch-7, Ch-6 and Ch-1.

This work mainly focuses in the analysis of architectural elements recognized in a turbidite fan outcrop succession of the Yanchang Formation located at the southeast of Ordos Basin. From outcrop studies, a new classification scheme of lithofacies and lithofacies associations for lacustrine turbidite fan strata has been proposed. Different deep-lake channels (i.e., slope channel, leveed channel), and lobe subenvironments have been identified. These architectural elements are juxtaposed vertically and laterally. The controlling factors for the development of lacustrine turbidite fans in the Yanchang Formation are also discussed. Based on the above observations and interpretations, a new depositional model for lacustrine turbidite fans (including the evolution of architectural elements) in the Late Triassic Ordos Basin has been proposed.

Sedimentary System Distribution and Lithologic Trap Characteristics of the 2nd and Lower 1st Members of Shahejie Formation in the South of Western SagLiaohe Depression

song bing[1*]
1. Experiment, Petrochina Hangzhou Research Institute of Geology, Hangzhou, Zhejiang, CHINA
E-mail: songb_hz@petrochina.com.cn

Keywords: Western Sag,Shahejie Formation,Sedimentary System,Lithologic Trap

Western Sag of Liaohe Depression is a typical Mesozoic and Cenozoic oil-rich fault sag which have been explorated for many years with very high exploration degree. In order to promote the process of tapping potential and increasing reservoir in the south of western sag, under the isochronous stratigraphic framework of 1st and 2nd Members of Shahejie Formation, the sand units are finely divided according to the sedimentary cycle and flooding mudstone. Combined with core, logging and seismic data, the types and distribution characteristics of sedimentary system are analyzed, and the development characteristics of lithologic traps are studied. The results show that the 2nd and lower 1st Members of Shahejie Formation in study area can be divided into 5 sand units, including 3 in 2nd Member and 2 in lower 1st Member. There are mainly three types of sedimentary facies: fan delta, slump turbidity fan and lacustrine. In study area, the fan delta mainly develops the underwater distributary channel sand body, and the lithology is gray cross bedding, parallel bedding sandstone and sandy conglomerate with scouring surface relatively developed, which is poorly sorted and moderately rounded; at the far side, anti grain sequence silt-fine sandstone estuary bar and far bar are often developed. The lithology of slump turbidity fan is mainly dark gray argillaceous sandy conglomerate, and crumpled and torn argillaceous gravel are developed. The main lithology of lacustrine facies is gray dark gray mudstone, and gray anti grain sequence silt-fine sandstone beach-bar sand bodies are locally developed. Laterally, controlled by paleogeomorphology, fan delta sand bodies are developed in a large area on both steep and gentle slopes, and the gentle slope extends further to the lake than the steep slope. In Yuanyanggou sub-sag, the fan delta front sand bodies collapse at fault slopes which caused by the development of synsedimentary faults, and a large number of slump turbidity fans are deposited under the fault slopes. Because the existence of basement strike slip, an inherited underwater low uplift developped in the south of Shuangtaizi structural belt mainly depositing beach-bar sand bodies . Vertically, controlled by the evolution of lake level, a process of water entering and sand retreating from bottom to top is presented. The scale of fan delta and beach-bar are gradually reduced, and slump turbidity fan is increasing.Three types of lithologic traps are mainly developed in study area: lithologic updip pinch out traps, widely distributed in the structural inversion zone of steep slope fan delta; beach-bar lens traps, mainly distributed in the south of Shuangtaizi structural belt ; slump turbidity fan lens traps, mainly distributed in Yuanyanggou sub-sag . Yuanyanggou sub-sag and steep slope structural inversion zone are potential areas for lithologic reservoir exploration and storage.

Evolution of the depositional environment of the early to middle Permian Roseneath-Epsilon-Murteree strata in the Cooper Basin, Australia: a multidisciplinary revisit with new data

Fengtao Guo[1,2*], Peter McCabe[2], Zhiqiang Feng[1], Zhongmin Zhang[1], Jinrui Guo[1]
1. Dept. of Overseas Exploration & Project Evaluation, SINOPEC Petroleum Exploration & Production Research Institute (PEPRIS), Beijing, CHINA

E-mail: fengtao.guo@hotmail.com

Keywords: Facies analysis, Paleogeographic Reconstruction, Roseneath Shale, Epsilon Formation, Murteree Shale, Cooper Basin

The Early to Middle Permian Roseneath-Epsilon-Murteree (REM) strata of the Cooper Basin in Australia host substantial conventional and unconventional resources, and are believed to be the most feasible shale gas play in Australia. Despite their potential resource significances, the REM strata are poorly understood with regard to regional facies architecture and paleogeographic evolution. Using a multidisciplinary approach with robust data (facies analysis, petrology, wireline logs, and geochemistry), the sedimentary evolution of the REM strata is described within a new sequence stratigraphic framework defined by key surfaces identified from cores and wireline logs. Detailed facies analysis of over 1400 m of cores and wireline logs from nine wells identified twelve lithofacies and eight facies associations for the first time which reveal various depositional processes and environments. The REM strata are interpreted as a fluvial-deltaic-lacustrine system with glacial influences. 1st-order and 2nd-order Maximum Flooding Surfaces (MFS) define a regional sequence stratigraphic framework which subdivides the REM strata into four sequence units, among which two Transgressive-Regressive (T-R) cycles can be observed. Paleogeographic maps of four depositional phases suggest that the REM strata were dominated by a lacustrine system with some delta and mire deposits. Rivers primarily drained from the Gidgealpa, Merrimelia, Packsaddle and Innamincka ridges (GMI Trend) in the north or northeast as indicated by sandstone percentage and gross unit isopach maps. Possible marine incursions into the lake probably came from the east when eustatic sea level was high. Far field effects from thermal subsidence of Eastern Australia and paleoclimate (glaciation, interglaciation) primarily controlled deposition of the REM strata. A similar multidisciplinary approach should help elucidate the evolution of other fluvial-deltaic-lacustrine systems in other basins and aid in resource prediction.

Keywords: Sedimentary characteristics ,sand-body distribution, Lower cretaceous Bashijichik Formation,Tarim Basin,Xinhe-Sandaoqiao area;

Abstract: In recent years, the discovery of Keshen and Kela gas pools indicates the great hydrocarbon exploration potential of the Cretaceous clastic rocks in Tarim Basin,NW China. Based on logging data, marcoscopic and microscopic petrology characteristics of lower Cretaceous Bashijiqike Formation in Xinhe-Sandaqiao area, sedimentary facies evolution and reservoir characteristics are comprehensively studied. The results show that:(1) Controlled by the provenance of the Southern Tianshan mountains and Xinhe-Yingmaili uplift, the cretaceous Bashijiqike Formation in Xinhe-Sandaqiao area is mainly characterized by brownish red,light brown and other oxidized colors. Two types of sand bodies are mainly developed: "thick sand" with large thickness and good transverse continuity and "thin sand" with thin thickness and poor transverse continuity. It is found that "thick sand" and "thin sand" developed at the bottom (Ba 1 and 2) and the top (Ba 3 and 4) of bashijiqike Formation, respectively. (2) the sedimentary facies analysis shows that the Bashijiqike Formation is shore- shallow lake and braided river delta sedimentary environment. "thick sand" developed in the delta front sedimentary subfacies.at the bottom, while the "thin sand" developed in shallow lake sedimentary facies on the top. The delta and lake sedimentary developed superimposly ,with the scope of lake basin grew and the delta was gradually reduced from early to late period(3) combined with physical properties and sedimentary facies analayses, high quality reservoirs in Bashkortostan Formation mainly developed in the underwater distributary channels of braided river delta front and littoral and sand dams of shore-shallow lake , which generally belongs to low porosity and high permeability reservoir.With the widely distributed thick sand body, and reconstruction from the Sandaoqiao fault , low-rising structure trap developed with good petrolem accumlation conditions.

Gravity Flow Geomorphology and its Controlling Factors in the Gently Sloping Zone of the Intra-sag High of the Liaodong Bay Depression

Hao Wang[1*], Shu Jiang[1], Yuying Zhang[1]
1. School of Resources, China University Geosciences, Wuhan, Hubei, CHINA
E-mail: wanghao321@cug.edu.cn

Keywords: gravity flow, sequence stratigraphy, sedimentary morphology, control factors, gently sloping zone of intra-basin, Liaodong Bay Depression

The stratigraphic traps formed by gravity flow have gradually become the focus of hydrocarbon E&P. The Eastern slope of Liaoxi uplift or western slope of the Liaozhong Sag is still in early exploration stage. Recently drilled gravity fan of high density turbidite is the potential target for future exploration. This study firstly established the high-resolution sequence stratigraphic framework for the 3rd member of Dongying Formation. The comprehensive study on the morphology and controlling factors of gravity flow sedimentation was then conducted within the systems tracts integrating seismic, well logs and core data interpretation. The results show four types of slope fans are mainly developed in the gentle slope zone of eastern Liaoxi uplift: tongue-shaped fan, petal-shaped fan, leaf-shaped fan and channelized-fan. The study indicates that the degree of slope gradient and the sand-richness of the gravity flow source (the braided river delta front) control the morphology of the fans. The more complex the slope break and the steeper the slope, the larger the aspect ratio of the sub-lake fan, which is long tongue-shaped, and the simpler the slope break and the gentler the slope, the smaller the aspect ratio of the sub-lake fan, which is leaf-shaped. The higher the sand content, the channel is unorganized, and the higher the mud content, the more stable and the more organized the channel. Therefore, the steep slope and sand-rich fan is easy to form a tongue-shaped fan, the gentle slope and sand-rich fan is easy to form a leaf-shaped fan, the gentle slope and mud-rich fan is easy to form a channel-shaped fan, and the petal-shaped fan is a transitional type.

Discovery and exploration potential analysis of the beach-bar sand in Shawan Sag, Junggar Basin

xin Guan[1*]
1. Western Exploration Institute, Northwest Branch of Research Institute of Pegtroleum Exploration & Development, PetroChina, Lanzhou, Gansu, CHINA
E-mail: guan_x@petrochina.com.cn

Keywords: exploration potential, beach-bar sand, Upper Urho Formation, Shawan Sag, Junggar Basin

Recently, Well ST1 in the Shawan Sag of the Junggar Basin has achieved major breakthrough in the Upper Urho Formation, of which the geological characteristics regarding hydrocarbon accumulation and reservoir forming are clearly different from those of the Mahu Sag, and present typical features of the beach-bar sand deposition. In order to explore the new frontier of hydrocarbon exploration, confirm the planar distribution and exploration potential of the beach-bar sand, this paper, on the basis of high-resolution three-dimensional seismic data combined with data collected during drilling, formation testing, well logging and core analyses. Elaborately depicts the planar distribution pattern of the beach-bar sand in the Upper Urho Formation of the shawan sag, and discussed its hydrocarbon accumulation potential, using seismic analysis techniques such as attribute extraction and stratal slicing. The results show that: (1) the target layer of the study area presents apparent characteristics of the beach-bar sand, which is distributed along the shore lake in a strip-like; and (2) it forms good hydrocarbon accumulation condition and has a huge area for exploration. The discovery and confirmation of the “beach-bar sand” field provides a model to shed light on exploration of the “beach-bar sand” oil and gas reservoir across the Shawan Sag, as well as a new exploration frontier for the “Greater Mahu” area in the Junggar Basin.

Evolution and Seismic reflection Characteristics of Subaqueous Distributary Channel Sand Bodies in the Braided River Delta

Duonian Xu[1*], Jianguo Pan[1], Shuxin Pan[1], Yongqiang Qu[1], Guodong Wang[1]
1. Northwest Branch, Research Institute of Petroleum Exploration and Development, Lanzhou, Gansu, CHINA
E-mail: xuduonian@163.com

Keywords: paleogeomorphology,subaqueous distributary channel,evolution,seismic reflection characteristics,Junggar basin

The sand bodies of subaqueous distributary channel in the braided river delta are superimposed vertically and vary greatly horizontally. At present, it is difficult to analyze the evolution and prediction of channel sand bodies. Taking the Jurassic Sangonghe Formation in the west slope of Mahu Depression, Junggar Basin as an example, evolution and seismic prediction of subaqueous distributary channel sand bodies in the braided river delta were researched. According to the lithological cycle characteristics, the strata of the Sangonghe are divided into J_1s_1, J_1s_2 and J_1s_3 from the bottom to the top. J_1s_3 is the main target stratum with a thickness of about 140m. It is mainly composed of gray mudstone, gray glutenite, a small amount of fine sandstone together with gray argillaceous siltstone. In order to better research the evolution and seismic prediction of the J_1s_3 channel sand body, the J_1s_3 are subdivided into three super short-term cycle according to the lithological cycle characteristics. From the bottom to the top, they are $J_1s_3^3$, $J_1s_3^2$ and $J_1s_3^1$ respectively. Each super short-term cycle is a positive cycle. $J_1s_3^3$ lithology is mainly thick glutenite and located in the inner zone of the braided delta front, and the channel sand bodies are distributed in a large area. $J_1s_3^2$ lithology is mainly fine sandstone and mudstone and located in the inner and outer transition zone of the braided delta front, and the channel distribution is relatively limited. $J_1s_3^1$ lithology is mainly siltstone and mudstone and located in the outer zone of the braided delta front, and the channel distribution is obvious. As a whole, $J_1s_3^3$ to $J_1s_3^1$ is a process for water transgression, the channel shrinks gradually, and the channel sand bodies migrate from south to north. Paleocurrent direction and channel distribution range are determined by restoring the palaeo-geomorphology and combining with dip logging data. Along the paleo-current direction, the channel sand bodies mainly show three seismic response characteristics: The first is the reflection characteristic of “flat top and convex bottom”. Downcutting erosion is caused by water flow, and gullies are formed. Due to the strong hydrodynamic force, flowing water carries a large amount of coarse particulate matters to the middle and lower reaches, and the channel sand bodies deposit in a little amount. The second is the filling reflection characteristic of “flat top and convex bottom”. As the hydrodynamic force weakens, the particulate matters deposit partially, which is shown to be an increase of seismic event. The third is the multiple stages sand bodies superposition characteristic of “flat top and convex bottom”. As the hydrodynamic force becomes weak, the sand bodies deposit in the river channel. Under the guidance of this model, the spatial distribution of the channel sand bodies is predicted by using strata slicing, seismic attributes, frequency division inversion and other methods. The newly drilled wells prove that the prediction methods for the channel sand bodies are effective and feasible.

Huge lake-tsunamis and related tsunami deposits in the Cretaceous Songliao Basin, NE China

shuxin Pan[1*]

1. sediment , Research Institute of Petroleum Exploration and Development Northwest Branch, PetroChina, lanzhou, Gansu, CHINA

E-mail: pansx@petrochina.com.cn

Keywords: lake-tsunamis, tsunamiites, deep-water deposits, the Songliao Baisn

AbstractTsunami deposits (tsunamiites) in lacustrine settings are some of the most understudied facies associations in the ancient or modern rock record. In recent year, three giant sublacustrine landslides (volumes of 1.5×10^9 to 3×10^{10} m^3) have been identified in the Songliao paleo-lake (SLPL), NE China. To understand the possible consequences of these landslides, we conducted tsunami simulations showing that these sediment failures could generate waves >2.5 m high, hitting the west lakeshore of the SLPL in approximately 95 min. What is even more devastating is that the disaster would magnify exponentially when three landslides with same direction of motion occurred simultaneously. This worst-case scenario may cause tsunami waves of up to 32 m, and most parts of adjacent land would have been inundated. Moreover, based on seismic geomorphology, we investigate the external morphology and internal architecture of the tsunamiites caused by this huge lake-tsunamis. Seismic facies reveals that the tsunamiites can expressed several distinguishing seismic characteristics in different parts of the SLPL. Large sediment waves, with wavelength 1-2 km, were identified in the lake centre. In onshore or offshore, tsunami deposits may consist of inflow and backflow deposits. The new depositional model built from the SLPL is vital to understanding the distribution of tsunami deposits in a sublacustrine settings.

Difference of depositional characteristics and its controlling factors of deep-water gravity flow in the first member of Liushagang formation, in northern steep slope, Weixinan Sag

Jin Jiehua[1*]
1. Working Station for Postdoctoral Scientific Research, Geophysical Research Institute, Sinopec Shengli Oilfield Company, Dongying, Shandong, CHINA
E-mail: jinjiehuaupc@163.com

Keywords: difference of depositional characteristics, controlling factors, deep-water gravity flow, the first member of Liushagang formation, Weixinan Sag

Integrating 3-D seismic data, logging data, drilling cores and testing data, Using core observation, paleogeomorphology restoration, seismic facies analysis, seismic attribute extraction and analysis, depositional types and distribution features of deep-water gravity flow in the first member of Liushagang formation, in northern steep slope, Weixinan Sag has been analyzing in detail and the controlling factors of depositional fans' development have been discussed.

Deep-water gravity flow deposition in north steep slope of Weixinan sag is zoning obviously. Nearshore subaqueous fan developed in the west of the steep slope. The lithology is manly glutenite which particle size is coarse. The seismic profile is wedge-shaped along the direction of sediments transportation. Perpendicularly to the direction of sediments transportation the seismic profile is lentoid with thickness in the middle and thinness on the sides. Average energy seismic attributes of each stage fan show low energy band which is along fault strike in the fault root. While the high energy band shows fan-shaped from the fault root to the basin. Hyperpycnites developed in the middle of the steep slope. Hyperpycnal channel is mainly filled in sandstone and pebbly sandstone, while the lobes are mainly fine sandstone and siltstone which are rich in terrigenous plant debris. In vertical, each sequence shows normal-reverse graded structure. The amplitude attribute shows the characteristics of narrow channel and lobe in front which energy is stronger than surrounding rock obviously. Small scale hyperpycnites and mass transport deposits developed in the east of the steep slope. The MTDs shows isolated teardrop-shaped area with strong energy. Vertical to the transportation, the seismic reflection shows pit with strong amplitude. Along the transportation, the seismic reflection shows isolated strong amplitude. Structural characteristics reacting block transportation such as thrust fold and thrust fault have been presentation.

The factors difference of source-to-sink systems including type of parent rocks in source area, distance of sediment transportation, terrain differences and fault throw are the key to the difference of hyperpycnites north steep slope of Weixinan Sag. The parent rock in the west is mainly metamorphic sandy shale which is easy to weathering. This parent rock can supply large number of sediments. Large gullies develop and the No.1 fault throw is big. The sediments can be deposited by transporting short distances. Thus, large nearshore subaqueous fan can be developed in the terminal of the source-to-sink system. The parent rock of the middle and east source-to-sink system is magmatite that is hard to physical weathering, which can only supply lesser sediments. In the middle of the slope, because of the intersection of fault, the drainage is well which can transport large amounts of sediments over long distances. As a consequence, at the end of the middle source-to-sink system, hyperpycnites develop. However, since sediments need to be transported long distance via small valley and the fault fall is small in the east source-to-sink system, small scale of hyperpycnites and mass transportation deposits develop.

Characteristics and genesis of tight oil reservoir sandbodies in Chang 6 Oil Member of Yanchang Formation, Ordos Basin

Jingchun TIAN[1*], Qingshao LIANG[1], Feng WANG[1]
1. Institute of Sedimentary Geology, Chengdu University of Technology, Chengdu, Sichuan, CHINA
E-mail: tjc@cdut.edu.cn

Keywords: Ordos Basin, Chang 6 Oil Member, Tight oil, Reservoir sandbody, Genetic model

Chang 6 Oil Member of Triassic Yanchang Formation in Ordos Basin is one of the tight oil rich intervals in the basin. The study on the characteristics and genesis of tight oil reservoir sandbodies has important guiding significance for the further exploration and development of tight oil in the basin. Therefore, based on many previous research results, this paper takes the Chang 6 Oil Member in Huachi-Qingyang area in the middle of the basin as the research object, focuses on the characteristics and genesis of tight oil reservoir sandbodies, and expounds the types and characteristics of tight oil reservoir sandbodies of Chang 6 Oil Member through detailed observation and description of many drilling cores and comprehensive analysis. Then, the superimposition relationship of different types of reservoir sandbodies is analyzed, and the genetic model is established. The results show that there are four types of tight oil reservoir sandbodies: delta front sandbody, seismite sandbody, clastic flow sandbody and turbidite sandbody, which form different superposed relationships in vertical direction, mainly including: seismite sandbody and delta front sandbody; The superimposition of seismic sand body and clastic flow sand body; The clastic flow sandbody overlaps with turbidite sandbody; Seismic sandbody, clastic flow sandbody and turbidite sandbody are superposed. On this basis, the genetic evolution models of the four types of tight oil sand bodies are established.

Sedimentary Sequence of Geological Events under the Influence of Tectonic Activities: A Case from Chang 7 Oil Member of Yanchang Formation in Ordos Basin

Qingshao LIANG[1*], Jingchun TIAN[1]
1. Institute of Sedimentary Geology, Chengdu University of Technology, Chengdu, Sichuan, CHINA
E-mail: liangqingshao@foxmail.com

Keywords: Ordos Basin, Chang 7 Oil Member, Sedimentary Event, Sedimentary Model

Under the background of tectonic activity that the Middle-Late Triassic Indosinian Orogeny led to the uplift of Qinling Mountains, the geological events caused by earthquake and volcano are frequent. The Change 7 Oil Member of Triassic Yanchang Formation in Ordos Basin has typical sedimentary characteristics of large depression lacustrine basin, among which many geological event sedimentary layers are preserved. Taking the event sedimentary layers in the Change 7 Oil Member of Triassic Yanchang Formation in Ordos Basin as the research object, and guided by the relevant theories of sedimentology, stratigraphy and event sedimentology, the field section around the basin and the event sedimentary layers in the drilling core inside the basin are studied. The main types of geological event deposits found in the stratum of Chang 7 are summarized. Through the analysis of the sedimentary types of the events, the sedimentary types of the main geological events found in the stratum of Chang 7 are summarized. The superimposition relationship of the seismicity, turbidite, tuff and organic shale corresponding to the earthquake events, turbidite events, volcanic events and anoxic events are analyzed, and the coupling relationship of various geological events is discussed, the formation and evolution of Ordos Lake Basin in the Chang 7 period are recognized from a new perspective. Finally, the sedimentary sequence and sedimentary model of geological events in Change 7 Oil Member of Triassic Yanchang Formation in Ordos Basin are established.

Lithofacies and typical sedimentary cycle model of penesaline lacustrine shale association: A case study of the Yingxiongling Depression, the Qaidam Basin

Guangyong Song[1*]
1. PHIG, Petrochina Hangzhou Research Institute of Geology, Hangzhou, Zhejiang, CHINA
E-mail: 305098792@qq.com

Keywords: lithofacies, sedimentary cycle, mixed sediments, chemical deposition

The sedimentary records of shale formation in penesaline lacustrine basins are distinctly different from those in freshwater lacustrine basins and marine basins, and are unique. Taking the Paleogene of the Yingxiongling Depression in the Qaidam Basin as an example, this paper shows the rock and mineral composition, lithofacies types and associations of the shale formation in the penesaline lacustrine basin by dissecting a large number of drilling cores, whole-rock X-ray diffraction, thin sections, scanning electron microscopy and other test data. And an ideal model of sedimentary cycle is proposed. The results show that the mineral composition is dominated by dolomite, calcite, clay minerals, quartz, albite and anhydrite, and also contains a small amount of pyrite, glauberite, halite and potassium feldspar. Among them, clay minerals, quartz and feldspar minerals are all terrigenous mechanical deposits, and most carbonate and sulfate minerals are chemical deposits. That is to say, the penesaline lacustrine shale system is formed by the interaction of terrigenous mechanical and chemical depositional mechanisms. According to the differences in mineral composition, sedimentary texture and structure, the penesaline lacustrine shale formation are classified into 7 types of typical lithofacies, i.e., massive inequigranular sandstone, massive argillaceous siltstone, massive mudstone, felsic shale, calcareous shale, lamellar dolomicrite, and patchy gypsum-bearing dolomicrite. The above seven lithofacies depositing from bottom to top form a typical complete sedimentary cycle on meters scale. Among them, inequigranular sandstone, massive argillaceous siltstone and massive mudstone constitute an ascending semi-cycle, dominated by turbidite depositional systems. On the other hand, felsic shale, calcareous shale, lamellar dolomicrite, and patchy gypsum-bearing dolomicrite constitute a descending semi-cycle, reflecting the gradual increase in the dominance of chemical deposition. The Paleogene shale formation of the Yingxiongling Depression in the Qaidam Basin are the sedimentary records formed by high-frequency superposition of this complete cycle or a part of its. The results of this study have theoretical significance for the application of high-resolution sequence stratigraphy in penesaline lacustrine shale formation, and have certain enlightenment significance for the current evaluation of shale oil resources.

Major Factors Controlling Quality of Nonmarine Shale Reservoir in the Lower Jurassic in Sichuan Basin, China

Jinyi Wang[1], Zhenkui Jin[1*]
1. College of Geosciences, China University of Petroluem, Beijing, CHINA
E-mail: jinzhenkui@188.com

Keywords: nonmarine shale reservoir,controlling factors,pore type,compaction,Sichuan Basin,Lower Jurassic

Industrial gas flows have been yielded in the lower Jurassic nonmarine shale in Sichuan Basin in recent years, indicating that the great potential of shale gas resources in the shale reservoir in China. The purpose of this study is to determine the major controlling factors of nonmarine shale reservoir quality in the Lower Jurassic of Sichuan Basin. The study based on an integration of thin-section observation, whole-rock X-ray diffraction, helium gas for pore permeability, elemental geochemistry, organic geochemical analysis and scanning electron microscopy. The type and composition of rocks, the structure, type and storage capacity of the pores as well as the factors controlling the pore growth were revealed. Results show that the main constituent minerals of the Lower Jurassic nonmarine shales in the Sichuan Basin are clay minerals, quartz and carbonate minerals. Clay minerals and quartz are generally high in content, and carbonate minerals are locally enriched. The lithology of the shale reservoir are mainly clay shales, quartz shales, shell shales and silt shales. Clay shales and mesoscopic shales in Da'anzhai and Dongyuemiao member are high-quality shale reservoirs with relatively high organic matter content and high reservoir capacity of an average porosity about 3.9 %. Pores in the shales are mostly intergranular pores between clay minerals and other terrigenous debris, followed by organic-matter pores and some local micro-cracks. The intergranular pores show signs of strong influence of clay mineral and compaction intensity. Compaction is the main factor controlling the quality of shale reservoir. Semi-deep lake is favorable depositional environment for preservation of organic matter. Accordingly, we propose a new method for predicting high-quality shale reservoirs: finding the undercompacted zones in semi-deep lacustrine shale formations.

Study on Reservoir Diversity Controlled by Multiple Factors:An example from Liushagangzu 3rd member of Northern Steep Slope Zone in Weixinan Depression ,Beibuwan Basin, South China Sea

sheng Liu[1], hongtao Zhu[1*]
1. , , , , CHINA
E-mail: htzhu@cug.edu.cn

Keywords: Weixinan Depression,Reservoir,Multiple Factors

Combined with a series of analysis and test data such as seismic, core, drilling, logging and carbon oxygen isotope, this paper analyzes the reservoir differences of the East Zone, middle zone and West zone of the third member of Liushagangzu in the steep slope zone of Weixinan Sag, Beibuwan Basin, analyzes the main reservoir controlling factors of the three zones, and summarizes the reservoir development model. In the study area , reservoir diversity is mainly affected by five factors; 1) Structural factors: structural factors control trap types. In the study area , West zone and middle zone fans mainly develop glutenite deposits controlled by linear provenance, and structural traps are developed; The East zone mainly develop glutenite deposits controlled by point provenance, and lithologic traps are developed. 2) Sedimentary facies factors: sedimentary facies types control reservoir characteristics. Fan delta sedimentary system is developed in the three zones in the study area. The main dominant sedimentary microfacies are underwater distributary channel, with large sand body thickness, low matrix and cement content The main characteristics are the development of primary and secondary pores. 3) Sand thickness factors: sandstone thickness mainly controls the oil and gas bearing property of the reservoir. Taking the oil and gas bearing property of 50% as the boundary, the sand thickness of the West Zone in the study area is 3m; The sand thickness of the middle zone is 5m; The sand thickness of the East Zone is 8m; 4) Physical factors: physical factors mainly control reservoir classification. In the study area ,type I conventional reservoirs (porosity > 12%, permeability > 10md) are mainly developed in the West Zone; middle zone mainly develops type II low permeability reservoir (porosity 6-12%, permeability 1-10md); West Zone mainly develops type III tight reservoir (porosity < 6%, permeability < 1md) 5) Diagenetic facies factors: diagenetic facies factors control the reservoir type. In the study area, West Zone mainly develops weakly compacted and weakly cemented diagenetic facies (type I diagenetic facies); middle zone mainly develops medium compaction medium dissolution and strong compaction medium strong dissolution diagenetic facies; East Zone mainly develops strong compaction medium strong dissolution diagenetic facies. Combined with reservoir control factors and reservoir differences in steep slope zone, two types of multi-factor control reservoir prediction models are summarized: steep slope zone prediction model and conversion zone prediction model. The high-quality reservoir in the steep slope zone is mainly in the middle of the sand body, mainly medium coarse sandstone. The organic acid + atmospheric fresh water two-stage acid fluid is active, the dissolution is strong, and the dissolved substances migrate out of the system. The intergranular dissolved pores, intragranular dissolved pores and matrix dissolved pores are developed, and the physical properties are the best. The high-quality reservoirs in the conversion zone are mainly located in the middle of the sand body, mainly medium coarse sandstone, dissolved by organic acid fluid, developed intergranular dissolved pores, intragranular dissolved pores and matrix dissolved pores, and have the best physical properties.

Discovery of hyperpycnites and its petroleum geological significance in paleogene of Jiyang Depression

Liu Haining[1*]
1. School of Geoscience , China University of Petroleum(East China), Qingdao, Shandong, CHINA
E-mail: liuhaining632.slyt@sinopec.com

Keywords: hyperpycnites, Jiyang Depression, gravity flow, turbidity channel, deep water tubidites

Researches show that not only fine suspended sediments, but also hyperpycnites are developed in deep basin. Hyperpycnal flow is a kind of stable layered undercurrent formed by transporting flood of long distance with density higher than that of lake/sea water.

Compared with the marine environment, continental lake basin is more prone to the occurrence of hyperpycnal flow due to the characteristics of intense tectonic activity, large difference of topographic height, low salinity and density of lake basin water, and the main source of medium and small rivers. Many researchers have found hyperpycnites in nenjiang Formation of Songliao Basin, Chang 7 Member of Ordos Basin, Sha1 Member of Qikou Sag, Huagang Formation of Xihu Sag and Sha 3 Member of Jiyang Depression.

Previous studies on sedimentary characteristics in Jiyang Depression have been carried out, and corresponding evidences have been found. And the depositional models of hyperpycnites have been established. In the Exploration of Shengli Oilfield, some sandbodies with shape of bands or fans from long distance transport have been found in the deep sag. These sandbodies are often called turbidite channels and deep-water turbidite fans, etc.. However their genesis and depositional characteristics are lack of study. Different from the slumping turbidites, large delta or other near-source deposits do not develop in the root of these sandbodies, Such as the area of niu876 well, wang 58 well, li 988 well, etc..

Preliminary analysis suggests those turbidity channels and deep-water turbidity fans widely developed from the upper of Es4 formation to the lower of Es3 formation in Jiyang Depression are related to the hyperpycnal flow. A lot of simulation experiments and theoretical analyses of hyperpycnites have been carried out, but few studies on sedimentation process and distribution law of hyperpycnites in faulted lake are carried out.

In jiyang Depression, the climate was humid from the upper of Es4 to the lower of Es3 formation, and flood was widely developed. In this period, the basin was wide and deep. The near-source deposition was relatively undeveloped. In such, Carrying out the study of hyperpycnites is significant to the origin of fine-grained sediments and filling mode in the deep sag.

lithological reservoirs of turbidites have been found in Jiyang Depression. These reservoirs are mainly slumping turbidite from delta front. The study of hyperpycnites will expand the exploration potential of conventional hydrocarbon reservoirs in areas which are far away from the delta. Some isolated channels and fan-lobes can form lithological reservoirs. Fan-lobes can form fault-block reservoirs in sand-rich background. Channel-embankment complex can form "fault-cut sausage" structural lithological reservoirs.

As an important source of fine-grained sediments in the basin, hyperpycnal flow can bring rich organic matter, which is in favor of hydrocarbon generation. Meanwhile, lobes at the front of hyperpycnites may be the sweet spots of interbedded shale oil which can guide the selection of favorable exploration areas for sandy interbedded shale oil.

Paleolacustrine environment and high-quality source rock development model of Eocene Wenchang Formation in Yangjiang Sag of Pearl River Mouth BasinNorthern South China Sea

Guo Fu Cai[1*]
1. Nanhai East Petroleum Research Institute, Shenzhen Branch of CNOOC China Limited, Shenzhen, Guangdong Province, CHINA
E-mail: 704361642@qq.com

Keywords: Yangjiang sag,paleolacustrine environment, lake-basin type, high-quality source rock

Yangjiang sag is a newly confirmed hydrocarbon generating sagwhere several oil fields were found, signified great breakthrough on oil exploration in the past four years in the Pearl River Mouth Basin, Northern South China Sea. However, the controlling factors for the formation of high-quality source rocks in long-neglected small rift basin are not clear. Based on comprehensive analyses of organic, element geochemical and seismic data, we revealed the source rock characteristics, restored the paleoenvironment and lake-basin types, and established high-quality source rock development models of Eocene Wenchang Formation in Yangjiang Sag of the Pearl River Mouth Basin. The research found that: (1) The Wenchang Formation in Yangjiang Sag has developed thick middle-deep lacustrine source rocks with high abundance of organic matter. The organic matter types are mainly I-II1 types. The lower part of Wenchang Formation has strong lateral heterogeneity, with an average TOC of 2.2 -3.5%, the upper part of the Wenchang Formation has strong homogeneity, with an average TOC of 2.3-2.6%. The original organic-matter input is mainly bacterium and algae materials in the basin, whist with some contribution of high terrestrial plants in the steep slope. (2) The coupling of small- and medium-sized provenance input and rifting activities in Yangjiang Sag creates accommodating space that is conducive to the development of middle-deep lakes. Warm and humid climate conditions are the prerequisite for the blooming of aquatic plankton algae. Volcanic eruptions promote the increase of local initial productivity in the lake basin , The highly reducing water environment makes the organic matter storage conditions good. (3) Three lake-basin types are classified. Among them, the balanced-fill lake basins develop a fluctuating deep lake lithofacies combination of thick mudstone and thin sandstone in the depression zone. The underfilled lake basins have full basins and wide coverings. With the characteristics of homogeneous mudstone, over-filled lake basins basically do not develop medium-deep lacustrine source rocks. (4) The balanced-fill lake basin has a high-quality source rock development model controlled by the dual factors of "productivity + preservation conditions". The lake has high initial productivity and is generally in a medium reduction environment, forming a good type of source rock with high organic matter abundance. The abundance of organic matter on gentle slopes is better than that on steep slopes. The underfilled lake basin has a high-quality source rock development model controlled by a single factor of "preservation conditions". The lake has a medium productivity, but the water level has strong reducibility, forming medium-organic abundance source rocks. Comprehensive analysis suggests that Enping 21, Enping 20 and Enping 27 sub-sag are superimposed with high-quality source rocks in the balanced and under-filled lake basins, and they have high exploration potential. This study has important guiding significance for the prediction of source rocks in the Yangjiang Sag and other similar sags in the Pearl River Mouth Basin.

Study on the development and preservation of shore-shallow lacustrine beach and bar in Mesozoic Yanchang Formation of Ordos Basin based on the modern sedimentary characteristics of Qinghai Lake

JING WANG[1*]
1. Department of Resources & Exploration Planning, PetroChina Research Institute of Petroleum Exploration & Development-Northwest (NWGI), LANZHOU, GANSU, CHINA
E-mail: jing_wang@petrochina.com.cn

Keywords: beach and bar, modern sedimentation,Qinghai Lake,Yanchang Formation,Ordos Basin

Employing the basic principle in geology that "the present is the key to the past", this research carried on the comparative study of the beach and bar sediments in modern Qinghai Lake and ancient Ordos Basin. The study suggests that the development of beach and bar sediments was mainly controlled by the provenance, (wind) hydrodynamic force, topography of lake basin, lake shoreline and lake level cycle (base level)in which the fluctuation change of lake level (base level) is the key factor which determines the preservation of beach and bar sediments, only the sand deposits at the early stage of the second-order sequence or lacustrine transgression phase of the third-order sequence can be well preserved. Through the comparative study, the research confirmed that only Chang 9-8_2-7 member of Mesozoic Yanchang formation situated at the early stage of the second-order sequence, meanwhile, at the lacustrine transgression phase of the third-order sequence, which is conducive to the preservation of the terrigenous clastic beach and bar, and thus this research establishes the prediction model of sand distribution of shore-shallow lacustrine beach and bar in Mesozoic Yanchang formation and points out that the southern basin (including southwest and southeast) in Chang 9-8_2-7 period is the favourable areas for formation and preservation of the beach and bar sand bodies, which is the favourable beach and bar reservoirs in the future. Because beach and bar sediments may have certain universality in continental lacustrine basin, this paper also points out that this research has a certain reference significance for the exploration and development of lithologic oil and gas reservoirs in other basins in China (including fault depressions and depression basins).

Hybrid event beds in deep-lacustrine basins

Tian Yang[1*], Yingchang Cao[2]
1. Institute of sedimenttary geology, Chengdu University of Technology, Chengdu, Sichuan, CHINA
2. Key Laboratory of Deep Oil and Gas, China University of Petroleum (East China), Qingdao, Shandong, CHINA
E-mail: tianyang9645@gmail.com

Keywords: turbidity currents, debris flows, hybrid event bed, geological significances, lacustrine basin

Hybrid event beds are common in lacustrine basin, their formation and distribution is significant for understanding the evolution processes of gravity-flow and the conventional and unconventional oil and gas exploration and development in their deposits. Taking the gravity-flow deposits in the first member of the Liushagang formation in the Weixinan sag and the seventh member of Yanchang formation in the Ordos basin as examples, the sedimentary characteristics, types, formation mechanisms, depositional model as well as the oil and gas geological significances of hybrid event beds in lacustrine basin are discussed. The gravity-flow deposits in lacustrine basin including slide and slump deposits, sandy and muddy debris flow deposits, high and low density turbidity-current deposits, and the common hybrid event beds. Three types of hybrid event beds are subdivided, which include sandwich structure, bipartite structure, and banded structure. The bipartite structured hybrid event beds can further subdivided based on the thickness difference between the upper and lower division. Sandwich structured hybrid event beds are mainly caused by flow erosion or liquefaction and located in the proximal of hybrid event beds. Bipartite structured and banded structured hybrid event beds, which located in the distal of hybrid event beds, are mainly attributed to flow decelerate and expand, the different settling of detrital grains in muddy debris flow. The vertical stacking of different beds with the same internal depositional unit composition in core is the reliable identification mark for hybrid event beds. If we couldn't reveal the formation processes of these hybrid event bed, it may cause misunderstanding of the depositional information. At the same time, the development of hybrid event bed will add the depositional heterogeneity of gravity-flow deposits, which is bad for conventional oil and gas preservation. However, the fine-grained deposits caused by hybrid event beds are the good lithofacies associations, which is the sweet spot for unconventional oil and gas development.

Sedimentary character of gravity-flow deposits in a lacustrine depression basin: examples from the late Triassic Chang 7 Member of Yanchang Formation, Ordos Basin, Central China

Tian Yang[1*], Wenqiang Yu[1], Thomas Dodd[2]
1. Institute of sedimenttary geology, Chengdu University of Technology, Chengdu, Sichuan, CHINA
2. The Lyell Centre, British Geological Survey, Edinburgh, UNITED KINGDOM
E-mail: tianyang9645@gmail.com

Keywords: Gravity-flow deposits, depositional model, lacustrine depression basin, Yangchang Formation, Ordos Basin

Understanding the flow processes that form gravity-flow deposits is vital for modeling and predicting sandstone bodies in the subsurface, which is of great significance for conventional and unconventional oil and gas exploration and development in lacustrine basins. This study analyses gravity-flow deposits in the Late Triassic Chang 7 member of Yanchang Formation in the Ordos Basin, using a combination of well-log analysis, core observations, thin section analysis, and laboratory measurements. The sedimentary facies, formational mechanisms, distribution patterns, and depositional models of gravity-flow deposits are investigated. Thirteen facies and eight-bed types are recognized in the gravity-flow deposits. Bed types represent deposits of sandy slides, sandy slumps, muddy debrites, sandy debrites, hybrid event beds, transitional flow deposits, surge-like low-density turbidites, and quasi-steady low-density turbidites. Gravity-flow deposits, particularly those caused by sediment failure, are composed of slides, slumps, sandy debrites, hybrid event beds, transitional flow deposits, and surge-like low-density turbidites. These deposits form as isolated lenticular sand bodies, with retrogradational internal stacking patterns. Gravity-flow deposits caused by hyperpycnal flow are composed of sandy debrites, hybrid event beds, transitional flow deposits, and quasi-steady low-density turbidites. These deposits exhibit elongate morphologies in the southern part of the basin, with progradation internal stacking patterns. The collision between the North China Block and the South China Block, which occurred during the closing of the Qinling Ocean, lead to frequent volcanic eruptions and earthquakes. This likely promoted the development of gravity-flow deposits associated with sediment failure from delta fronts in both the northeastern and southwestern parts of the basin. Concurrently, extremely humid climatic conditions promoted increased fluvial drainage, leading to enhanced hyperpycnal flows into the deep-lacustrine basin depocenters. This study emphasized that detailed facies analysis and distribution pattern analysis are the fundamental way to identify the formation mechanisms of gravity flow deposits in lacustrine depression basins.

Sedimentary Characteristics, Origin and Model of Gravity Flows in a Lacustrine Rift Basin, Eastern China

Zehua Zhang[1], Hongliang Wang[1*]
1. School of energy resources, China university of Geosciences , Beijing, CHINA
E-mail: Whliang@cugb.edu.cn

Keywords: Gravity flow deposits, Sedimentary model, Sedimentary characteristics, Bohai Bay Basin, Shahejie Formation

Gravity flow deposits play an important role in petroleum exploration and development. The genesis and sedimentary architecture of lacustrine gravity-flows deposits (LSGFs) influenced by multiple provenances are ongoing questions requiring persistent attention and investigation. Based on the lithology observation, logging data, and three-dimensional seismic data from the southern Bohai Bay Basin, this study analyzes the characteristics, fluid types, genesis, and models of LSGFs. Twenty lithofacies types are classified into nine lithofacies associations caused by five genetic types: cohesive flows, inflated sandflows, concentrated-density flows, turbidity currents and hybrid events. LSGFs is divided into sublacustrine fan deposits caused by floods and slump olistolith induced by sediment failures. The sublacustrine fan can be subdivided into the inner, middle, and outer fans. Inner fan deposits are dominated by thick massive coarse debris and are mainly created by cohesive flows and inflated sandflows. The middle fan primarily features channel-filled deposits, which are composed of organized sandstones. Hybrid event beds with rich mud clasts caused by particles of cohesive debris flow rearrangement develop in middle fans. The outer fan deposits are characterized by turbidite lobes extending to the center of the lake basin. Hybrid event beds with sharp contact and that with gradual contact caused respectively by turbidity current deceleration and turbidity current erosion jointly develop at outer fans. Classified by the distance from slumps, the slump olistolith without channel deposits can be further divided into proximal lobes and distal lobes. The proximal lobe deposits mainly consist of slumps at their beginning and high-density frictional flow deposits at their end. The distal lobe deposits are composed of thin concentrated-density flow deposits and turbidites. Hybrid event beds with sandball construction and rip-up clasts caused by slumping develop at transition zones between proximal lobes and distal lobes. Based on the analysis results and the probe of sedimentary characteristics, the sedimentary model and triggering mechanism of LGSFs caused by 4 types of flows and hybrid events under the influence of multiple provenances and the paleogeomorphology has been established. This paper provides some insights about LSGFs with multiple provenances.

Multi-scale Quantitative Characterization and Fractal Evaluation of Pore Structure of Mixed Rock Reservoir in Bohai Bay Basin

Lin Wan[1*], Liming Dai[1], Wenjing Pan[1], Tao Ye[1], Yiwei Hao[1]
1. Bohai Petroleum Research Institute, CNOOC China Limited, Tianjin Branch, Tianjin, CHINA
E-mail: wanlin2@cnooc.com.cn

Keywords: lacustrine mixed rock,pore-throat combination,fractal evaluation,sedimentation,Bohai Bay Basin

Bohai Bay Basin is one of the most developed areas of continental mixed rocks in China. This study investigates the mixed-rock reservoir of the Shahejie Formation in the steep slope of the Shijiutuo uplift in the Bohai Sea area. The macroscopic understanding is established by observing the core and thin sheet, mineral composition and distribution of mixed rock reservoirs is quantitatively evaluated by QEMSCAN, multi-scale selection and evaluation across order of magnitude is established by Maps technology, submicron pore size distribution is quantitatively characterized by using high pressure mercury data, three-dimensional distribution and seepage capacity of reservoir space is precisely characterizated by using multi-scale CT. Based on the capillary pressure data, the key parameters of pore-throat distribution in mixed rock were evaluated by fractal characterization. The quantitative relationship between reservoir physical properties, pore structure parameters and fractal dimension is further studied, classification and evaluation of pore structure of mixed rock in study area is established.

The results show that: There are various rock types, strong heterogeneous properties and complex pore-throat structure in the mixed rock reservoir in the study area. The millimeter-micron pore-throat network is mainly developed in high porosity, medium to high permeability bright crystalline dandruff dolomite. Dissolution pores and biological cavity holes contribute greatly to the expansion of reservoir space, the fractal dimension of pore-throat is the lowest. Submicron-micron and micron pore-throat is mainly developed in medium-high porosity, medium-low permeability dolomitic lithogenic sandstone and continental dolomite. The main storage space types are inter-granular dissolved pore, mold hole, inter-crystalline pore and so on. The pore-throat fractal dimension is medium. The pore-throat of nanometer-submicron is mainly distributed in mud crystal sand dolomite and calcareous siltstone. Inter-granular pores and micro-cracks are the main types of reservoir space. The fractal dimension of the pore throat is the highest. Multi-scale characterization and evaluation of pore-throat combination characteristics of lacustrine mixed rock reservoir provide basis for fluid identification and effective development of mixed-rock reservoirs in Bohai Sea area.

Geological characteristics and paleoenvironmental evolution of fine-grained sedimentary rocks in the third member of Xujiahe Formation in Western Sichuan Depression

Yunfei Lu[1], Qingshao Liang[1*]
1. Institute of sedimentary geology, Chengdu University of Technology, Chengdu, Sichuan, CHINA
E-mail: liangqs@cdut.edu.cn

Keywords: 3rd member of Xujiahe Formation,Geochemical characteristics,Paleoenvironment, Paleoclimate, Fine-grained rock

The Xujiahe Formation is an important stratum that records the tectonic transformation of the western margin of the Yangtze Plate and the early formation process of the Longmenshan foreland basin, and is also an important set of hydrocarbon-bearing strata. In order to clarify the palaeoenvironmental evolution characteristics of the third member of Xujiahe Formation in the western Sichuan depression during the deposition of fine-grained sedimentary rocks, and to provide basic geological data for the in-depth study of the third member of Xujiahe Formation and the exploration and development of shale gas in the western Sichuan region. The mineralogy, petrological and geochemical characteristics of the fine-grained sedimentary rocks of the third member of Xujiahe Formation in the Western Sichuan Depression in the Late Triassic were studied in detail by using the analysis methods of mineral petrology and whole-rock geochemical elements. The research results show that the mineral types in the fine-grained sedimentary rocks of the third member of Xujiahe Formation are mainly brittle minerals such as quartz and feldspar, the main type of clay minerals is illite, and siderite is more developed in some areas, and the content of carbonate minerals is relatively small, and the rock type is mainly felsic dark fine-grained sedimentary rocksThe discovery of multiple siderite strips indicates that there were multiple warm periods in the paleoclimate at the time of deposition, and combined with geochemical analysis, it is shown that the paleoclimate type during deposition was mainly warm and humid, but there have been several climate changes in the vertical direction, and the northern part of the basin was warmer and humid than the southern part; The paleoproductivity shows a cycle of increasing-decreasing-increasing vertically, and it is high in the north and low in the south in the plane distribution; The sedimentary water body is dominated by marine salt water, and fresh water is injected at the same time; The redox environment of the water body is mainly sub-oxidative-sub-reduction environment; The chemical weathering degree of the provenance area is moderate weathering, and the climate is similar to that of the sedimentary area.

Development mechanism and sedimentary model of gravity flow in the west area of Fushan Sag, Beibu Gulf Basin

Ma JiangHao [a], Chen Si [a], Wang HUA [a] , Gan Huajun [a]

[a] China University of Geosciences (Wuhan)

Two sets of gravity flow sediments with different provenances and different genesis are developed in the west area of Fushan Sag, Beibu Gulf Basin, and mixed in the center of the basin, forming a large set of gravity flow sand bodies in Yong'an area. According to the latest drilling, the gravity flow sand body in this area has high reservoir forming potential. Taking the west of Fushan sag as the research area, this paper systematically analyzes the gravity flow sand body of Liushagang Formation Weizhou formation of Paleogene by using core, logging, high-precision three-dimensional seismic, heavy ore, zircon and other provenance analysis. Through the careful observation 218m long cores from 4 wells in the deep lake area of Yong'an area, three types of deep lake gravity flow sedimentary lithofacies are identified in the sedimentary period of Liushagang Formation, namely argillaceous clastic flow deposition, sandy clastic flow deposition and turbidity flow deposition. They not only represent the fabric of sediments with different grain sizes, but also have different genetic mechanisms and rheological characteristics. The lateral distribution and vertical combination of the three gravity flow sedimentary lithofacies can also be used as the characterization of the two sets of sedimentary systems in the study area.

The north and south parts of the study area develop delta front gravity channel system and pure gravity flow system respectively. There is no obvious sand transport channel in the north, which is mainly due to the activity of the fault slope, resulting in the spontaneous collapse of the sand body in the northern fan delta or sand rich part under the action of gravity. The scale is small, there is little overlap between the fans, and it is mainly dominated by the alternating distribution of argillaceous debris flow and turbidity flow. There are sufficient Braided River Delta provenances in the south. Under the action of two major fault slopes, a large-scale waterway gravity flow system is formed. There are many overlaps between gravity flow fans, and due to the difference of provenance supply intensity in different directions, there is a large lithologic gap between different fans. The lithofacies is characterized by the development of sandy debris flow and turbidity current. At the intersection of the two gravity flows, a good reservoir cap combination with sandy debris flow, turbidity flow as reservoir, argillaceous debris flow and deep lake mud as cover is formed.

This paper studies the development mechanism and sedimentary model of two sets of gravity flow sand bodies in the north and south of the west area of Fushan Depression, which has positive geological significance for further reservoir exploration in the study area, and can also provide a theoretical basis for the study of gravity flow sand bodies in similar continental lake basins.

Glutenite depositional distributary-controlling mechanism of rifted lacustrine basin in the northern actic region of Chexi Depression

Sihan Wang[1], Liqiang Zhang[1*], Jinyou Wang[1]
1. School of Geosciences, China University of Petroleum (East China), Qingdao, Shan Dong, CHINA
E-mail: zhanglq@upc.edu.cn

Keywords: glutenite deposition, distributary-controlling mechanism, rifted lacustrine basin, Chexi Depression

Glutenite reservoir with rapid horizontal change, strong heterogeneity and complex main control factors has difficulties in exploration and development. In order to solve the difficulty of glutenite reservoir exploration in faulted lacustrine basin caused by sand bodies distributary controlling mechanism, the glutenite deposition in lower Es3 subsection of rifted lacustrine basin in the northern actic region of Chexi Depression as the study target, the effects on glutenite distribution of various controlling factors are analyzed emphatically such as base type, fault pattern, sediment supply and the scale of depositional accommodation. In addition, according to determined stratigraphic sequence framework, sedimentary facies markers are identified by using core analysis data and logging response characteristics. Moreover, the combination of following flow profiles and across flow profiles is used to carry out sand body correlation between wells guided by sedimentary facies and the framework of quaternary sequence (sand group). The sand body distribution patterns are determined based on paleogeomorphology, and the distribution scale of glutenite sedimentary is quantitatively described by fine sand body characterization. The main results and understanding are as follows.

(1) Stratigraphic division makers are identified by core and logging data. The lower subsection of the third member of the Shahejie Formation in Chexi Sag develops a positive cycle and a counter-cycle divided by the maximum lake flooding surface and is divided into four sand-layer groups, while, the stratum as a whole is thick in the north and thin in the south. Moreover, through facies identification of single well and stratigraphic correlation between wells, four types of conglomeratic fan determined in the study area: distal neritic subaqueous fan, proximal neritic subaqueous fan, fan delta and slump turbidite fan.

(2) Based on fine glutenite characterization carried out by combined seismic interpretation with logging data, four types of sand body distribution pattern based on constructional morphology are defined: slope break model, shallow slope model, graben fault step compound model and slope-fault step model.

(3) Comparing the distribution sizes of various sand bodies which quantitatively characterized by logging and seismic association in horizontal and vertical direction, a rule is indicated that: the fan type mainly controlled by the provenance transport system, the sand body size mainly controlled by the fault pattern, and the sand body distribution range mainly controlled by the base type.

Impact of sedimentary environment on the development of continental shale laminae Insights from the XRF core scanning

Hengyuan Qiu[1], Zhenxue Jiang[1*], Hairuo Qing[2], Xiaofei Xiong[1]
1. Unconventional Oil and Gas Science and Technology Research Institute, China University of Petroleum, Beijing, Beijing, CHINA
2. Department of Geology, University of Regina, Regina, SK, CANADA
E-mail: jiangzx@cup.edu.cn

Keywords: continental shale, sedimentary environment, laminae, XRF core scanning

Laminae refers to the smallest or thinnest original sedimentary layer that can be distinguished in sediments or citrine, and is the smallest unit that constitutes a spread. Shale laminae are usually 0.02 ~1.00 mm. Formation of shale laminae is a complex physical and chemical process involving biological productivity, bottom water redox state and deposition rate in the sedimentary evironement and post-deposition degradation process. The shale laminae is one of factor that could influence the properties shale reservoirs because it controls the material composition, distribution, and heterogeneity of shale reservoirs. XRF core scanning measurement technology is used to conduct high-resolution elemental measurement in a rapid, non-destructive, and continuous manner, with resolution range from 0.1–10 mm,.

The Jurassic Qianfoya Formation in the Sichuan, China, was chosen as the research object. This strata is primarily a terrigenous clastic shallow lacustrine sediments with siliceous clastic laminae, carbonate laminae, clay laminae, and organic matter laminae.

The analysis revealed that in the early stages of lake formationin arid climates the water body gradually becomes shallow due to strong evaporation, forming a relatively closed lake basin. The terrigenous input gradually decreased as water depth increased, and bivalves proliferated in large numbers. The lake water body was shallow, and the oxygen content at the bottom of the lake was high. The loss of reducibility had a negative impact on organic matter production and preservation. As a result, shale with carbonate and siliciclastic laminae developed more frequently in arid climates,.

The river could recharge a large amount of fresh water into the lake when the climate changed from arid to warm and humid, the water body gradually deepened, the land source inputs (such as clay minerals) gradually increased, the lake basin gradually opened up, and the clay minerals gradually increased as the climate changed from arid to warm and humid due to input of terrestrial materials. The water body was relatively quiet due to the deep lake water, creating conditions for the production and preservation of organic matter. Thus, terrigenous siliciclastic laminae, clay laminae, and organic laminar shale were primarily formed. The depth of the water body reached its maximum after the climate became warm and humid, terrigenous inputs brought abundant clay minerals. The lake had the characteristics of water stratification, implying that the upper water body had sufficient oxygen content, the lower water body was oxygen-poor or anoxic. So that the lake bottom was a strongly reducing environment and well preserved organic matter. The carbonate minerals were less developed, resulting in more homogeneous structures. Therefore, the shale was mainly massive under humid climate conditions, with occasional laminae.

When the warm and humid climate transitioned to the arid climate, the water body gradually became shallow. The water environment was relatively calm with high organic content. Occasionally, carbonate laminae formed by storms breaking up shoal carbonates. When the study area transitioned from a warm and humid climate to an arid climate, the shale mostly developed carbonate and clay laminae, with occasional organic laminae.

Control mechanisms of tectonic paleogeomorphology on the Lower Cretaceous sedimentary basin fills in Tanan Sag, Tamtsag rift basin, Mongolia

Yong Zhou[1*]
1. College of Geosciences, China University of Petroleum-Beijing, Beijing, CHINA
E-mail: zhouyong@cup.edu.cn

Keywords: syndepositional faulting movement,transfer zones, structural slope-break zones, control mechanism of sand distribution,; Tanan Sag

Tanan Sag is a typical faulted lacustrine basin during the early Cretaceous, which experienced multi-stage episodic faulting activities. Tectonic activities are an important factor for the formation of paleogeomorphology and sand distribution. However, the controls of paleogeomorphologies generated by synsedimentary tectonic activities on sequence architectures, sedimentary system and sand body distribution are still unclear. Based on seismic, well logging and core data, under the guidance of sequence stratigraphy theory and paleogeomorphic sand control theory, the sequence stratigraphic frameworks of the lower Cretaceous in Tanan sag are established. Combined with the analysis of the major fault activity during different rifting stages, the controlling effects of different paleogeomorphologies on sedimentary system and sand body distribution are clarified. The investigation of the tectonic evolution and sediment fill of Tanan Sag during the early Cretaceous indicated that the episodic rifting and various activities of major faults created complex paleogeomorphologies including transfer zones and structural slope-break zones, which significantly controlled the development and distribution of both depositional systems and sand bodies. The transfer zones including transverse uplift and relay ramp were the sites for drainage catchment, and controlled the locations of sedimentary provenances, entry points of sedimentary material into the basin, and the resultant development of depositional systems. According to fault geometry and the location of the slope-break zones, the structural slope-break zones of Tanan Depressoion during the climax rifting stage would be subdivided into four types, they are fault scarp zone, fault terrace zone, gentle slope zone and intrabasinal fault break zone, which played significant roles in controlling the changes in accommodation and the distribution of depositional systems and sand bodies. Three syndepostional faults arrangement patterns were identified according to their distribution on the structure map, which are “comb-like”, “fork-like and “parallel” faults. Areas where the structural slope-break zone overlapped with transfer zones are sites for major drainage systems and the optimum locations of fan deltas and sublacustrine fans. The sand bodies deposited here are favorable targets for the exploration of litho-stratigraphic traps in Tanan Sag. The results have important theoretical significance and practical value for deepening the theory of source-to-sink system and guiding the prediction of sand body distribution in faulted lacustrine basins.

Keywords: lamina, lacustrine shale, physical properties, Shahejie Formation, Bohai Bay Basin

The development of lacustrine shale lamina makes the shale heterogeneity change obviously, and the degree of lamina development has an important influence on the quality of shale reservoirs. Based on nitrogen adsorption, X-ray diffraction, total organic carbon, pyrolysis experiments and scanning electron microscopy experiments, the lamina characteristics and their influence on shale reservoirs in the first Member of Shahejie Formation were studied in the Nanpu Sag, Bohai Bay Basin. Combined with ImageJ software(binarization, mean filtering and map value conversion), the purpose of this paper is to systematically study the types and assemblages of lamina, the structure of lamina, and the factors controlling the development of lamina. According to the mineral composition and lamina thickness, the laminas were divided into organic-rich-felsic laminae and organic-rich-clay laminae. The thickness of the organic-rich-clay lamina was 25-210μm, and its total organic carbon content was about 1.2%. The thickness of organic-rich-felsic lamina was 15-170μm, and its total organic carbon content was about 0.9%. The development of lamina had a good effect on reservoir. The number of lamina and areal density had a good positive correlation with the physical properties and specific surface area of the reservoir, and had a negative correlation with the total pore volume and average pore size. However, the lamina thickness showed the opposite trend with the above reservoir parameters. The development of lamina was controlled by the content of total organic carbon and mineral components. The lamina shale were characterized by rich in organic matter and high clay or felsic mineral content. As the total organic carbon content and carbonate mineral content increased, the lamina was more developed.

Genetic model and reservoir prediction of braided river delta prograding body in the middle submember of 3rd member of Shahejie formation in the Laizhouwan

[1*], Xiaofeng Du[1], Dayong Guan[1], Qiming Wang[1], Hongguo Zhang[1]
1. , (), , CHINA
E-mail: 819452063@qq.com

Keywords: Laizhouwan depression, Shahejie formation, braided river delta, prograding body

The discovery of oil and gas in braided river delta prograding body in the middle submember of 3rd member of Shahejie formation in the Laizhouwan depression have confirmed its large lithologic exploration potential. Through the combination of well and seismic data, PaleoScan software was used to intelligently identify the interface of parasequence sets inside the prograding body, and strict isochronous high-frequency sequence stratigraphic framework was established to divide the prograding body into five parasequence sets. The fine characterization of topset beds, foreset beds and bottom beds in prograding body were conducted with the paleogeomorphology restoration of each parasequence set. Furthermore it was founded that the relationship among foreset angle and sand content follows the uniform inverse function .The spatial distribution patterns of sand bodies in each parasequence set were clarified, one is the high-angle S-type prograding body sand enrichment model which the favorable reservoirs mainly distribute in the deltaic front subaqueous distributary channel in steep foreset beds of parasequence set I-II, and another one is the low-angle oblique type prograding body sand enrichment model which the favorable reservoirs mainly distribute in the prodelta turbidite body in gentle bottom beds of parasequence set III-V. Those reservoirs have favoured the formation of lithologic oil–gas reservoirs by means of good trap sealing conditions, excellent oil–gas reserving performance, and effective oil source communication of high-quality source rock.

Keywords: unconventional geology,lacustrine shale oil,sweet spot,fine-grained sedimentary,nano-pores

The characteristics of laminae are critical to lacustrine shale strata. They are the keys to the quality of source rocks and reservoirs, as well as engineering operations in shale plays. This study uses organic geochemistry, thin section identification, X-ray diffraction, field emission scanning electron microscopy, and other analytical methods, to reveal the detailed lamination texture and vertical distribution of laminae in the second Member of the Kongdian Formation in Cangdong Sag. The principal results are as follows: (1) A classification of laminae is proposed to characterize reservoir and geochemical properties. The five types of laminae are as follows: feldspar-quartz laminae (FQL), clay laminae (CLL), carbonate laminae (CAL), organic matter laminae (OML), and bioclastic laminae (BCL). There are also four significant lamina combinations (with the increasing TOC values): FQL-CLL combination, FQL-CLL-BCL combination, FQL-CLL-OML combination, and FQL-CAL-CLL-OML combination; (2) differences between laminae occur because of the variability in pore types and structures. There appears to be a greater abundance of intercrystalline pores of clay minerals in the FQL, CAL, BCL, and OML, and well-developed organic pores in the CAL and CLL, and the counterparts of intragranular pores of bioclastic material in the BCL. This detailed characterization provides the following comparative quantification of the thin section porosity of laminae in the second Member of the Kongdian Formation can be differentiated: CAL > FQL > OML > BCL > CLL; (3) differentiation between vertical distributions of laminae is carried out in a single well. The FQL and CLL are widely distributed in all the samples, while the BCL is concentrated in the upper part of the second Member of the Kongdian Formation, and CAL is concentrated in the lower part. This detailed classification method, using geochemical analysis and vertical distribution descriptions, offers a detailed understanding of lamination texture and its effects on reservoir and geochemical properties, which will provide a scientific guidance and technical support to better estimate reservoir quality and to identify new sweet spots in the second Member of the Kongdian Formation in the Cangdong Sag.

Discovery of Late Cretaceous Tidal fearture – new evidence of marine transgression in the West African continental rift basin Termit, Niger

Shengqiang Yuan[1*], Xingyang Zhang[1], Fengjun Mao[1], Hairong Wang[2]
1. Research Institute of Petroleum Exploration & Development(RIPED), Petrochina, Beijing, CHINA
2. College of energy resources , China University of Geosciences, Beijing, CHINA
E-mail: yuanshq04@126.com

Keywords: Niger,Termit basin, Late cretaceous, Tidal, marine transgression,prototype basin

Termit Basin belongs to West African continental rift system, and formed in early Cretaceous as lacustrine depositon system. According to literatures, transgressive activity across the Sahara seaway happened in the Late Cretaceous global sea high level period, and including Termit baisin. And none of marine deposition evidence was reported in these area, perhaps because the basin is under the Sahara desert, and lack of outcrops. In this paper, based on the cores recently obtained in the Termit Basin, typical sedimentary facies marks such as herringbone cross-bedding, double mud drapes, tidal rhythm, and tidal bedding (flaser bedding, wavy bedding, and lenticular bedding) were identified. And then the tidal-generated superimposed transgressive succession was interpreted. Accordingly, the existence of tidal flat deposits was confirmed in combination with palaeontological fossils (e.g., fossil foraminifera) and trace fossils, which illustrates the generality of tidal action in the Late Cretaceous Termit Basin. Based on the above, the prototype basin of the Termit Basin is restored with the aid of thorough data integration. It is considered that the Termit, Iullemeden, Tefidet, Tenere, Grenin, and other basins were within a unified basin setting in the Late Cretaceous that was wide in the east-west direction and connected with Tethys and South Atlantic in the north-south direction. The prototype basin constitutes the central main part of the Saharan seaway. The paleogeographic conditions of this seaway, which is affected by oceanic action (especially tidal action) and contains abundant marine deposits, may be similar to the Late Cretaceous North American Western Interior Seaway.

The evolution and characteristics of sublacustrine fan types in different stages during the process of delta progradation in rifted lacustrine basin, Liaozhong Sag, Bohai Bay Basin, China

Yimeng Liu[1*], Li Zhang[1], Xin Cheng[1], Chao Yang[1], Junpei Yue[1]
1. Bohai Oilfield Research Institute, Tianjin Branch of CNOOC China Ltd. , Tianjin, Tianjin, CHINA
E-mail: liuym33@cnooc.com.cn

Keywords: sublacustrine fan, delta progradation process, rifted lacustrine basin, spatial evolution, Liaozhong sag

Liaozhong sag in the Bohai Bay Basin is a graben-type rifted lacustrine basin with east-west double faults. During the Paleogene period, the ancient Daling River and the ancient Liao River entered the basin along the long axis of the fault depression, forming two large-scale meandering river deltas superimposed with each other. During the progradation process of the two deltas, 14 sublacustrine fans deposits were formed, with the characteristics of vertical superposition and horizontal connection. Drilling revealed that these sublacustrine fans coexisted with sand-rich and mud-rich types, with complex spatial evolution laws, and unclear correspondence between sublacustrine fans and deltas. To solve these problems, on the basis of clarifying the relationship between each sublacustrine fan and the two deltas, starting from analysis of the sand-rich changes in the delta progradation process, this paper defines the types, characteristics and mechanisms of sublacustrine fans formed at different stages in the delta deposition process.

The study shows that: The two deltas have different foreset directions and heavy mineral assemblages. The ancient Daling River enters the basin from north to south, and the heavy mineral combination was zircon-magnetite-limonite-tourmaline; the ancient Liao River entered the basin from northeast to southwest, and the heavy mineral combination was tourmaline-magnetite-zircon-limonite. The thickness trend of the sublacustrine fans has obvious affinity with the provenance. The trend of No.1-4 sublacustrine fans is between 195° and 202.17°, which is consistent with the ancient Daling River delta; The thickness of No.5-14 sublacustrine fans strikes between 230.4° and 262.5°, which is consistent with the ancient Liao River delta. The sublacustrine fans can be divided into 3 types with non-channelized sandy-debris-flow(SDF) sublacustrine fan, non-channelized turbidite-current(TC) sublacustrine fan and channelized fan. SDF sublacustrine fans and TC sublacustrine fans have no evident channel, and the SDF sublacustrine fans are rich in sand, TC sublacustrine fans are rich in mud; channelized fans have evident channel, and the sand is main in the channel. Sand-richness of provenance plays a major role in controlling sublacustrine fan types. The sand rich provenance, which is non-viscous and easy mixed with water when slumping, cannot form the channel easily; the mud rich provenance, which is viscous and hardly mixed with water when slumping, can form the channel with ease. Therefore, when the sand content of the delta front is greater than 30% in the early stage, non-channelized sublacustrine fans will be formed. When the sand content is less than 30% in the late stage, it is easy to form a channelized sublacustrine fan. The scale of the slope break zone plays a secondary role in controlling the sublacustrine fan types. Under the sand-rich provenance background, due to the long transportation distance with large scale of the slope break, the sand and mud are fully differentiated, both SDF sublacustrine fan and TC sublacustrine fan can be formed. However, only SDF sublacustrine fan can be found in the condition that the slope break scale is small.

Topset-to-foreset rollover trajectories and stratal stacking patterns: Their relation to sediment and sand dispersal to southern Bozhong deep water, Bohai Bay Basin

Puyu Liu[1], Chenglin Gong[1*], Yang Peng[1], Dayong Guan[2], Dongwei Li[1], Qiming Wang[2]
1. College of Geosciences, China University of Petroleum (Beijing), Beijing, CHINA
2. Bohai Oilfield Research Institute, China National Offshore Oil Corporation, Tianjin Branch,, Tianjin, CHINA
E-mail: chenglingong@hotmail.com

Keywords: rollover trajectories, stratal stacking patterns, sand dispersal, sequence stratigraphy, southern Bozhong sag of Bohai Bay Basin.

The analysis of stratal stacking patterns and shelf-edge trajectories is considered as a recent advancement in sequence stratigraphy and they are reliable predictors of sand dispersal to deep water. Using 3D seismic and borehole data, the current research documented Oligocene topset-to-foreset rollover trajectories and explored their sequence stratigraphic significances and implications to sand dispersal to southern Bozhong deep water, Bohai Bay Basin. Two main types of topset-to-foreset rollover trajectories and their associated stratal stacking patterns were recognized: (1) flat and then rising trajectories and associated progradational-aggradational stacking patterns, and (2) initially rising, and then flat, and finally turn to descending trajectories and associated aggradational-progradational-degradational stacking patterns. The former has low trajectory angles (T_r) (0.32°-1.07°, averaging 0.72°), topset-to-foreset rollover aggradation to progradation ratios (d_y/d_x) (0.01-0.03), and differential sedimentation on the slope and basin (A_s/A_b) (0.14-0.23, averaging 0.18), whereas the latter is with higher Tr (0.57°-1.17°, averaging 0.94°), d_y/d_x (0.02-0.04) and A_s/A_b (0.47–2.31, averaging 1.16). Each trajectory regime represents a specific stratal stacking patterns. Moreover, flat and then rising topset-to-foreset rollover trajectories and progardational-aggradational stratal stacking patterns were related to massive, extensive, and sand-rich sub-lacustrine fan systems that were linked to straight channels updip. Initially rising, and then flat, and finally turn to descending topset-to-foreset rollover trajectories, however, were fronted by laminated, diminutive, and sand-rich sub-lacustrine fan systems that were fed by sinuous channels. Therefore, given a constant sediment supply, T_r, d_y/d_x and A_s/A_b are negatively correlated with the amounts of sand dispersal to deep water. These relationships between topset-to-foreset rollover trajectories (or stratal stacking patterns) and depositional characteristics of sub-lacustrine fan systems provide a quantitative method to predict the sand dispersal to deep lake in continental rift basins.

Sandbody distribution and tight sandstone genetic mechanism in a rift basin with strike-slipA case study from Shuangyang Formation of Chaluhe Fault Depression in Yitong Basin

Jiang Xiao Hua[1*], Cui Jun Feng[1], Wu Song Tao[1], Wu Xue Qiong[1]
1. RIPED, CNPC, Beijing, CHINA
E-mail: luckyjxh2004@126.com

Keywords: rift basin, strike-slip, provenance, tight sandstone, genetic

The Yitong graben represents a rift basin under a typical strike-slip setting. In recent years, its deep tight sandstone gas reservoirs have shown good exploration prospects.However, the distribution of sand bodies and the characteristics of tight sandstone reservoirs are unclear. In this study, taking the Shuangyang Formation in the southern part of the Chaluhe fault depression in the Yitong Basin as the research object, on the basis of seismic and logging analysis, combined with various experimental methods such as rock thin sections observation, scanning electron microscopy, and micro-CT, three findings were obtained as follows:(1)The Shuangyang Formation develops two provenances, the fan delta in the northwest margin and the braided river delta in the southeast margin, and is dominated by the southeast provenance. The sand body in the southeast margin covers 2/3 of the area of the fault depression, and the fans are distributed obliquely along the depression-controlling fault.(2) The tight sandstone of the Shuangyang Formation is in the middle diagenetic stage B, dominated by detrital feldspar sandstone, mainly siliceous cementation, with porosity of 4-10% and permeability of 0.02-5×10-3μm2. Mechanical compaction, conversion of clay minerals to illite and the formation of secondary minerals are the main porosity reduction effects.(3) The sandstone of the Shuangyang Formation changed into tight sandstone at the E2y period (about 35 Ma) , while the main gas accumulation period is the E3w (about 30 Ma). Therefore, the tight sandstone gas reservoir was formed after the sandstone reservoir densificated. These findings could provide guidance for tight sandstone gas exploration in rift basins.

Sedimentary microfacies, diagenetic process and reservoir quality of sandstones from the No. 1 structural belt in Nanpu Sag, Bohai Bay Basin, China

Zhenghong Yu[1], Si Chen[1*]
1. School of Earth Resources, China University of Geosciences (Wuhan), Wuhan, Hubei, CHINA
E-mail: sichen720@hotmail.com

Keywords: Sandstone reservoir quality, Sandstone diagenesis, Sedimentary microfacies, Nanpu Sag

Reservoir quality is generally evaluated by porosity and permeability, which are critical parameters for petroleum and natural gas exploration and production (Shang et al., 2022; Xie et al., 2021a). Reservoir porosity defines the hydrocarbon storage ability, whereas permeability limits hydrocarbon production capacity, and both have a significant impact on the economic feasibility of a petroleum accumulation (Worden et al., 2000, 2018; Xie et al., 2021b, 2021c). Prediction of rock properties must be based on integrated study of sedimentary and diagenetic processes.

Nanpu Sag is a petroliferous sag in the Bohai Bay Basin and has produced a significant quantity of industrial oil flows in shallow to deep layers (depth ranges roughly from 2500 km to 4000 km) (Chen et al., 2014; Jiang et al., 2018; Wang et al., 2020; Yang et al., 2022). The No. 1 structural belt is located in the southwestern Nanpu Sag. At present, many sets of oil-bearing strata have been found in Paleogene Shahejie Formation, Dongying Formation, and Neogene Guantao Formation, Minghuazhen Formation, and the primary exploration strata are Dongying Formation (28.5-23.8 Ma) (Hao et al., 2019).

To address the roles of sedimentary processes and diagenesis on reservoir quality, a study of the sandstones from the No. 1 structural belt in Nanpu Sag, Bohai Bay Basin, China, was undertaken based on wireline and core analysis data, petrography, scanning electron microscopy, and X-Ray diffraction of core samples. Five types of sedimentary microfacies are recognized: subaqueous distributary channel (fan delta), subaqueous interdistributary bay, subaqueous distributary channel (braided delta), distal bar, and turbidite fan. The major diagenetic processes, including compaction, cementation, and feldspar dissolution of the feldspathic litharenite sandstones, have been tested. The dominant diagenetic cement includes calcite, smectite, kaolinite, illite, and I/S mixed-layer minerals, with minor quantities of pyrite, chlorite, siderite, K-feldspar, and quartz cement. Reservoir quality is best in subaqueous distributary channel (fan delta) sandstones, followed by subaqueous distributary channel (braided delta). Subaqueous interdistributary bay, distal bar, and turbidite fan are of poor reservoir quality. The grain size is the primary reservoir quality controlling factor, highly affected by sedimentary microfacies. Subsequent controls are diagenetic processes such as mechanical compaction, clay minerals formation, grain replacement, and dissolution that collectively influence the porosity and permeability.

Genetic evolution and exploration significance of large restricted gravity flows: A case study of the second member of the Southeast slope belt in the Bohai Sea

Qiming Wang[1*]
1. Bohai Oilfield Research Institute, CNOOC_ Ltd, Bohai Oilfield Research Institute, CNOOC_ Ltd, tianjin, CHINA
E-mail: wangqm@cnooc.com.cn

Keywords: Sublacustrine fan,Channel,Evolutionary characteristics, Developmental pattern,Bozhong sag

The Dongying formation in the Bohai Sea showed a paleo-tectonic pattern of post-rift transition period . Subsidence rate and filling thickness of the basin were much higher than those of the surrounding continental areas. Depression zone as a whole showed a process of rapid deposition and leveling, and gravity flow deposits were widely developed.

Large gravity flow deposits are developed in the lower second member of the Dongying formation in eastern section of the southeast slope belt of central Bohai depression, which has great potential for lithologic exploration. In view of the unclear genesis mechanism and temporal and spatial evolution law of the fan body under the condition of no well, the seismic data were comprehensively used to analyze the response characteristics and genesis mechanism of gravity flow deposition, clarify the plane distribution and vertical evolution characteristics of the sublustrine fan, and summarize its development model. Research results show that: (1) under early of the lower second member of the Dongying formationproximal deposit were given priority by the Bonan low bulge, under later period show the fault depression transformation stage, the Bonan low bulge gradually fadeout in underwater, mainly by Jiaoliao-Miaodao southeast of drainage system, the formation of braided river delta in the bulge high parts passing flow, under the lower parts of the sedimentary slope break in slope unload, controlled by the restricted paleogeomorphology under the slope break, the fan-shaped large gravity flow deposits were formed. Under the condition of sufficient material supply and long-distance transportation, the gravity flow sand body has good conditions for the development of sand-rich and high-quality reservoirs. (2) early restrictive paleogeomorphology can accommodate large space, from the top of the settlement of gravity flow sand body to select uninstall, formed A, B, C three big gravity flow deposits, due to space constraints on both sides, hydrodynamic conditions, formation of the channel characteristics of seismic facies cluttered with incised, lateral migration overlay, characterized by rich sandy debris flow characteristics of the sand. Mid with continuous replenishment gravity flow sand body, can accommodate space gradually decreases, and gravity flow along the supply channel in front of the overflow, to two steps under the open lake basin center handling, formed two gravity flow fan body, D, E, due to water concentration dilution and the ancient landform changes, energy gradually weakened, seismic facies with layered strong amplitude reflection characteristics, channel characteristic is not obvious. The late provenance supply and energy were weak, and the seismic facies showed weak amplitude reflection for local erosion and reconstruction of early fan body, which was dominated by muddy channel. The vertical gravity flow has a spatio-temporal distribution and evolution law of early restriction filling, mid-maturity overflow adjustment and late erosion reconstruction, which constitute the development characteristics of transverse connected and vertical multi-stage gravity fans.

Large restricted gravity flow sandbodies have favorable hydrocarbon migration, accumulation and accumulation conditions close to oil source and reservoir cap combination, which are important targets for lithologic reservoir exploration in Bohai Sea in recent years.

Keywords: gravity flow deposits in a lacustrine basin, sandy debris flow, turbid current, Chang 6 member of Yanchang Formation, Ordos Basin

Deep-water gravity flow deposits in a lacustrine basin is the focus of sedimentology research and the main target of tight oil exploration. Based on three-dimensional (3-D) seismic data, logging data, core analysis and laboratory data, the sedimentary characteristics, sand body distribution and sedimentary model of the Chang 6 member of Yanchang Formation are studied in Yanchi area of Ordos Basin. The results show that the gravity flow deposits in the study area is given priority to with mudstone, siltstone and fine sandstone deposition, grain size probability cumulative curves is given priority to with two stages on the arch arc. The gravity flow types are divided into sandy debris flow and turbidity current. The sandy debris flow is given priority to with gray, gray fine-grained sandstone, silty sand rock, massive bedding, normally graded and inverse graded; The turbidity current is mainly composed of gray and gray silt and silty clay with incomplete bauma sequence such as cross bedding, wavy bedding and normal graded bedding. The gravity flow deposit is sandy debris flow deposit with bandedsandstone beds in the proximal, and turbidity current deposit with sheet-like sandstone beds in the distal lobes.The thickness of sandy debris flow sand body is 20-30 meters, and it is in short strip shape. The turbidity current sand body is 2-5m, and it is distributed in the shape of lobes. The sediment of gravity flow in Yanchi area belongs to slump accumulation of Yanchi delta front.

E-mail: yang100808@126.com

Keywords: debrites, turbidites, hyperpycnites, Eocene, Dongying Depression, Bohai Bay Basin

The Dongying Depression in the Bohai Bay Basin (E China) is an asymmetric dustpan-shaped fault basin with a steep slope in the north and a gentle slope in the south. These differences in steepness controlled the sedimentary systems. Sedimentary systems with shallow lakes and deltas developed on the gentle southern slope, whereas deep subaqueous fan systems developed on the steep northern slope. Mass flows occurred in both slopes, but with different characteristics. The sandstones that they deposited and their depositional conditions nowadays attract much attention in the context of oil and gas exploration. The joint occurrence of various types of mass-flow deposits, their spatial distribution and their relationship with reservoir development are still badly understood, which hampers successful prediction of reservoir occurrences in the lacustrine sediments.

Well logs, cores and profiles based on seismic reflections have, in combination with datings, been analyzed to determine the characteristics and distribution of these sediments. It was found that, on the southern gentle slope of Dongying Depression, debris flows and turbidity currents (due to slope failure of delta fronts) and hyperpycnal flows (developed during high-discharge phases of ricers) reached the deep-water environment, building vertical successions of debrites, turbidites and hyperpycnites. On the northern (steep) slope of the Dongying Depression, debrites and turbidites did not existed because deltas were not or hardly developed. On the northern (steep) slope of the Dongying Depression, debrites were deposited from the lower parts of deltaic slopes to the slope toes; turbidites were deposited from the slope toes to the centre of the basin. Turbidites did not developed because deltas were not or hardly developed. Most sandstones on the northern sloped were deposited, however, by hyperpycnal flows. In the central graben of Dongying Depression, hyperpycnites were deposited simultaneously from flows that followed either the long axis or the short axis of the basin.

The results obtained concerning the characteristics and distribution of the various types of gravity flow deposits in the deep lake, as controlled by the steepness of the slope help effective reservoir prediction not only in the Dongying Depression, but also comparable basins elsewhere in the world.

Deep Lacustrine sedimentary systems interaction with breached relay ramp structures

Gayle Plenderleith[1*], Thomas Dodd[1]

1. Decarbonisation and Resource Management, British Geological Survey, Edinburgh, Scotland, UNITED KINGDOM

E-mail: gaylep@bgs.ac.uk

Keywords: breached relay, deep lacustrine, Early Cretaceous

Fault relay ramps serve as sediment delivery points along rift margins and often provide persistent flow pathways in deepwater sedimentary basins. Relay ramps first form as tilted rock volumes between en-echelon fault segments. Through progressive deformation the tilted rock volume becomes faulted and fractured. Eventually, a through-going fault may develop which breaches the relay ramp structure. It is well established that hinterland drainage (fluvial/alluvial systems) is greatly affected by the presence of relay ramps at basin margins, with these systems commonly exploiting the relay structures as a route into basins. However, the impact on deepwater (deep-marine/lacustrine) subaqueous sediment gravity flow processes, particularly by breached relay ramps, is less well documented. To better evaluate the complex geology of breached relay settings, this study examines a suite of high-quality subsurface data from the Early Cretaceous deep-lacustrine North Falkland Basin (NFB). The Isobel Embayment breached relay-ramp is an ideal example and was formed during the syn-rift. Using a 3D seismic volume, the structure and stratigraphy of the Isobel Embayment has been interpreted, providing the context for the study. The study analyses the transitional and early post-rift succession of the Isobel Embayment which contain Horizons A, B, C and D of this study. Seismic amplitude maps have been generated from a root mean square (RMS) amplitude interval of 20 ms (10 ms above and below the horizon) for each study horizon. Seismo-geomorphological analysis and interpretation of the study horizons identified a series of well-imaged fan systems and internal lobes at the breached relay location. These high amplitude, lobate features align with sandstone gamma ray responses intersected in wells 14/20-2 and/or 14/20-1. The breached relay ramp was progressively covered by a thick transitional and early post-rift succession. Major transitional and early post-rift fan systems are observed to have consistently entered the basin at the breached relay location. The systems were directed through a significant palaeo-bathymetric low which is likely to be associated with the lower, abandoned ramp of the structure. More minor systems also entered the basin across the structure-bounding fault to the north. Reactivation of basin-bounding faults is shown by the introduction of new point sources along the basin margin. This study shows the prolonged influence of margin-located relay ramps on sedimentary systems throughout the transitional and into the early post-rift phase. In particular, a palaeo-bathymetric low which is associated with the abandoned lower ramp of the structure, remains prominent into the early post-rift and appears to direct deep lacustrine sedimentary systems into the basin across the breached relay location. It suggests that these structures can become reactivated during post-rift times, providing continued control on deposition and sourcing of overlying sedimentary systems. Importantly, breached relays exert control on fan distribution, characterised by laterally extensive lobes sourced by widespread feeder systems, and hanging walls settings by small scale lobes, with small, often line-sourced feeders. Further characterising the likely sandstone distribution in these structurally-complex settings is important as these systems often form attractive hydrocarbon reservoirs.

Characteristics of Chang 8 Palaeo-lacustrine Basin of Yanchang Formation in Longdong Area, Ordos Basin and Its Controlling Effect on Sand Body Distribution

Ma Yao[1*]
1. School of Earth Sciences and Engineering, Xi'an Shiyou University, Xi'an City, Shaanxi Province, CHINA
E-mail: mayao90s@163.com

Keywords: Ordos Basin,Longdong area,Yanchang Formation,Chang 8 sedimentary period, characteristics of palaeo-lacustrine basins,sedimentary environment

Major breakthroughs have been made in oil and gas exploration and development in Longdong area, southwest of Ordos Basin. The Longdong 10 million-ton oil and gas production base has been fully built in early 2022. Chang 8 oil-bearing formation of Triassic Yanchang Formation is one of the key oil bearing strata in Longdong area of Ordos Basin. The characteristics of palaeo-lacustrine basins include palaeoclimate, palaeobathymetry and palaeogeomorphology, which control the distribution of sedimentary facies, clastic composition, sand body and source rock. The study of palaeo-lacustrine basin features is the basis of the study of continental sedimentary basin. At present, there are few studies on the characteristics of palaeo-lacustrine basin in chang 8 sedimentary period of Yanchang Formation. In order to study the sedimentary facies and sand body distribution more finely, this paper analyzes the characteristics of the palaeo-lacustrine basin of Chang 8 sedimentary period, such as the palaeobathymetry and the bottom shape of it, and summarizes their control effect on the sand body type and distribution.

Based on core data, organic carbon isotope geochemical analysis, stratigraphic thickness correction, paleobathymetric recovery and 3D visualization techniques, the characteristics of the Chang 8 lacustrine basin in Longdong area are studied. The data show that the lacustrine basin of Chang 8 period in Longdong area is in humid climate and the water body is generally shallow, which accords with the sedimentation characteristics of shallow water braided delta front. The organic matter of Chang 8 mainly comes from terrestrial higher plants. Local water bodies deepened, mainly in Luopangyuan-Tiebiancheng and Chenghao-Qingcheng areas in the northeast of Longdong area, and Ningxian in the southeast and Jingchuan in the southwest. According to the diagram of lacustrine bottom shape in Chang 8, the lake bottom shape in Chang 82 and Chang 81 was higher in the west and south and lower in the northeast, and there were low-lying areas basically consistent with the above range. It is concluded that there are water downslope break zones in both Chang 82 and Chang 81 lakeside basins in Longdong area. The water downslope break zone of Chang 82 is widely distributed, mainly located in Luopangyuan - Mubo - Qingcheng - Heshui area, which plays an important role in controlling and influencing the development characteristics and flat distribution of Chang 82 sand body in the study area. The Chang82 sand body near the downslope break zone presents an obvious lenticular distribution, and the multi-stage sand body is superimposed and developed. The total thickness of the sand body in a single well is large, but the transverse connectivity is poor. However, the water downslope break zone of Chang 81 stage has a small distribution range and has little influence on the distribution of sand bodies in the study area.

New insights into hybrid event beds in deep-lacustrine fan systems

Thomas John Henry Dodd[1,2*], Gayle E Plenderleith[1], Stuart M Clarke[2,1], Dave J McCarthy[1], Lawrence Amy[3]
1. Decarbonisation and Resource Management, British Geological Survey, Edinburgh, Scotland, UNITED KINGDOM
2. School of Geography, Geology and the Environment, Keele University, Keele, Staffordshire, UNITED KINGDOM
3. School of Earth Sciences, University College Dublin, Dublin, IRELAND
E-mail: tdodd@bgs.ac.uk

Keywords: Hybrid event beds (HEBs), deepwater, flow processes, deep-lacustrine, hydrocarbon reservoirs, North Falkland Basin

Hybrid event beds (HEBs) are texturally and compositionally-diverse deposits formed by flows exhibiting ‘mixed behaviour’. These flow types typically form complex successions of sandstone and mudstone in the subsurface. HEBs tend to be clay-rich and are well-known for their ability to reduce reservoir quality/hydrocarbon pore-volume, as well as acting as vertical fluid transmissibility barriers and baffles in reservoir units. Consequently, their character and likely distribution within deep-marine hydrocarbon reservoirs has been studied somewhat extensively. However, (and by contrast) there are far-fewer studies that focus on HEB character and distribution in deep-lacustrine settings. Understanding HEBs within the context of deep-lacustrine fan models is therefore of great importance to continued hydrocarbon exploration success and efficient development of deep-lacustrine reservoirs in basins worldwide. To improve our understanding of these complex sedimentary successions, this study presents a detailed analysis of 3D seismic data, wireline logs and core from a series of ancient deep-lacustrine fan systems in the North Falkland Basin. Results of this study confirm that deep-lacustrine HEBs comprise a similar idealised sequence of the ‘H1–H5’ divisions as observed in deep-marine settings. However, in this study the H3 ‘debrite’ units is subdivided into three internal divisions (H3a, H3b, and H3c), based on: sharp or erosional intra-H3 contacts, bulk lithology, mud-content and discrete sedimentary textures. Spatially, HEBs are observed within lobe fringes, where flow types, energies, and transport mechanisms diversify as a result of flow transformation. The temporal context of HEBs is considered in-relation to stages of fan evolution, with HEBs being observed typically in either the initiation phase, where flow interaction and erosion of initial substrates promoted mixed flow behaviour, or in the abandonment phase, as facies belts retreated landward. The results of this study have important implications in terms of the prediction of HEB occurrence and character within ancient deep-lacustrine fan settings.

Abstract

Seismites are well known particularly from Quaternary silty and muddy sediments in lacustrine settings, but hardly from lithified ancient equivalents, because the uniform grain size in shales tends to obscure the deformation. The Early Cretaceous Tianjialou Formation, developed near the village of Xiahouzhuang (Shandong Province, E. China) in a shallow-lacustrine facies, is an exception. The sediments are predominantly silty mudstones, with a few thin intercalations of fine sandstone. The formation at this site shows a slightly shallowing tendency. Layering in the pure mudstones present in the lower part of the exposed section is difficult to trace, but it is obvious that some entirely deformed levels are present interbedded between non-deformed levels. In the upper part, where the layering is better discernible, it appears that even numerous completely deformed layers exist, intercalated between non-deformed levels. All deformed levels show the characteristics of seismites.
The seismic activity must be ascribed to fault activity along a zone that is now occupied by the Shuhe River. The rocks with the deformations dealt with here are cut by the river. Taking into account that the faulting was active already during the Early Cretaceous, this implies that the distance between the sediments under study and the contemporaneously active fault zone was only a few to maximally a few hundred metres. This explains not only the occurrence of seismites in these lacustrine sediments, but also the presence of deformed mudstones in not well discernable levels: even though many of the earthquakes may have had low magnitudes, the distance of the epicentre to the water-saturated muds was so small that locally deformation of the mud could take place. This implies that the magnitude of an earthquake required for seismically-induced deformation of soft sediments need not necessarily have been at least 4.5-5 as commonly mentioned in the literature, but may have been less if water-saturated sediments were located very close to the epicentre.

A research on relative lacustrine level changes and sedimentary characteristics of Paleogene Kumugeliemu Group in the Dibei-Dina area of Tarim Basin

Lisha Yang[1*], Qingzhou Yao[1], Qifei Fang[1], Zhenqing Wang[1]
1. NWGI, Research Institute of Petroleum Exploration & Development, Petrochina, Lanzhou, Gansu, CHINA
E-mail: yanglisa86@petrochina.com.cn

Keywords: lacustrine level changes, sedimentary characteristics, two-step lithological identification

The lower sand member of Paleogene Kumugeliemu Group in the Dibei-Dina area of Tabei Uplift in Tarim Basin is a favorable exploration target for lithological reservoirs in recent years. However, the shallow water deltas and beach bars deposits were superimposed, it is difficult to identify the high-resolution sequence stratigraphy characteristics, sedimentary microfacies, and temporal-spatial evolution laws. On the basis of core, drilling, logging and 3D seismic data, the quantitative analysis of relative lacustrine level changes is helpful to determine sedimentary fades type and reveal their distribution rules. The markers, sequence boundaries and flooding surfaces have been identified and isochronally tracked to construct a high-resolution sequence stratigraphy framework. Under the constraint of sequence stratigraphy, the types and characteristics of sedimentary micro-facies of each high-frequency sequence unit were analyzed and the temporal-spatial evolution laws of sedimentary microfacies have been revealed. Compared with previous results, we find that relative lacustrine curve on overall trend in this research was quite in accordance with previous results. Several subtle small-scale relative lacustrine level changes can be used as a theoretical basis for follow-up geological research in this area. The lithological identification charts are established using two-step lithological identification method according to multiple logging response curves sensitive to lithology, such as natural gamma ray, density, acoustic time difference and induction resistivity, providing foundation for further exploration for lacustrine lithological reservoirs.

Characteristics and classification evaluation of pore throat structure in Chang 7 tight reservoir of Yanchang Formation in Ganquan Oilfield

Du Guichao[1*]
1. School of Geosciences and Engineering, Xi'an Shiyou University, Xi ' an City, Shaanxi Province, CHINA
E-mail: duguichao@sina.com

Keywords: Ganquan Oilfield, chang 7 oil layer, tight reservoir, pore throat structure, reservoir classification

Abstract: Tight reservoir has become one of the most important fields of oil and gas exploration and development in China, and tight reservoirs typically developed in Chang 7 oil layer of Yanchang Formation in Ganquan Oilfield. Based on a series of method of thin section identification, casting thin section, scanning electron microscopy, mercury injection, etc, detailed characterization of petrological characteristics, reservoir physical properties, reservoir space types and pore throat structure characteristics of Chang 7 tight sandstone reservoir in Ganquan Oilfield are carried out. In addition, the tight sandstone reservoirs are classified and evaluated. The results show that the lithology of Chang 7 reservoir in Ganquan Oilfield is mainly lithic feldspathic sandstone and feldspathic lithic sandstone. Its median value of air permeability is less than 1 mD, and the median value of pressure permeability is 0.0554 mD, which is a typical tight reservoir. The reservoir space of sandstone is dominated by residual intergranular pores and feldspar dissolved pores, with a small amount of micro-fractures, and the average face rate was 3.45 %. The pore throat radius of reservoir sandstone is distributed in a wide range and large scale, and the pore diameter is generally 0.23 μm~57.35 μm. The pores are mainly small pores, and the average pore diameter is about 22.35 μm. The throat radius is generally 0.03 ~ 3.5μm, with an average of 0.35μm. Tight reservoirs in the study area generally show characteristics of complex pore throat structure and strong heterogeneity, mainly include small pore-fine throat type, small pore-fine throat type of reservoirs, which play a major contribution to reservoir physical property in study area. Finally, the classification and evaluation criteria of Chang 7 tight sandstone reservoirs were established, and the tight sandstone reservoirs in the study area were divided into five types. Among the five types of reservoirs, II and III types of reservoirs are widely developed in Chang 7 oil layer of the study area, which are favorable reservoir types, followed by I and IV types of reservoirs.

Autogenic and allogenic controls on the characteristics of meter-scale cycle in the Nenjiang Formation from the Cretaceous Songliao Basin (northeastern China)

Daming Yang[1], Yongjian Huang[1,2*], Chengshan Wang[1,2]
1. State Key Laboratory of Biogeology and Environmental Geology, China University of Geosciences, Beijing, CHINA
2. School of the Earth Sciences and Resources, China University of Geosciences, Beijing, CHINA
E-mail: huangyj@cugb.edu.cn

Keywords: sedimentary cycle, autogenic process, allogenic process, Songliao Basin

The characteristics of meter-scale sedimentary cycles, such as thickness, abundance, continuity and “missed beats”, are considered to be controlled by local topography and autogenic processes (depositional hiatus, erosion and differential compaction). However, it is difficult to distinguish the control of short-term local autogenic processes and long-term allogenic processes on sedimentary cycles. The cyclicity at this scale can be defined by stratal repetition of physical characters of sedimentary rocks, such as grain size which can be can be identified from natural gamma-ray logging (GR). The GR logs of multiple wells of the members 1 and 2 of lacustrine Nenjiang in the Songliao Basin are collected to study the control of autogenic and allogenic processes on meter-scale grain-size cycles. The number of meter-scale grain-size cycles in the collected GR logs and the maximum, minimum and average values of cycle thickness were counted. The power spectral analysis was performed to the GR logging data to the identify the Milankovitch cycles and then calculate the deposition duration of these logs. The results show that the number of grain-size cycles and the deposition duration vary between wells and that these differences are not spatially regular. This suggests that the difference in abundance and continuity of the grain-size cycles and the "missed beats" are caused by autogenic processes. However, when the the thicknesses of the cycles in each well are successively connected according to the form of change-point analysis in the Fischer plot, these GR-Fischer plots show the same pattern of variation. The same variations in these GR-Fischer plots are interpreted as being controlled by basin-wide relative lake-level changes, that is, by allogenic processes. Thus, we concluded that both autogenic and allogenic control of stratigraphic records can be reflected in the characteristics of meter-scale sedimentary cycles in the basal Nenjiang Formation.

New insights on the Late Pleistocene-Holocene evolution of a giant lake in the central Kalahari (Botswana)

Keywords: Kalahari, playa lake, evaporites, ostracods, late Quaternary

The Makgadikgadi Basin in Botswana developed from the Late Pleistocene onwards due to gradual shrinking of the giant Lake Palaeo-Makgadikgadi (LPM). This lake, in the central Kalahari, is a key site to understand the climatic variability in southern Africa during the Quaternary and it holds an important role for the evolution of numerous species, including our own.

Four highstand phases were dated over the last 40 ka: 38.7 ± 1.8 ka, 26.8 ± 1.2 ka, 17.1 ± 1.6 ka and 8.5 ± 0.2 ka (Burrough et al., 2009; Schmidt et al., 2017). Today the Makgadikgadi Basin hosts the world's largest salt pans complex, including the Sua and the Ntwetwe Pans. This work is focused on the reconstruction of the evolution trends of the LPM between the penultimate highstand phase (17.1 ± 1.6 ka) and the current condition of ephemeral lake (playa). Here, a detailed sedimentological characterization (grain size and major elements) of shallow sediments from the Makgadikgadi Pans was combined, along cores, with the encountered ostracod fauna in order to track late Quaternary environmental trends. Ostracod assemblages are dominated by the Limnocythere ssp., an opportunistic taxa colonizing the littoral areas of shallow evaporative, ephemeral lakes, together with the subordinate occurrences of Sarcypridopsis ochracea, Sclerocypris cf. bicornis, Candonopsis spp. and Ilyocypris spp. The sediments from the pans show fluctuations in the Cl/K and Ca/Cl ratios, often in phase with the relative abundance of Limnocythere suggesting a cyclicity induced by changes of salinity and alkalinity in the water.

This multi-proxy study documents the occurrence of a Late Pleistocene shallow, playa lake environment typified by strongly alkaline waters. Between ~16 and 2 ka BP, a prolonged drought with sustained aeolian conditions affected the study area. A temporary shift toward more humid conditions is suggested by an increasing diversity of ostracod fauna atop the cored successions (around 20-30 cm core depth). This humid period is followed by an overall desiccation trend that likely started with the Little Ice Age and continues until the present day.

Changes of sedimentary style and its controlling factors in Heimahe delta of Qinghai Lake

di Ma[1], He Xing Yu[1*], Li Shun Li[1], Jie Zhi Zhang[2]

1. School of Energy Resources, china university of geoscience(beijing), BeiJing, CHINA

2. 2. Research Institute of Petroleum Exploration and Development, Experimental Research Center of Petroleum Geology, BeiJing, CHINA

E-mail: billyu@cugb.edu.cn

Keywords: Qinghai Lake,Hemahe Delta,Sedimentary pattern,Controlling factor,Quaternary

The Heimahe Delta is located on the south shore of Qinghai Lake, which is fed by five streams from the Xiangpi Mountain. The lower part of the sedimentary profile of this delta is dominated by gravels and the upper part is mud, showing diverse sedimentary facies and complicated formation processes. The lithofacies and their assemblages, architecture units, facies distribution and evolution stages of the Heimahe Delta in Qinghai Lake were studied by unmanned aerial vehicle, field outcrop measurements, and grain-size analysis. A total of 4 kinds of gravel facies, 4 types of sandstone facies, and 2 types of mudstone facies were classified. The delta plain has been developed with debris-, swinged-, migrated-channels, and vertical-, bilateral-aggradation bars; the delta front has been developed by migrated-, filled-channels, and bilateral-, lateral-aggradation bars, etc. Described from the field profiles, we reconstructed lake level and sedimentary evolution of Heimahe Delta which can be divided into three stages: low-stand, lacustrine transgression and forced lacustrine regression tracks. The stacking pattern in the low-stand stage present a sigmoid type high-angle progression with coarse-grained sedimentation dominating and por textural and compositional maturity. The stacking pattern of the lacustrine transgression stage is imbricated regression, fine-grained sedimentation, with medium textural and compositional maturity; the stacking pattern of the forced lacustrine regression stage is step-like progression, fine-grained sedimentation, with high textural and compositional maturity. Based on the interpretation of outcrop lithofacies association and architecture stacking pattern and analysis of fossils and bioclasts, we clarified diverse depositional association and constructed a sedimentary evolution model of the depositional system in this area. We suggest that the depositional system transitioned from an early single-provenance gravel-rich fan delta to a multi-provenance mud-rich delta and two factors mainly controlled the transition: southern boundary fault activities and Lake level variations. The early tectonic activities made the Nanshan Mountain uplift and Lake level strongly down, developing a large accommodation area providing space for gravel-rich coarse debris deposits. The strong activities of the Nanshan boundary fault in the mid-term caused the lacustrine basin to fall in the meantime the Lake level to rise, and large-scale lacustrine transgression occurred; The continuous activity of the Zongwulongshan-Nanshan Fault zone in the late stage caused Nanshan to continuously uplifting and the lacustrine continued sinking, resulting in the rapid retreat of the lacustrine and the formation of three-level terraces between the basin and the Nanshan Mountain.

Controls on Late Cretaceous aeolian desert systems in South China

Xiaocan Yu[1], Chuanlian Wang[1*], Jiuyi Wang[1]
1. Institute of Mineral Resources, Chinese Academy of Geological Sciences, Beijing, CHINA
E-mail: wangchunlian312@163.com

Keywords: subtropical highs, monsoon climate, water table, orogenic topography, desert depositional systems

Extensive aeolian desert systems were distributed in South China during the Late Cretaceous. These systems are characterized by alluvial, fluvial and aeolian deposits based on the sedimentological and facies architectural analyses. They reveal the evolution of paleoclimate and paleogeography in the South China hinterland during this period. The Late Cretaceous South China was marked by distinct basin-mountain systems due to subduction and retreat of the paleo-Pacific Plate. Intra- and epi-continental topography, combined with planetary-scale subtropical highs, obstructed the transport of moisture, enclosed the low-lying land, and caused the aridification in the South China interior and the development of desert depositional systems. The fault-dominated basins provided accommodation space for the preservation of the aeolian desert accumulation system. Furthermore, monsoon rainfall exerted an important role in the formation of desert depositional systems. Monsoonal water discharge carried extra-formational clasts into desert basins and led to variations in the groundwater level. Three types of aeolian deposits, dry, damp and wet aeolian systems developed. Periodic water influx to the Late Cretaceous desert margin systems can generate a cyclic aeolian–fluvial interaction system. The alternating wind and water activities driven by climate forcing created diverse wind- and water-related sedimentary facies types. Overall, the formation and development of Late Cretaceous aeolian desert systems in South China reflected the coupling result of subtropical highs, epi- and intra-continental orogeny, monsoon climate, tectonic subsidence, and variable groundwater level.

Aeolian system subenvironments spatial variability, morphology characteristics and complexities, in modern desert system.

Mohammed Ali Al-Masrahy[1*]
1. Gas Reservoir Characterization , Saudi Aramco, Dhahran , Eastern Province , SAUDI ARABIA
E-mail: mohammed.masrahy@aramco.com

Keywords: Aeolian system, Dune spatial variability, aeolian subenvironments, desert morphology, remote sensing , modern desert system

Significant advances in our understanding of the spatial arrangement of aeolian dune patterns have been made possible through the increasing availability of high-resolution satellite imagery in recent years. Major world desert systems are covered by the latest generation of public-release satellite imagery, which reveal spatially diverse dune patterns characterized by a varied range of dune types, the morphology, scale and orientation of which change systematically from central to marginal dune-field areas where non-Aeolian sub-environments become dominant within the overall desert setting. Analysis of geomorphic relationships between dune and interdune sub-environments within four regions of the Rub' al-Khali desert system reveals predictable spatial changes in dune and interdune morphology, scale and orientation from the center to the outer margins of dune fields. A quantitative approach is used to characterize the complexity present where large, morphologically complex and compound bedforms gradually give way to smaller and simpler bedform types at dune-field margins. Parameters describing bedform height, spacing, parent morphological type, bedform orientation, lee-slope expression, and wavelength and amplitude of along-crest sinuosity are recorded in a relational database, along with parameters describing interdune size (long- and short-axis dimensions), orientation and style of connectivity. The spatial rate of change of morphology of Aeolian sub-environments is described through a series of empirical relationships. Spatial changes in dune and interdune morphology have enabled the development of a model with which to propose an improved understanding of the sediment system state of the modern Rub' al-Khali desert sedimentary system, whereby the generation of an Aeolian sediment supply, its availability for Aeolian transport, and the sand transporting capacity of the wind are each reduced in dune-field margin areas.

Ultra-long-distance transport of aeolian sand: the provenance of an intermontane desert, SE China

Shuo Cao[1*]

1. School of Earth Sciences and Resources, China University of Geosciences (Beijing), Beijing, CHINA
E-mail: caoshuo@cugb.edu.cn

Keywords: intermontane desert, provenance analysis, U-Pb zircon ages, sand supply mechanism, ultra-long-distance transportation

Intermontane deserts are an important type of arid-climate sedimentary system. They were common in the past greenhouse world, and they might re-develop in the near future in response to the intensification of global warming. Investigating the provenance and mechanisms of sand supply to intermontane deserts is important to demonstrate the potential impact of future climate on environmental evolution and change in arid and semi-arid regions. During the Late Cretaceous, a typical intermontane desert developed in the Xinjiang Basin, southeast China. In this study, the origin, spatial variability, and transport pathways of both aeolian and alluvial-fluvial sediments in this intermontane desert have been investigated by applying bulk-petrography analyses and detrital-zircon U-Pb geochronology. Our results demonstrate that the sand in the Xinjiang intermontane desert was mainly extraneous and wind-derived. The nearby South China Craton and South China Magmatic Belt were primary sources; the distant Western Yangtze Craton was an important secondary source, despite being ~1000 km away. It suggests that this ultra-long aeolian sediment transport pathway was enabled by two factors: (i) the strengthening of intermittent westerly winds during short-lived glacial episodes; (ii) the presence of a low-relief corridor that served as a sediment transport pathway from source to sink across South China during the Mid-Late Cretaceous.

3 Collage of Earth Science, Chengdu University of Technology, Chengdu, Sichuan, 610059, China.

Abstract: The main exploration horizon of the Upper Paleozoic in Ordos Basin is from Taiyuan Formation to Lower Shihezi Formation. The study of sedimentary facies and its evolution in this period has playing a guide role in oil or gas exploration. Based on the observation and description of cores, the types and characteristics of sedimentary, and logging curve characteristics, studying the aspects of petrological and sediment characteristics from Taiyuan Formation to Lower Shihezi Formation of Ordos Basin. The results show that the rock types are primarily composed of interbedded quartz sandstone and dark mudstone. It is developed fan delta deposit, which can be divided into braided distributary channel, flood plain and peat swamp microfacies in Taiyuan Formation. The rock types of Shanxi Formation are mainly gravelly medium sandstone, siltstone, mudstone and coal. During the period of Shanxi Formation, the provenance supply in the north and northeast of the basin is sufficient. Primarily developed braided river delta plain subfacies, which can be divided into main distributary channel, secondary distributary channel, depression and peat swamp microfacies. The sedimentary facies are greatly affected by landform. There are gravels of different sizes in the Lower Shihezi Formation, with poor sorting and roundness. Rock types are mainly coarse sandstone, siltstone, and mudstone. Due to the weaken of tectonic activity and the change of paleoclimate, the material source supply decreased continuously in this period. It mainly developed alluvial fan and braided river sedimentation, the microfacies such as heart beach, natural dike and flood plain can be identified. Controlled by the fault zone, the sedimentary facies of Taiyuan Formation are mainly distributed in the south of borjiang Haizi fault, the sedimentary facies of Shanxi Formation and Lower Shihezi Formation continue to advance southward.

Late Permian laterites as paleoclimate proxies of Low-latitude continent of Eastern Tethys: South China

Zheng Gong[1], Maochao Zhang[2,1], Jun Li[3], Chengmin Huang[1*]

1. Department of Environmental Science and Engineering, Sichuan university, Chengdu, Sichuan province, CHINA
2. College of Resources and Environment, Aba Teachers University, Wenchuan, Sichuan province, CHINA
3. College of Geography and Environmental Engineering, Lanzhou City University, Lanzhou, Gansu province, CHINA

E-mail: huangcm@scu.edu.cn

Keywords: Late Permian, Paleoclimate, South China, Laterites

The climate of tropical Pangea in the late Permian was characterized by extremely aridity, while the contemporaneous South China, a typical low-latitude continental block of Eastern Tethys, had contrary humid climate condition (Tabor and Poulsen, 2008). The quantitative temperature and precipitation of South China is critical for understanding the global climate system in the late Permian. The paleosols developed from The Emeishan basalts of Late Permian, Guizhou, China, are used to investigate local paleoclimatic conditions. The paleosols are described in detail and analyzed for morphology, clay mineralogy, and bulk geochemistry. The majority of paleosols are typically dark red or red in color, has large thickness of 4-10 m and a dominant mineral assemblage of kaolinites, hematite, and anatase, with only few primary minerals. Moreover, these paleosols have high CIA values of 90–99 and evident Al_2O_3 and Fe_2O_3 enrichments. These pedogenesis features suggest that these paleosols are laterite, a highly weathered soil type commonly forms under tropical or subtropical warm and seasonally humid climate (Hill et al., 2000). Using Saf geochemistry climufunction (Zhang et al., 2022), the paleosols yield mean annual temperature (MAT) and mean annual precipitation (MAP) of 18-23 °C and 1800-2200 mm, respectively. The estimated MAT is mild than modern tropics, and may reflecting the low pCO_2 in late Permian (Godd´eris et al., 2014). The estimated MAP is consistent with existing geological evidence: coal, bauxite, and Cathaysian flora in late Permian strata in South China (Tabor and Poulsen, 2008; Guo, 1991), which suggested a tropical warm and humid climatic conditions with pronounced precipitation seasonality. The monsoon caused by thermal difference between ocean and South China continent may play important role for the high MAT with pronounced seasonality in South China.

Keywords: aeolian deposits, bedforms reconstruction, atmospheric circulation, Xinjiang Basin, paleoclimate simulation

The aeolian deposits system is an important carrier for the study of the ocean-land-atmosphere system, providing unique information of prevailing winds and atmospheric circulation. The Late-Cretaceous aeolian deposits is widely distributed in the South China Block basin group, indicating the extensive desertification events in the terrestrial system. However, studies on the formation process of ancient aeolian dunes, especially before the Cenozoic, are relatively weak. And the identification of aeolian dune types and its bedforms reconstruction remain poorly understood, which are the key to the reconstruction of original palaeowind direction and even the distribution of ancient aeolian deposits. The study takes the upper Cretaceous aeolian dunes in the Xinjiang Basin as the research object based on the division of aeolian bounding surface, the identification of sedimentary structure, the data set of dipping cross-bedding of multiple sections, reconstructing the two-dimensional architectural element panels of the aeolian dunes. On this basis, stereonet plots are drawn based on trend of the superimposition surface and crossing bedding, and the corresponding bedforms are depicted, indicating that the transverse dunes and barchan dunes are mainly developed in the Late cretaceous Xinjiang Basin. Besides, the original palaeowind directions are obtained by the mean azimuth of the transverse bedform, suggesting that the palaeowind in Xinjiang Basin was northeastward and the prevailing winds were westerlies. The work preliminary lays the foundation for reshaping atmospheric circulation and paleoclimate simulation of the South China Block and Asian interior.

E-mail: xh0816@ynu.edu.cn

Keywords: North China, Late Jurassic-Early Cretaceous, Eolian deposits, Eolian sedimentary system, East China Plateau, Biota succession

Late Jurassic-Early Cretaceous eolian deposits widely distributed in North China are characterized by temporal and spatial distribution in Shanxi in the early stage, western Shandong, northern Hebei and western Liaoning in the middle stage, and extended to the Ordos basin and the west region in the late stage. These eolian deposits develop various typical eolian stratigraphy and bounding surfaces, which are arranged into simple and compound dunes types and dry eolian sedimentary system with the subordinate wet eolian sedimentary system. Late Jurassic-Early Cretaceous eolian deposits in North China were controlled by the subtropical high belt and the rain shadow effect derived from the East China Plateau. Its temporal and spatial evolution shows a strong correlation with the die out of the Middle-Late Jurassic Yanliao biota and the radiation of the Early Cretaceous Jehol biota. We suggest that more attention should be paid to the high-precision age of the eolian deposits, detailed eolian sedimentary system, 3D/4D models and its implications for the major scientific questions (such as North China destruction, inland aridity in North China, biota succession) in future studies.

Keywords: SE Tibetan Plateau, Cretaceous, eolian erg system, drainage system evolution, rain shadow, desertification

Trigger mechanisms of widespread aridification in the Cretaceous of southeastern Tibetan Plateau are is not fully understood. Intracontinental basins along the southeastern Tibetan Plateau suffered a profound transformation and commonly regarded as consequence of unclear interaction among allogenic controls including extreme greenhouse climate, general atmospheric circulation, tectono-magmatic processes, variations in sea level, and topography variability. The main factors are up to now ambiguous and the coupling correlation between the atmosphere-land-ocean system remains complex. The Lanping Bains in China constitutes a key junction in the southeastern (SE) Tibetan Plateau, and the integrate multidisciplinary datasets from Cretaceous depositional systems from this basin will help to constrain Cretaceous sediment provenance routes and reconstruct the paleotopography as well as to figure out the most probable drainage network throughout the Cretaceous. This research presents results dealing with the sedimentology, paleocurrents, and U–Pb detrital zircon geochronology in the Jingxing Formation, Nanxing Formationi, and Hutousi Formation in the Lanping Basin, and our results indicate that mid- to Late Cretaceous tectonically induced surface uplift occurred in the SE Tibetan Plateau, leading to the formation of the paleo-plateau landform, and resultant rain shadows in east Asia interior. Superimposition of this topographic pattern by uplands in the eastern margin of Asia meant that the Cretaceous topography of east Asia was characterized by an enclosed paleo-relief pattern that was high in both the east and west, with drainage from the east and west to the south, contrasting with previously proposed configurations. This topographic pattern interrupted climate systems and generated widespread intracontinental desertification and drainage network evolution in east Asia. Our study constrains a key part of the late Mesozoic growth of the Tibetan Plateau prior to the Cenozoic collision between India and Eurasia and improves our understanding of the paleoclimate, atmospheric circulation, and modern drainage system evolution of the East Asian continent.

Wet aeolian system: The impact of fluctuated water table on the lateral and vertical lithological elements of aeolian depositional setting

Houssin Hassan Albarri[1*], Anar Nabiyev[1], Mohammed Masrahy[1]
1. Gas Reservoir Characterization Department , Saudi Aramco , Alkhobar , SAUDI ARABIA
E-mail: houssin.albarri@aramco.com

Keywords: Aeolian, Water Table, Damp Interdune, Wet interdune

In aeolian depositional settings water table can play an important function in the formation of the system stratigraphic record. Aeolian sediment transport across wet and damp sediment surfaces is severely restricted, which limits the volume of sediment available for aeolian dune construction, i.e., more stable system. Moreover, fluctuations between relatively higher and lower water-table levels can allow system subenvironments (e.g., interdunes) to change from a dry, to damp, to wet state on a seasonal basis, the rate of fluctuation will also determine the thickness of the preserved elements.

The lithofacies distribution and the stratigraphic organization of the architectural elements at the Permo-carboniferous section highlight wet aeolian sub-environments. Wet and dry aeolian sub-environments are likely controlled by local topographic relief that governed a hybrid dry-wet aeolian setting. The wet sub-environment is represented by extensive sand flats, non-climbing dunes, and possibly continuously shallow water table, specifically the lower part of the succession.

The integrated analysis of core, petrography, image logs, and standard wirelines log data reveals the diversity of sedimentary facies, which were deposited under different wet and dry conditions. They occurred on a variety of vertical and lateral scales, ranging from areas where dune bedforms dominate to other arears where they interact with other systems. The resultant sedimentological signature gives rise to preserved stratigraphic heterogeneities that typically influence facies and rock type properties. Characterization of core and image log data help the reconstruction of the preserved rocks depositional setting, which in turn provides the optimum framework for describing and predicting subsurface facies properties and distribution.

This study demonstrates the sedimentological characterization of aeolian deposits that reflect features that were created by the wind and water actions, and the consequent impact on lithological elements lateral and vertical trends. The accumulation of thick packages of wet sand flats and mud flats strata in this setting is attributed to: (1) high rates of vertical accumulation of the sub-environment substrate due to high rates of sediment input for aeolian construction, and (2) progressive relative rise of the water table that covers large low relief areas. These conditions enabled the long-term accumulation and preservation of flat irregular laminated argillaceous sand associated to the aeolian system. The accumulation and preservation of interdune deposits for example, is favored by a reduction in the rate of dune migration and the trapping of sediment on the wet/damp accumulation surface. A relative rise in the level of the water table can enable vertical sand accretion. The wavy and planar-parallel bedded sandstone element is typical of the Permo-carboniferous aeolian subenvironments, it comprises three lithofacies: (i) planar-parallel laminated sandstone; (ii) undulated cross-laminated sandstone; and (iii) sandstone with ripple cross-lamination.

Understanding the behaviour of the continental fluctuating water table in aeolian setting in response to climate or sea-level is important to establish a correlation between aeolian stratigraphic sequences and external parameters of changing water table.

Keywords: Proterozoic, australia, permafrost, aeolian

The sedimentary record of the geological transitions from snowball Earths to ice-free worlds and vice versa are still not well understood. The Cattlegrid Pit at Mt. Gunson in South Australia offers an exceptional opportunity of addressing this knowledge gap. Here, the Mesoproterozoic Pandurra Formation sediments, composed of cross-bedded sandstones of fluvial origin, are erosively overlain by large-scale cross-bedded aeolian sediments of the Neoproterozoic Whyalla Sandstone. The stratigraphic contact between both Proterozoic units is characterized by extensive Cu mineralization and deformation structures that have been interpreted as a result of permafrost cryospheric processes. We show that synsedimentary deformations at the top of the Pandurra Formation and the base of the Whyalla Sandstone occurred during the onset of the early deposition of the Whyalla Sandstone during the Marinoan glacial period. This subglacial deformation event affected a non-consolidated permafrost, incorporating fragments and clasts in the overlying sediments, including breccia injections. Subglacial deformation led to extensive sand blocks injected in the underlying permafrost system and active folding and shearing, showing shear bands and alignment of clasts. Sand intraclast morphologies and deformation structures are very similar to subglacial deformation of permafrost in the Mid-Pleistocene of north Norfolk (UK), the thermo-mechanics effects of the Weichselian ice sheet in Poland, and the ice-sheet marginal processes in the Ordovician of Libya. The deformations observed are compatible with repeated ice–bed decoupling and subglacial meltwater sediment deposition observed in recent analogues from Denmark. The progradation of the overlying proglacial aeolian dunefield of the Whyalla Sandstone occurred as a consequence of the retreat of the ice sheet front postdating the subglacial deformation stage.

E-mail: wuchi-hua@foxmail.com

Keywords: Cretaceous, desertification, ice sheets, plateau, palaeoclimate

More than 96 climate-sensitive lithologies accumulated in Early, mid-, and Late Cretaceous basins have been tracked in east Asia, including China and Mongolia. Although the Cretaceous desertification of southeastern Eurasia has been proposed to be driven by deep changes in atmospheric circulation patterns, the spatio-temporal analysis of the paleoclimate proxies indicate that both cryospheric and lithospheric forcing may have played a fundamental role triggering high-altitude desert basin dynamics in the Cretaceous of south-eastern Eurasia. A shift in subduction style from an early Cretaceous Paleo-Pacific Plate slab roll back to a Late Cretaceous flat-slab mode triggered plateau formation and accelerated desertification of the overriding Eurasia lithosphere. The early Cretaceous rollback of the steep Pacific slab led to back-arc extension, creating plateau salars in the Eurasia plate similar to those of the Atacama Desert in Andes Cordillera. The transition to a flat-slab subduction mode during the Late Cretaceous triggered regional plateau uplift, blocked intraplate volcanism, increasing denudation and sediment availability, and created wind corridors that led to the construction and accumulation of extensive Late Cretaceous aeolian sandy deserts (ergs) that covered mid-Cretaceous plateau salars. Some of these plateau desert systems reached paleoaltitudes able to develop cryospheric processes. We attribute these cryospheric processes to the crustal uplift due to terrane accretion in the Tethyan collision zone although it could be exacerbated because of a global mid-Cretaceous cold snap. The drastic reduction in the number of mid-Cretaceous aeolian systems in China correlates with the build-up and expansion of an ice sheet which front could have reached the southern sector of Mongolia and northern edge of China. During Late Cretaceous, desertification speeded up and ergs prograded towards northern latitudes.

Keywords: Intermountain desert, aeolian and aqueous processes, grain-size end-member, alluvial/braided fluvial deposits, sand sheet deposits

Differentiating pre-Quaternary aeolian depositional systems when they are dominated by the interaction with coeval aqueous environments is not that easy. The South China Block contains the sedimentary record of widespread intermountain deserts during the Late Cretaceous associated with paleotopography and rain shadow effects. These plateau-desert systems are characterized by complex assemblages of wind- and water-laindeposits, hosted wind-water interaction processes that generated a myriad of facies sometimes difficult to interpret in terms of physical processes and the relative role of wind and water agents during transport and deposition. In this study, we analyzed the Late Cretaceous Tangbian Formation in the Jitai Basin, from which parametric grain-size end-member analysis models were carried out. Four grain-size end-members related to aeolian and aqueous processes were identified. including alluvial/braided fluvial deposits, aeolian sand sheet deposits, sheet flood deposits and paleosoils. Locally superimposed dune facies with high-angle tabular cross-beds have been recognized and paleosoils developed over wadi channel facies. These environments highlight the wind-water interactions and depositional environments in semiarid-arid environments in the Jitai Basin during Late Cretaceous. where aeolian sand sheets facies are hegemonic compared with other nearby basins such as the Xinjiang basin, which is dominated by aeolian sand dunes.

Keywords: NE Tibetan Plateau, Early Pleistocene, aeolian deposition, lacustrine sediments, climate evolution, cyclostratigraphy

The Pleistocene epoch is characterized by global changes affecting both the atmosphere and oceanic realms, driven by climate forcing. Aeolian deposits constitute an excellent record of paleoatmospheric dynamics. Aeolian depositional systems in plateau settings constitute a good record of aridification. The recognition of windblown sediments in coeval sedimentary environments is crucial to decipher past desertification and aridification events that could have not been recorded in coetaneous continental aeolian dunefields. The majority of studies on aeolian systems in inland Asia have focused on the records of the Loess Plateau, while relatively few studies have been conducted on the Tibetan Plateau, of which only the relevant targets have been Cretaceous and Holocene deposits. In this study, the aeolian sedimentary record in the Early Pleistocene lacustrine sedimentary system was identified by grain size end-member and cyclostratigraphic analyses of the continuous and thick Qigequan Formation in the eastern Qaidam Basin on the northeastern margin of the Tibetan Plateau. The high proportion of the coarse dust component (EM2) transported by wind from short-distance sources corresponds to high values of the sedimentary noise model (DYNOT), indicating that the basin climate became arid during ~2.15-1.84 Ma, which is consistent with the climate records of the Loess Plateau and the South China Sea during the same period. Ice volume variability at high latitudes may be a major factor in the early Pleistocene arid climate of the Qaidam Basin and associated aridification and possible katabatic winds may have played a role on the transport of aeolian sediments to lacustrine plateau depositional systems. Our study provides a unique geologic record for the study of aridification in inland Asia since the Pleistocene.

Keywords: Clay minerals, paleosol, paleoclimate

Clay minerals in soils are often used to qualitatively reflect paleoclimatic features (Churchman, 1980; Folkoff and Meentemeyer, 1985; Keller, 1970). The clay minerals in paleosols record the climatic characteristics during diagenesis. The paleosols developed on the last phase of volcanic ejected basalt (Emeishan Basalt) in the Emeishan Large Igneous Province are characterized by large thickness and wide distribution, representing the regional continental weathering process at the termination of the eruption of the Emeishan Large Igneous Province (ELIP). These paleosol profiles develop placic horizons that occur only in soils with a higher degree of soil development. The main clay mineral composition of the nine paleosol profiles collected in this study is kaolinite, with abundant hematite and small amounts of anatase. Kaolinite is a typical mineral of soils developed under modern humid and hot climatic conditions (Hobbs and Parrish, 2016), suggesting the climatic characteristics of the paleosol during soil formation. Diagenesis is essentially a process of primary mineral decomposition and elemental redistribution. The content characteristics of rare earth elements (REEs) in soils and sediments are indicative of the degree of chemical weathering during soil formation or in the source area (Lu et al., 2020; Marker and de Oliveira, 1994; Singh, 2009). There are two significant REE enrichment zones in paleosol profiles (∑REE between 88.2 ppm and 1684.2 ppm, mean 582.2 ppm), which are significantly higher than in bedrock basalts (mean ∑REE 271.2 ± 93.0 ppm). These paleosol profiles have similar REE enrichment characteristics to those of the South China REE deposits produced in the present-day subtropical climate. The clay mineral compositions and REE geochemical signatures indicate that indicate that there was a hot and humid climate similar to that of present-day South China at the terminal stage of volcanic activity in the ELIP area.

Quantifying the Impact of Sedimentological Heterogeneity on Aeolian Hydrocarbon Reservoirs
[Text Box: Mouathe AlEssa and Mohammed Al-Masrahy, Saudi Aramco]

Abstract
The depositional studies of the aeolian environment have survived scientific scrutiny. This is hardly surprising given that they are one of the main siliciclastic hydrocarbon-bearing reservoirs worldwide. This study assesses the depositional setting and facies distribution of these terrestrial-based aeolian sediments. Attempts are also made to investigate diagenesis stages pertained to these sediments. The sedimentology and petrography analyses are conducted on cores from seven localities across the study area. Core samples were examined in detail to identify lithofacies, textures, facies, and facies association aspects. The ultimate aim is to have a comprehensive depositional setting of their aeolian packages. The petrography analysis entails description and interpretation of thin section, scanning electron microscope (SEM), and X-ray diffraction (XRD) samples. Such data are used in conjunction with borehole logs to achieve a scientific conclusion of their vertical and spatial configurations.
The analyses conclude the sediments were deposited in terrestrial arid to semi-arid aeolian settings, governed by a wide range effects of water table, post depositional processes, and aqueous fluids. Four prominent aeolian facies associations were recognized and are attributed to their sedimentological characteristics; aeolian dunes, aeolian sandsheets, aeolian interdunes, and playa lake deposits. The aforementioned facies associations commonly display three primary overprinting processes; silica overgrowth, clay minerals, and anhydrite cements. These diagenetic processes frequently disturb sediments' fabric and occlude intergrain spaces. The occurrence of silica overgrowth is observed interchangeably with the other diagenetic features and is mainly witnessed on grain surfaces. This suggests that the development of the silica cement is possibly subsequent to burial and compaction episodes. In contrast, the predominant post depositional clay minerals are narrow down to two main leading types; early-stage fibrous illite and later stage kaolinite cements. The tube-like geometry of the illite typically fills in permeability pathways. The intermittent presence of illite-coating sand grains, however, substantially protects the sediments from the significant destruction by silica overgrowth. Other identified cements, Kaolinite and anhydrite cements, are negatively impacting aeolian sand bodies in the form of sheet like and spherical nodules, respectively.

Keywords: Mid-Cretaceous, South China block, aeolian erg system, east Asia, palaeoclimate, paleotopography

The Cretaceous has been traditionally considered as a greenhouse climate period with a duration of 79 myr Earth's history. The Cretaceous of China contains a varied record of different allogenic controls, including a complex interaction between palaeoclimate and paleotopography. The interplay between tectonics and climate contributed to a wide range of arid climate zones in East Asia that triggered the accumulation of widespread areas of sandy deserts and evaporite deposits. The Matoushan Formation has been formerly considered to be dominated by water-related deposits. This work provides a re-evaluation of the sedimentary environment of the Matoushan Formation of the Upper Cretaceous in the Chuxiong Basin on the western margin of the South China Block. Here, the reconstruction of aeolian bedforms based on field-data analysis indicates that the unit is a dominated by aeolian faciesincuding draas and crescentic dunes that accumulated and migrated in extensive intermontane desert systems, showing local aeolian-fluvial interaction deposits attesting for subordinate recurrent fluvial interludes. The uplift of north to south trending highlands on the west side of the Chuxiong Basin during the Early Cretaceous blocked the the input of water vapor from the Tethys Ocean to the South China Block, increasing the prevalence of inland aridification during the Mid-Cretaceous. Simultaneously, the abundant detrital input with tensional tectonics in the Chuxiong Basin also provided favorable conditions for accumulating and preserving the aeolian desert sands due to deflation of wadi channels in the inner erg margins.

Keywords: Upper-Cretaceous, aeolian sandstones, South China block, palaeoclimate, Carbon Neutral

Aeolian sandstones have excellent poroperm values and are global targets for subsurface Carbon sequestration. This paper focused in Honghuatao formation Cretaceous units, that accumulates as large-scale sand desert dunes in the Hengyang Basin and Dongtinghu Basin, The petrophysical properties of these rocks are determined and their suitability as potential subsurface reservoirs for carbon capture and storage (CCS) and and underground energy storage (Compressed Air Energy Storage in Aquifers) is preliminarily evaluated. The Cretaceous units are a key element for the Target of Carbon Emission Peaked and Carbon Neutral in China. Inorder to evaluate the suitability of carbon dioxide geological storage and underground energy storage in Cretaceous basins in Hunan Province, it is necessary to carry out exploratory research on the petrology, geochemistry, rock mechanics characteristics and commercial development potential of aeolian sand bodies. At the same time, it is a natural laboratory for in-depth research on the earth's extreme greenhouse climate and its ecological response. The research on Cretaceous aeolian desert will bring us more enlightenment on long-term climate change studies in the future.

E-mail: lizhiwu06@cdut.edu.cn

Keywords: Late Cretaceous, Aeolian sands, Sichaun Basin, Longmenshan, Garnet geochemistry, Sedimentary Provenance

During the Late Cretaceous, the Yibin Liujia area in the southeast of the Sichuan Basin was covered by desert aeolian sands, but its source area is still unclear. Previous data, including limited clastic zircon U-Pb dating and heavy mineral assemblage, suggested a source area located to the western edge of the basin, but did not allow to establish a clear source-to-sink pattern. The Cretaceous aeolian sandstones of the Yibin Liujia area are rich in garnet, but the specific geochemical characteristics and the type of parent rock of these heavy minerals are not clear. In order to explain its provenance and establish a relationship with the tectonic evolution of the nearby orogenic belt, the detrital garnet geochemical analysis was carried out on 6 samples of the Liujia section in Yibin.Our results show that the garnets of the 6 samples predominantly scatter in the Bi and Bii region in the Fe+Mn-Ca-Mg triangular classification diagram but, nonetheless, show distinct characteristics. The clastic garnets from the Cretaceous Wotoushan to Sanhe Formation are mainly of type Bi (72%-82%) and Bii (12%-28%). In contrast, the Gaokanba Formation exhibits considerably higher amounts of Bii (75%), but lower percentage of Ci (13%) and A (8%) type grains with negligible amounts of garnet from type Bi (3%). Compositional data of garnets from the Wotoushan Formation to Sanhe Formation are very homogenous and suggest mainly intermediate to felsic igneous rocks as host lithologies. However, the Late Cretaceous Gaokanba Formatio show that the amphibolite-facies metasediments are absolutely dominant, which is closer to the metamorphic rock characteristics of the middle-south section of the Longmenshan orogenic Belt. These results indicate that the Late Cretaceous erosion of the Longmenshan Orogenic Belt is the source of the deposits in the Gaokanba Formation.

Keywords: Luminescence dating, alluvial-aeolian sand, Adriatic sea, Quaternary

The extension of Pleistocene alluvial and aeolian sediments along the eastern Adriatic coast and on the islands documents terrestrial environments during a time period of the lowest sea-level stand of the Adriatic Sea. On the southeasternmost Adriatic island of Lopud such deposits were studied along two lateral sections showing alluvial and aeolian sands intercalated with breccia lenses and a tephra interlayer. Alluvial deposits are represented mostly by recycled aeolian sands, accumulated by tractional sheet flows in a small-scale alluvial plain during a relatively long-lasting humid phase. Aeolian sands were probably deposited by sand sheet migration under the influence of the NNE wind during a more arid and relatively windy phase. Sporadically occurring breccia lenses composed of limestone fragments of the Cretaceous basement are the result of occasional high sediment concentration flows, and deposition in shallow stream channels(Kovačić et al., 2018). The reworked and pedogenically altered tephra belongs to the high-K calc-alcaline and shoshonite series having a trachyte-trachydacite composition indicating the Campanian Province in Southern Italy as the most probable source area (Kovačić et al., 2018). This suggests the influence of a southern wind during the humid phase of the Pleistocene.
The luminescence dating method was applied to these deposits to establish their chronological framework. Both quartz and feldspar grains were tested and measured to obtain the most reliable ages. While the OSL very likely implies to the maximum dating limits and shows problematic dose recovery test results, the pRIR290 ages can be correlated to the OIS4 and OIS5. The results imply that during that time the Island of Lopud in the south Adriatic was part of the mainland exposed to significant fluvial activity of the palaeo-Neretva river and its tributaries.

A holistic view on avulsion dynamics in a dryland river fan based on comprehensive geomorphological analysis

Keywords: Autocyclic avulsion dynamics, dryland river, floodplain, crevasse splay

Dryland river fans form by repeated switching (avulsion) of an ephemeral stream as it progrades and accumulates sediment onto a low-gradient alluvial plain. Successive channel belts are organised in a radial pattern through a process of compensational stacking, where each consecutive river path avoids the positive relief left by its predecessors. Several criteria have been proposed for the likelihood of where and when an active channel in such a setting switches its path, including super-elevation, ratio of along-channel slope and cross-floodplain gradient, and hydraulic capacity of crevasses. A key role for the overbank domain is implied in each of these – largely interdependent – parameters for avulsion proneness, but the exact avulsion dynamics remain insufficiently understood.

In this study, we combine differential-GPS measurements and a resampled open-source global digital surface model (DSM) to quantify along-channel changes in hydraulic parameters and reconstruct subtle geomorphology across an undisturbed and non-vegetated dryland river fan. This approach allows us to propose a holistic view on autocyclic avulsion dynamics in prograding dryland river systems.

The results support the idea that the downstream gradient of an active river decreases over time as result of basinward lengthening (by both progradation and increased sinuosity) mirrored by near-channel deposition. This process gradually decreases the drainage effectiveness of the stream profile and elevates the channel belt relative to the surrounding floodplain. Crevasse splays play a key role in determining whether the river switches or not by effectively testing alternative flow paths. Crevasse channels develop along a local path of steepest descent across the floodplain and build out as long as their stream profile is hydrodynamically more favourable than that of their parent channel, after which they heal up. As the river profile lengthens and rises, crevasse splays extend further onto the floodplain until one reaches base level in a shorter distance than the river itself. At this point, it will receive an increasing proportion of total discharge and the parent river is abandoned. The avulsion process is gradual rather than abrupt and its frequency likely increases downstream, resulting in a dendritic pattern of abandoned river paths.

The process proposed here brings together existing criteria for autocyclic avulsion in prograding dryland river systems devoid of vegetation. It incorporates the role of subtle floodplain morphology and the evolution of crevasse splays and explains the resulting depositional architecture. Moreover, our findings enable us to predict when and where a next avulsion will take place, which could help flood risk analysis and mitigation in similar settings.

Architecture Model of Dryland Gravel Braided River Based on 3D UAV Oblique Photogrammetric Data: A Case Study of West Dalongkou River in the Eastern Xinjiang, China

Senlin Yin[1], Baiyu Zhu[1*], Zhenhua Xu[1]

1. Research Institute of Mud Logging Technology and Engineering, Yangtze University, Yangtze University, Jingzhou , Hubei, CHINA

E-mail: 631579905@qq.com

Keywords: UAV,Oblique photogrammetry,Gravel braided river,Architecture, Modern deposition,West Dalongkou River

Three-dimensional unmanned aerial vehicle (UAV) oblique photogrammetric data were used to infer mountainous gravel braided river lithofacies, lithofacies associations, and architectural elements. Hierarchical architecture and lithofacies associations with detailed lithofacies characterization were comprehensively described to document architectural model, architecture element scale, and gravel particle scale. (1) Nine lithofacies (i.e. Gmm, Gcm, Gcc, Gci, Gcl, Ss, Sm, Fsm, and Fl) are identified and classified as gravel, sand, and fine matrix deposits. There are typical deposit features of a dryland gravel-braided river. (2) Three architectural elements are identified, including channel (CH), gravel bar (GB), and overbank (OB). CH can be further divided into flow channel and abandoned channel, while GB consists of Central Gravel bar (CGB) and Margin Gravel bar (MGB). Different architectural elements are associated with distinctive depositional cycle styles and mechanisms. (3) Gravel bar is the most important architectural element of gravel braided river due to its favorable reservoir attribute. The dimensions of GBs and their particles are various, but exhibit good relationships with each other. The grain size of GB decreases downstream, but the dimensions of GB do not. The bank erosion affects the GB dimensions, whereas channel incision and water flow velocity influence the grain size of GB.

Dating geological Mars analogue using Luminescence technique

Myriam Francesca Stelletti[1*], Daniele Sechi[1], Stefano Andreucci[1], Giulia Cossu[1], Mario De Luca[1], Giulia Faedda[1], Federica Perazzotti[1], Nicole Ruperti[1], Antonio Santonastaso[1], Vincenzo Pascucci[1]
1. Architettura, design e urbanistica, Università di Sassari, Sassari, ITALY
E-mail: myrimy@hotmail.com

Keywords: Luminescence, Geochronology, Mars, Analogues, Sedimentology

During the last 60 years, the robotic exploration on Mars has made many tantalizing geological discoveries, and retrieving rock samples from the Martian surface will be the next major goal for the scientific community. It is increasingly clear that accurate estimation of absolute ages is a fundamental step to understand the evolutionary processes that led to the formation of planet and its atmosphere. In this respect, occurrence and time frequency of surficial geological processes on Mars are needed to understand the Red planet's evolution. The chronology of recent geological events on Mars is a challenging task, due to uncertainties associated with the current dating methodology based on crater counting.

Luminescence dating could be a reliable method to date the recent deposits of Mars and better understand climate and tectonic changes occurred in the recent time. Knowledge of the luminescent properties of Martian sediments is necessary for the success of this purpose. The choice of a Martian analogue is therefore fundamental to validate the dating protocol. With Luminescence, we date the last moment sediments were exposed to sunlight and, therefore, the time of the formation of sedimentary deposits.

No area on Earth is similar to Mars, not even in the past. However, there are certain areas that, due to their uniqueness and geological significance, are of great importance in order to understand the processes occurred in the Red Planet.

Lanzarote (Canary Island, SP) was chosen as the best Martian analogue since its geological features and climatic conditions are similar to those of Mars: basaltic products, low quartz and k-feldspar concentrations, dry weather, very low vegetation.

The aim of the work is to reconstruct the late Pleistocene geological evolution of the Famara cliff area pointing out which have been the different depositional environments through time. The Famara cliff is the remnant of a Miocene caldera made of basalts. Ephemeral streams deeply incised the cliff rim and a suite of colluvial fans eventually evolving in alluvial fans developed. These alternate with aeolian deposits that become dominant toward the caldera centre. Sediments are all basalt derived except for some dust blowed from the Sahara during major storms. The described features could be considered similar to those developing on rim and floor of a Martian impact craters.

Ages of the colluvia and dunes were determinate using luminescence technique and 14C. The obtained results indicate that deposition occurred during Marine Isotopic Stage 3 (59 and 29 calendar (cal) kyr BP). MIS 3 is a cold interglacial characterized by high frequency, millennial climatic variability. In particular derived ages indicate that colluvial-alluvial deposition occurred during the wet and more humid Dansgaard Oeschger (D-O) events, while aeolian during the cold and dry D-O stadial and/or Heinrich events.

The obtained data are encouraging and prove that luminescence could be the correct and more suitable method to date the Martian basalt derived recent deposits.

Sedimentary architectures of seasonal braided river alluvial fans dominated by episodic floods and the controlling factors of its evolution — A Case Study of Quaternary Poplar Fan in Junggar Basin, Northwest China

Youliang Ji[1*], Yue Zhang[1,2]
1. college of geoscience, China University of petroleum,beijing, Beijing, CHINA
2. State Key Laboratory of Petroleum Resource and Prospecting, China University of Petroleum (Beijing) , Changping, Beijing, CHINA
E-mail: jiyouliang@cup.edu.cn

Keywords: Seasonal braided river alluvial fans dominated by episodic floods; Sedimentary architectures,Controlling factors, Architectures model,High quality reservoirs

Seasonal braided river alluvial fans dominated by episodic floods are common types of alluvial fans system. To elucidate our understanding of the sedimentary architectures and controlling factors, a study has been undertaken on the Quaternary Poplar Fan, in the endorheic Heshituoluogai Basin, China as the dissection of modern sedimentary. Based on observations from outcrops and trenches on the Poplar Fan, together with flume tank simulation, sedimentary evolution processes and architecture characteristics are systematically studied. The formation and reworking mechanisms under different types of flows in different units of sedimentary architectures are also researched. Then we clarified the sedimentary characteristics, established its depositional model and discussed the controlling factors of seasonal braided river alluvial fans dominated by episodic floods.

The results show that: (1) the 7th to 3th units of architectures have been studied. The 7th units of architectures are characterized by semi-lenticular composite fans, which are formed by superposition of the 6th architectures units. A single alluvial fan is formed by the superposition of 5th architecture units (high flow stage deposits and low flow stage deposits). At the proximal fan, there are two types of 4th architectures units, which are the downcut channels during the high flow stage and the hosting channels during the low flow stage. At the proximal to medial fan, three types of 4th architectures units (sheet-like flow deposit during the high flow stage, the hosting channels and braided channels with primary bifurcation) are seen in this sector. At the medial to the distal fan, unconfined braided streams deposits during the high flow stage and the braided channels with channel bars during the low flow stage are the types of 4th architectures units. At the distal fan, narrow and shallow channels deposits during the high flow stage and the braided channels with channel bars during the low flow stage are the types of 4th architectures units. The 4th architectures units are composed of different types 3th architectures units, which are various lithofacies. (2) Topography and provenance are the main controlling factors affecting the architectures. With the increase of the topography slope, the fan tends to grow in the axial direction, the length-width ratio increases, and the architectures units become narrower. When the provenance supply increases, the fan area and architectures units grow, but has little effect on the fan length-width ratio. As the number of provenances increase, the intersection area of fan enlarges, the length-width ratio of single fan decreases, and the architectures units become more mixed and difficult to distinguish. (3) Seasonal braided river alluvial fans dominated by episodic floods are associated with both high and low flow stages. From the proximal to the distal fan, incised channel deposits, sheet-like deposits, unconfined braided streams deposits and narrow with shallow channels deposits cover the high flow stage. And the braided channels with channel bars cover the low flow stage. The temporal and spatial variability in the occurrence of these flow processes controls the types and spatial distribution of different types of architectures units.

Keywords: Keywords: Facies, Architecture, Paleoenvironment, Upper Cretaceous Shendi Formation, Shendi-Atbara Basin

This study examines both vertical and lateral facies changes as well as petrographic characteristics of the outcropping section of the Upper Cretaceous Shendi Formation in Musawwarat-Naga area with a view of interpreting the depositional environment, provenance, and tectonic setting that prevailed during the deposition of the sediments. Field studies revealed the presence of Eight different sedimentary lithofacies. The predominant is the trough cross-bedded sandstone facies (St), representing 75% of the total succession. Four architectural elements were recognized: channel fill (CH), sandy bedforms (SB), gravelly bars, and bedforms (GB), and overbank fill (OF). Moreover, the mean value of paleocurrent directions was 285.3° which is suggestive of a southeasterly located source area. The majority of the sandstones are classified as quartz arenites with subordinate sublithic-arenites. Ternary plots of Quartz-Feldspar-Lithic fragments (QFL) revealed that the tectonic setting of the area is predominantly within the interior craton. It can be suggested that the sediments were sourced from the southeast region and associated with a braided, proximal, fluvial depositional environment. The results of this study provide outcrop analog data that might be useful in the exploration of hydrocarbons. Specifically, it can enhance the understanding and prediction of the proximal fluvial depositional styles in the subsurface deposits in the Shendi-Atbara Basin, Sudan, and the region.

Keywords: Stratigraphic Forward Modelling, Sensitivity Analysis, Sedimentary Factors, Experimental Design, Fan Delta

Traditional structure and sedimentary researches don't capture the measurable coherent relationship between the sedimentary architectures and factors. The four-dimensional stratigraphic forward modelling has facilitated a better assessment of the vertical and lateral sediment extent and connectivity in depositional basins. This paper presents a new quantitative approach for sensitivity analysis in the stratigraphic forward modelling of the terrestrial clastic reservoirs in the west branch of East African Rift on a field scale. A fluvial channels dominated fan delta in the upper Miocene formation in the south of Albert rift is used to exemplify the sensitivity analysis in the stratigraphic forward modelling. A reference base case model is calibrated to sedimentary parameters that derived from seismic interpretation and well data. The number of investigated factors is four (including initial bathymetry, eustasy, sand proportion in sediment supply, fluvial discharge) and they both have three levels, an orthogonal experimental design table helps to reduce the number of test cases from 81 to 9. Moreover, two response surface functions which use formation thickness and net-to-gross (NTG) distribution as the output of the simulator are constructed for uncertainty quantification respectively. The uncertainties analysis of the four sedimentary factors provides the variation range for each parameter. The facies belts and palynology results indicate a range of 0 to 20m for initial bathymetry. For eustasy, the relative lake level curve that is calculated from the GR spectrum gives a fluctuation of 10m. The statistical results of lithological interpretations from well logs are used to set the uncertainty of sand proportion in sediment supply. Fluvial discharge is usually given by a specific multiplier of sediment supply rate. The selected nine cases based on experimental design are conducted to the practical model realizations. Formation thickness and NTG distribution maps of the test cases show different sensitivity responses to the changes of sedimentary factors. The most sensitive factor is sand proportion in sediment supply because its slight variation plays a significant role in impacting a wide range of the thickness and NTG. Whereas, initial bathymetry is found to be the least sensitive parameter to affect the simulation results. The two functions built by response surface proxy model are used to quantitatively and directly estimate the thickness and NTG distribution from the four considered sedimentary factors.

Study on Sedimentary Architecture Model and Sedimentary Dynamic Mechanism of Channel Bar in Sandy Braided River

Wenjie FENG[1*], Changmin Zhang[1]
1. School of Geosciences, Yangtze University, Wuhan, Hubei, CHINA
E-mail: fwj1017@yangtzeu.edu.cn

Keywords: Sandy braided river, Channel bar, Sedimentary architecture, Numerical depositional simulation, Sedimentary evolution process

Through sediment numerical simulation and big data analysis, this project has obtained the following understandings: The general evolution process of sandy braided river(SBR) includes six stages, namely, the formation of the embryonic form of CB, rhombic bar(RB), tongue-shaped bar, unit bar(UB), composite channel bar(CCB) and transformed CCB. In this process, the scale of CB first increases rapidly, then increases slowly, and finally maintains stability. The evolution is dominated by flow patterns and their changes. On the flat bedform, the flow is blocked by the bank to generate a secondary flow and conducts to the opposite bank to form water wave interference, resulting in the formation of embryonic form of CBs and gradually grows into RBs. A RB constrains water flow and causes sediment and water flow to converge and then diverge, creating a tongue-shaped CB. Then, the tongue-shaped CBs grow to contact each other, causing the water flow to become irregular and gradually converge to form braided channels(BCs) and further lead to the formation of UBs. The UBs undergo differential downstream migration driven by different intensities of water flow in different BCs. The difference in the migration rates of different UBs causes the independent UBs to "catch up" with each other and eventually "collide", thus forming a CCB. Then, BCs gradually become stable, and water flows over the top of the CCB and transforms its morphology, forming a reformed CCB with many gullies on the top. The architecture patterns of RB, tongue-shaped bar and UB are relatively simple. It is composed of multiple upward-thinning progradational accretions in the downstream direction, while it is flat at the bottom and convex at the top in the transverse direction, and is composed of multiple upward-thinning aggradation accretions. CCBs and reformed-CCBs are complex in architecture, and are formed by repeated cutting and stacking of progradational and lateral accretions that gradually become thinner from bottom to top, and occasionally filled with BC deposits; The sedimentary evolution of SBRs is sensitive to sediment particle size and river discharge. Sediment particle size mainly affects the evolution rate of rivers. The larger the particle size, the faster the evolution rate, and vice versa. In addition, the scale of CBs is less correlated with sediment grain size. River discharge not only controls the evolution rate of SBRs and the scale of CBs. The larger the discharge, the faster the evolution rate and the larger the scale of the CB.

IDENTIFICATION METHOD OF CHANNEL SAND AND LITHOLOGIC TRAP BASED ON PHYSICAL SIMULATION RESULTS

Haoyu Wang[1*]
1. Exploration Department, Petro China Huabei Oilfield Company, Renqiu, Hebei, CHINA
E-mail: 271960104@163.com

Keywords: Physical simulation,Channel sandstone,Lithologic trap,Recognition methods

As the most important hot field of oil and gas exploration, the research on channel sand body of deep-water channel deposition and fluvial facies deposition has been studied for decades.The research on the underwater distribute channel developed on the shallow Delta has gradually become the focus of attention. Domestic and foreign scholars have carried out research on its restrictive factors, but there is still a lack of in-depth analysis on the evolution of waterway configuration, sand body architectural structure and level, sand body heterogeneous distribution, sand body migration and superposition. This study analyzes the type, evolution, internal configuration and reservoir development characteristics of upper and lower distribute channels in shallow water delta through physical simulation experiments. Using the simulation results, the channel sand reservoirs in Linhe depression of Hetao Basin and Jizhong depression of Bohai Bay Basin are compared and analyzed. Based on the study of regional core, logging, logging, seismic, analysis and test data, it is considered that the paleogeomorphology from lin1 to lin2 of Linhe formation in Linhe depression and from sha1 to dong3 of Jizhong depression is relatively wide and gentle, the water body in the study area is wide and shallow, the lake water body fluctuates frequently, the material source supply is sufficient, and there are favorable sedimentary conditions for the formation of shallow water delta. In the study area, strong hydrodynamic sedimentary structures are mostly seen in the rock core, and the vertical progradation and aggradation sequences are developed. Parallel, subparallel and imbricate seismic reflection characteristics can be seen on the seismic profile. Taking the shallow water delta front subfacies as the research subject, the front subfacies are wide, and the inner and outer front deposits are identified according to the lake level and logging curve. The underwater distribute channel constitutes the main sedimentary framework sand body. The channel swings frequently laterally and the main reservoir sand body accumulates laterally, resulting in the thin thickness and small scale of the channel sand single layer. The instantaneous phase and 90°phase conversion are used to compare the weak reflection layer, identify the channel sand and reduce the multi solution of the horizon. Two typical seismic features are identified: "worm" seismic facies and "top flat bottom concave" filling seismic facies. Through the above analysis, the multi-stage channel range depicted by the stratigraphic slice is superimposed, and its external boundary and fault configuration form a trap. Drilling in the channel sand superposition area in the trap is preferred. To a certain extent, it has guiding significance for enriching the understanding of shallow braided river delta reservoir and expanding the new zone, even for the oil and gas exploration field of Linhe depression of Hetao Basin and Jizhong depression of Bohai Bay basin. It also provides a theoretical basis for the formulation of later development plan and resource evaluation of the oilfield.

Keywords: Sand and mud geochemistry, αAl indices, Clay mineralogy, Kaolinite as a weathering proxy, Pearl River catchment. Tropical monsoonal climate

This study presents an integrated mineralogical and geochemical database on mud and sand transported by the Pearl River (Zhujiang) and coastal rivers of SE China. Clay mineralogy and bulk-geochemistry of fluvial sediments are used to trace changes in weathering intensity across South China, a vast tropical to subtropical region characterized by a strong longitudinal rainfall gradient. The control of climate-induced weathering is manifest in the mineralogy and geochemistry of Pearl River mud, although mud and, to a greater extent, sand composition are also largely affected by the lithology of parent rocks. The depletion in mobile alkali and alkaline-earth metals increases steadily from the drier western part of the Pearl River catchment to the wetter eastern part and is most marked in easternmost tributaries of the Pearl River and in southern coastal rivers. Na and Ca are the most strongly depleted elements in Pearl River sediments, whereas the low concentration of Ca and Mg in river sand of coastal SE China also reflects the felsic character of parent rocks in the Cathaysia block. Eastward-increasing weathering conditions are most clearly highlighted by the progressive eastward increase in kaolinite across the Pearl River catchment, whereas the weathering effect in sand is blurred by quartz addition owing to widespread recycling of quartz-rich siliciclastic source rocks.

This actualistic case study from a region characterized by monsoonal climate underscores the care that should be taken while inferring climatic conditions from the geochemical composition of sediments and sedimentary rocks, which is controlled by multiple geological factors including the felsic versus mafic character of parent rocks and the presence of extensive carbonate or siliciclastic covers in source areas. Most reliable indications are provided by the kaolinite/(illite+chlorite) ratio and by αAl indices for Na, Ca, Mg and Sr, which consistently increase eastward across South China thus paralleling the marked eastward increase in monsoonal precipitation toward the coast.

Investigation of petrographic characteristics of glacio-fluival sandstones

Yufeng Cui[1*], Weihua Wang[2], Hasan Algheryafi[2]
1. Beijing Research Center, Aramco Asia, Beijing, CHINA
2. GRCD, Saudi Aramco, Dhahran, SAUDI ARABIA
E-mail: cuiyf314@126.com

Keywords: glacio-fluival sandstone, dagenesis, quartz overgrowth, authigenic clay mineral

The sandstones in the study field was deposited in a glacio-fluival environment, mainly including fluvial facies, glacio-fluvial facies, landslide/debris flow facies and glacial shear zone facies. The sandstones are mainly quartzarenite with quartz making up ~75% whole rocks. Minor rock fragments are present. Grain sizes range from silt to gravel, but the majority of samples fall into fine to medium-grained sandstone categories. The grain size distribution is mainly near symmetrical skewed. The grain sorting varies from very well to poorly-sorted, mainly moderately to moderately well-sorted. The variation in grain size and sorting mainly reflect the changes in the depositional environment. Authigenic clay minerals, mainly illite (av. 1.5%) and kaolinite (av. 2.8%), occur as pore fillings, which bridge and block pore space and pore throat. Detrital clays often occur as patches filling intergranular space. However, most samples are well cemented by quartz overgrowths (av. 11.2%). In addition, minor amounts of authigenic chlorite, dolomite, siderite, barite and pyrite also occur locally. The initial sediments combined with further various diagenetic processes play a significant role in controlling reservoir quality. Petrographic characteristics elaborately illustrate the role played by sediments and diagenesis, which will facilitate successful reservoir quality prediction in hydrocarbon exploration.

Sedimentary Characteristics and Distribution of Modern Distributive Fluvial Systems around the Large Depositional Basins in northwestern China

Changmin Zhang[1*]
1. School of Geosciences, Yangtze University, Wuhan, Hubei, CHINA
E-mail: zcm@yangtzeu.edu.cn

Keywords: Northwest of China, Nonmarine petroliferous basin, Distributive fluvial system, Sedimentary model

DFS is a depositional system which a river enters the basin from an apex in radial patterns, these include alluvial fan, fluvial fan and mega-fan etc., The earliest reports on DFS were a paper published in Geology by Weissmann et al. (2010), and Hartley et al. (2010) published the measurement of DFS in more than 700 sedimentary basins around the world. The concept of DFS has received a lot of recognition and support (Quartero et al., 2015; Zhang et al., 2017), but has also been criticized and questioned (Smith et al., 2010; Ashworth and Lewin, 2012; latrubesse, 2015) since the presentation.

The DFSs geometric and distribution in Qaidam Basin, Tarim Basin, Junggar basin, Zoulang basin and its adjacent mountainous and desert areas have been surveyed by using Google earth program and radar elevation data. The study built a DFS database of 2169 DFS in 50 DFS zones on the basis of delimiting the DFS boundary and measuring the area and perimeter of DFS and its drainage basin, the slope, the downstream profile and other DFS morphological parameters. The database collected DFS's geographical coordinates, tectonic condition, their geometry, the research cross sections and field trench information as well as experimental test data, some text and picture materials including the early research data and the village distribution have been stored in the database.

Heihe DFS, Yumen DFS, Dahalteng DFS, Huatugou DFS and Golmud DFS have been studied in detail about their sedimentary characteristics, facies and architectural element distribution with combination of UAV aerial photography and ground observation. DFS are classified based on the characters of their geometry, geographical location, termination and sedimentation.

The DFS anatomy in Permian-Triassic Mahu sag of Junggar basin proved that there are abundant DFS deposits in Chinese terrigenous petroliferous basins which can be important reservoirs for oil and gas migration and accumulation. The Study of DFS sedimentary system has great theoretical and applicational significance in sedimentary depositional model construction and new favorable reservoir exploration of terrigenous petroliferous basins.

The research of River Morphology transition and Sediment variation: Shule River, Northwest of China

zhang xianghui[1], zhang changmin[1*], wenjie feng[1]
1. school of geosciences, yangtze university, wuhan, hubei, CHINA
E-mail: zcm@yangtzeu.edu.cn

Keywords: Shule River, Fluvial Sedimentology, River Morphology, Sediment Variation, Gravel Refinement

Sediment grain size and river morphology are important objects in fluvial sedimentology. The research is well documented, but few prior studies have analyzed the response of Gravel Refinement and River Morphological. The downstream fining pattern observed in the Shule River is cited as a classic example of a morphology transition in a large alluvial channel. However, important questions regarding the River Morphology transition, Sediment variation unanswered. Here we present observations of the downstream change in bed gravel grain size, river morphology, and sediment element content through the reach within the Yumen fan. These observations indicate that the gravels are coarse in the bed of the braided river belt have a mean grain size of 36.09 mm, the element content of SiO2 was 69.34%, and Al2O3 was 17.00%. The grain size in the river transition belt is smaller than the upstream, with a mean grain size of 22.40mm, the element content of SiO2 was 65.01%, and Al2O3 was 19.41%. The mean grain size of gravel in the meandering river belt is 9.70mm, the element content of SiO2 is 63.55%, and Al2O3 is 25.96%. Through quantitative analysis of changes in river morphology, gravel grain size, and element content, we show that the changes of river morphology are mainly affected by slope, the grain size of gravel is mainly affected by hydrodynamic conditions, and element content changes are mainly affected by depositional environment. We also found that these three changes are interconnected, and not isolated. The Shule River is close to the apex, with a large slope and steep terrain. The river morphology is mainly braided river, the hydrodynamic conditions are strong, and the sediments are mainly coarse gravel. Downstream of the Shule Rive, the slope decreases, the terrain is gentle, the river morphology is mainly meandering river, the hydrodynamic conditions are weak, and the sediments are mainly fine gravel and sand. We propose that through a systematic study of the Shule River from macro to micro and from whole to local, it is of great guiding significance for the research of fluvial sedimentology.

Sedimentary characteristics of the Permian Upper Urho Formation distriblutive fluvial systems in the Mahu Sag, Junggar Basin, China

Kang Zhao[1], Changmin Zhang[1*]
1. School of Geosciences, Yangtze University, Wuhan, Hubei, CHINA
E-mail: zcm@yangtzeu.edu.cn

Keywords: Junggar Basin, Mahu Sag, Upper Urho Formation; Distributive Fluvial System

Distributive Fluvial System (DFS) refers to deposits of a fluvial system exhibiting a radial planform and distributive channel pattern. This concept emphasizes the overall analysis of the sedimentary system and integrates alluvial fans, braided rivers, meandering rivers and deltas in an orderly transitional sedimentary system (Weissmann et al, 2010; Hartley et al, 2010; Zhang et al., 2017; Zhang et al., 2020, Zhao et al., 2021). Based on detailed observation of 2268.42m cores in 78 wells from the Upper Urho Formation in the Mahu Sag of the Junggar Basin, the characteristics of the DFSs of the Upper Urho Formation were analyzed in detail with the logging data. The study showed that there were two terminal styles of DFSs in the Upper Urho Formation, one is terminating at the alluvial plain on land, mainly developed in first and second members of the Upper Urho Formation; the other was carrying sediments into lake waters and forming deltas, mainly developed in third member of the Upper Urho Formation. Three zones, proximal, middle and distal of the DFS, can be identified in the subaerial sedimentary area, and two zones, delta front and prodelta, can be identified in the underwater sedimentary area. Braided channel lithofacies association and cohesive debris flow lithofacies association dominate the proximal zone of DFS. The lithofacies associations in the medial zone are mainly composed of braided channel and inter-channel. The lithofacies associations in the distal zone are mainly composed of braided channel, sheet flow and inter-channel. There are lithofacies associations in the delta front: underwater distributary channel, interdistributory bay and debris flow, lacustrine mud lithofacies association dominates the prodelta. The thicknesses of coarse-grained channel deposits and inter-channel fine-grained deposits in different zones are significantly different. In the proximal zone, the glutenite deposits in the braided channel are in the form of thick layer superposition, the cohesive debris flow deposits are in medium-thin layers, and the inter-channel deposits are rarely preserved and mostly occur as thin interlayers. In the middle zone, the superimposed glutenite deposits of the braided channel are interbedded with the fine-grained deposits of the inter-channel. The thin-layered braided channel deposits and sheet flow deposits in the distal zone are isolated in the thick fine-grained deposits of the inter-channel. In the direction of DFS along the provenance, the total thickness of conglomerate and sandstone has the trend of gradually thinning, the thickness of mudstone has the trend of gradually thickening. DFSs of Upper Urho Formation belong to regressive types. From the first member to the third member of the Upper Urho Formation, the lake area increases gradually, the extension range of DFSs decrease gradually in the lateral direction, and the grain size decreases gradually in the vertical direction.

Sedimentary filling evolution under paleoclimate transition — A case study of Jurassic Zhiluo Formation in Ordos Basin

liwei cui[1*]
1. The Institute of Geology, Chinese Academy of Geological Sciences,Cores and Samples Center of Natural Resources, Langfang, Hebei, CHINA
E-mail: cuiliwei8855@163.com

Keywords: Ordos Basin, Jurassic, Zhiluo formation, Sedimentary system, Paleoclimate, Tectonism

Abstract: Under a certain tectonic background, the change of paleoclimate can show different sedimentary response characteristics in sedimentary strata. The Jurassic Chinese mainland was one of the important areas for the transformation of paleo-Tethys tectonic domain to the circum-Pacifi tectonic domain, and its paleoclimate information was completely preserved in the continental sedimentary strata. The Jurassic Zhiluo Formation in Ordos Basin was just at the critical period of both paleotectonic domain and paleoclimate transition, which preserves a large amount of sedimentological evidence, while previous few sedimentological research on the Zhiluo Formation under the dual transition. In this study, based on the field outcrop survey, thin section observation, geochemical data, stratigraphic correlation and sedimentary facies analysis, and the paleotectonic transition, the paper reconstructs the sedimentary filling characteristics of Zhiluo Formation under paleoclimate transition. The results show that with the transition of paleoclimate from warm and humid to hot and arid, vertically, the sedimentary facies of Zhiluo formation is characterized by the transformation from braided river (braided river delta) to meandering river and meandering river delta, and lacustrine was deposited in the southeastern part of the basin in the late stage. The combined action of the Tethys-circum-Pacifi tectonic domain caused the overall uplift of Ordos Basin and prevented the southern super monsoon from entering the basin, thereby changing the climate in the basin from warm and humid to hot and semiarid/arid. This study provides an important basis for the exploration and development of uranium resources in the basin and the sedimentology and paleoenvironment research in East Asia during the Middle Jurassic.

Garnet, Cr-spinel, and zircon geochemistry as provenance indicators for the climatic and tectonic evolution of the Mesozoic southern Central Asia

Xutong Guan[1], Chaodong Wu[1*], Yan Xu[1]
1. School of Earth and Space Science, Peking University, Beijing, CHINA
E-mail: cdwu@pku.edu.cn

Keywords: Sikeshu Sag, source-to-sink system, Precambrian basement, Tianshan Orogenic Belt, Western Junggar Orogenic Belt

Sedimentary provenance analysis remains an efficient method for constraining the evolution of orogenic belts and paleoclimate. Intracontinental basins with multiple provenances exhibit diverse provenance evolution. The provenance evolution of the Mesozoic western Junggar Basin recorded climatic and tectonic evolution in Central Asia. Here we reconstruct a four-phase evolution model of the Mesozoic source-to-sink system in the western Junggar Basin, an intracontinental composite basin, by employing multiproxy provenance proxies — paleogeographic analysis, paleocurrent, heavy mineral data, geochemistry of detrital garnet, Cr-spinel, tourmaline, and ilmenite, and zircon U-Pb geochronology. Detrital ugrandite and pyrope, metamorphic ilmenites, dravite, epidotes, and Precambrian zircons were used to identify the Tianshan Orogenic Belt (TSOB) provenance to the south, and the Cr-spinel were used to identify the Western Junggar Orogenic Belt (WJOB) to the north.

The results suggest that the sedimentary environment transitioned from fluvio-lacustrine to alluvial in the Late Jurassic, and evolved into a lacustrine environment in the Early Cretaceous. The southern basin was stably fed by the TSOB in the Triassic during the syn-rift phase. The TSOB dominated and basin center move northward from the Early to Middle Jurassic during the post-rift sag basin phase; During the transpressional basin phase, the basin was mainly sourced from the WJOB and basin center moved, which was followed by the dominance of the TSOB provenance in Late Jurassic. The basin center moved southward in the late Middle Jurassic and northward in the Late Jurassic. Syndepositional volcanic materials provided a large amount of sediments in the Late Jurassic. During the sag basin phase, lake transgression happened and the basin center moved southward.

We concluded that the source-to-sink system experienced a significant change from the syn-rift phase to the post-rift phase. The WJOB experienced transpression and obvious denudation in the late Middle Jurassic, and the TSOB uplifted under transpression in the Late Jurassic. Precambrian basement in the TSOB was not largely exposed until the Late Jurassic. The transpression controlled the change of major provenances and basin center. The aridification in the Late Jurassic in Central Asia was responded by the decrease in the ZTR index and the increase in epidotes and magnetites. The humidification in the Early Cretaceous was in response to the lake transgression and sediment recycling.

Quantitative prediction of gravel diameter with transport distance: A case study of the Karaza Formation of the Honggou section of the southern rim of Junggar

Changmin Zhang[1*], Yang Wang[1]
1. , , , , CHINA
E-mail: zcm@yangtzeu.edu.cn

Keywords: gravel diameter,transportation distance,alluvial fan

Studying the quantitative relationship between gravel diameter and its transportation distance in sedimentary rocks is very important to predict the scale and distribution range of sedimentary system. The study of modern gravel riverbed shows that the relationship between gravel diameter and transportation distance is often in the form of negative index. Based on the gravel data of Kaidu River and Malan Hongshan fan and negative exponential fitting, the quantitative relationship between gravel diameter and its transportation distance is established. The average gravel diameter is calculated to be 22.8-62.9km away from the peak of upstream alluvial fan, and the maximum gravel diameter is calculated to be 10.8-43.8km away from the peak of upstream alluvial fan. According to this formula, the average gravel diameter of Kalaza formation of well Tian'an 1 located at the downstream of alluvial fan 40km northeast of Honggou section is about 1.4-4.6mm, and the maximum gravel diameter is about 4.1-13.2mm. According to this result, it is considered that the Kalaza formation is widely distributed in the south of Junggar Basin and has the sedimentary conditions for the formation of large favorable reservoirs. This result provides a theoretical basis for oil and gas exploration in this area.

Quantitative relationship between distributive fluvial system area and drainage basin area

Qinghao Meng[1], Changmin Zhang[1*]
1. School of Geosciences, Yangtze University, Wuhan, Hubei, CHINA
E-mail: zcm@yangtzeu.edu.cn

Keywords: terrestrial petroliferous basins,distributive fluvial system,influencing factors,source to sink,quantitative prediction

Distributive Fluvial System (DFS) refers to a channel and floodplain sedimentary system that radiates from a vertex, including alluvial fans, fluvial fans, or megafans (Weissmann et al, 2010; Hartley et al, 2010). DFS is widely developed in continental basins and controls the distribution of terrestrial oil and gas reservoirs, sedimentary minerals and soil types, so it has become a research hotspot in recent years. Using Google Earth, Global Mapper and other geographic information software and radar digital elevation data, 1224 DFS areas and their drainage basin areas developed around many mountain systems and lake basins such as Tianshan Mountain, Altun mountain, Qilian Mountain, Chaka Salt Lake and Suhaitu Gobi are measured. It is found that the DFS area has a positive correlation with the source area, and the relationship is in accordance with: $A_{dfs} = aA_{da}^{b}$, the average correlation coefficient is 0.88 (A_{dfs} is the DFS area; A_{da} is the drainage basin area; a and b are constants, a is between 0.3945 and 6.1929, and b is between 0.3816 and 1.702).

Due to the differences in the structure, climate, parent rock and other factors in each region, the constants a and b are different to some extent. In areas with basically the same factors such as structure, climate and parent rock, the size of the DFS area is mainly affected by the source area. The larger the source area, the larger the DFS area. The a and b values of the foreland basin fluctuate the most; climate has a certain influence on the size of the DFS area and its drainage basin area, and the correlation of the formula fitting under arid climate conditions is better; the influence of the source rock properties on the DFS area is mainly related to the parent rock. The ability of rock to resist erosion and differentiation. This study provides a reference for predicting the distribution of sedimentary systems in terrestrial petroliferous basins.

Study on characterization method of thin interbedded reservoirs

gan liqin[1*], Xu Zhongbo[1], Shi Hongfu[1], Zhang Wenjun[1], xie yue[1]
1. Development geology, Bohai Oil Research Institute, Tianjin, tianjin, CHINA
E-mail: ganlq@cnooc.com.cn

Keywords: thin interbedded reservoirs, braided river delta, plane distribution

In the design stage of oilfield development plan, the distribution of reservoir determines the basic well pattern and well spacing. P oilfield is a shallow braided river delta deposit with a distribution area of 16.8km2. At present, there are 4 appraisal wells, and the average thickness of the reservoir is 2.1m, which is far less than the 9m sand body recognized by seismic data. The difficulty of reservoir characterization leads to high risk of development plan.

Referring to the modern sedimentary law, terrigenous materials are mainly transported by fluids, which is easy to form a large area of thin interbedding in the flood period. On the whole, the thin layer is attached to the thick layer. For thin interbedded reservoirs, this study proposes a method of gradually completing the plane distribution of reservoir from thick layer to thin layer. For reservoirs with thickness greater than 5m, the seismic attributes suitable for each oil formation are found by analyzing the correlation. Then, based on the well data, the plane characterization of thick layer is completed through the combination of well seismic and plane section. The plane distribution of thin layers is predicted by taking the sedimentary model based on thick layers as constraints and the actual drilled thin layers and seismic attributes as the reference.

The reservoir characterization results show that the delta in the oil field is unstable interbedding type due to the influence of source supply and channel plane migration. Thin sand bodies between channels change rapidly and have poor connectivity. In the low stand area period, the river channel is developed continuously, with large thickness and good connectivity. In the highstand period, the river channel is mainly narrow strip, with small thickness and poor connectivity. Based on the reservoir characterization results, 17 wells were optimized by focusing on thick layers, ensuring reservoir physical properties and connectivity, and taking into account thin layers. The actual drilling results show that the reservoir distribution is consistent with the description before drilling. The daily oil production of development wells exceeds the allocated production by 20%, and the oil production rate is increased by 1%.

Quantitative characterization of remaining oil based on fine reservoir characterization

Xie Yue[1*], Gan Liqin[1], Wang Meinan[1], Yan Guanshan[1], Fu Yongheng[1]
1. Development geology, Bohai Oil Research Institute, tianjin, tianjin , CHINA
E-mail: xieyue2@cnooc.com.cn

Keywords: braided river delta, horizontal well facies, remaining oil, tap the potential

S oilfield is a braided river delta deposit with large proved oil geological reserves. After more than ten years of water injection development, the oil recovery rate has been reduced from 1.2% to 0.4%. Horizontal well development has been tried in recent years, but the results are uneven. It is urgent to accurately characterize the remaining oil, guide the oilfield to tap the potential and improve the development effect.

According to the macro distribution of reservoir, the river channel, dam body and dam edge are characterized through multi-attribute optimization and well seismic combination. In view of the productivity difference of different horizontal wells on the dam body, starting from nearly 300 sample points, the dam body is divided into class I dam body and class II dam body according to physical properties, productivity and logging characteristics. Based on the sedimentary model, the horizontal well facies determination technology is adopted to complete the plane distribution of the main bodies of class I and II dams. The correlation of parameters such as the proportion of water flooded thickness and oil displacement efficiency of drilled wells is analyzed, and the connectivity coefficient G is introduced to quantitatively characterize the enrichment degree of residual oil at well points. On the plane, the plane distribution of connectivity coefficient is formed by combining the fault system, injection production well pattern and reservoir distribution, so as to realize the quantitative characterization of remaining oil

The results show that affected by the range of water drive, the main enrichment area of remaining oil is the phase transition area between class I dam body and class II dam body and dam edge. Based on the distribution of remaining oil, a horizontal well development model for developing the main body of class I dam is proposed. At present, 25 adjustment wells have been deployed and 14 have been implemented. The daily oil production of the oilfield has increased by 700 m^3, and the oil production rate has been doubled, which has successfully improved the development effect of the oilfield.

Sandy braided river architecture characteristics and evolution: A case study from outcrops in Yungang Formation of the Middle Jurassic in Datong, Shanxi Province, China

Weiling He[1*]
1. Petroleum Exploration & Production Research Institute, SINOPEC, Beijing, CHINA
E-mail: halahwl@163.com

Keywords: Yungang Formation, sandy braided river,architecture element, braided channel; lithfacies association sequences

There is typical sandy braided river deposition in Yungang Formation of the Middle Jurassic in Datong, Shanxi province. Through observation, field measurement, sand body interpretation and laboratory analysis, the geometrical morphology, scale, architecture, structure, lithofacies and lithofacies association sequences of 8 outcrops deposits in the Middle Jurassic Yungang Formation in the Datong Basin, Shanxi province, were systematically studied, 10 types of lithofacies in 8 associations and 5 typical 4th hierarchy architectural element including include braided channel, channel bar, flood plain, abandoned channel, and crevasse splay and chute falling which is 3rd hierarchy reservoir architecture element were identified. The comparative analysis of the comprehensive column of the section shows that channel bars is the major type in the sandy braided river deposits, which were alternately stacked with braided channel, abandoned channel, flood plain and crevasse splay. In terms of time evolution, ten stages sedimentary cycle had been developed below maximum dry water boundary surface forming 6 compound bars. The compound bars are presented in the form of “pan communicated sandy bodies”. The evolution process and rules of the sandy braided river are further summarized, and the strongly heterogeneous facies model with compound bars and main braided channels, which are the main body of deposition, is proposed. It will help to the further theoretical study and the quantitative parameters reservoir characterization and modeling of the sandy braided river.

Quantitative prediction of narrow&thin interbedded reservoirs based on waveform indication-vector sedimentary inversionA case study of Shahejie Formation in Bohai A Oilfield

Lan Zhang[1*], Shaopeng Wang[1], Cheng Guo[1], Qiongyuan Wu[1], Longtao Cui[1]
1. Bohai Oilfield Research Institute, Tianjin Branch of CNOOC Ltd, Tianjin, CHINA
E-mail: zhanglan2@cnooc.com.cn

Keywords: Bohai bay basin,waveform indication inversion,well seismic coordination, vector information,thin interbedded reservoir,coincidence

For Shahejie Formation in Bohai A oilfield, there are thin interbedded reservoir , deep buried, thin and fast changing laterally, most of single layer thickness of less than 5m, and obvious sand -shale interbeds, so it is difficult to predict the reservoir. In this paper, the well seismic joint inversion technology based on waveform indication vector deposition is adopted. The waveform information in high frequency band of seismic data body is used to replace the variogram function, and the sensitive curve reflecting lithology is selected to participate in the simulation. The vertical resolution and horizontal accuracy of reservoir prediction are effectively improved, and the spatial distribution characteristics of sand body in the target layer are more accurately depicted. The high-resolution reservoir prediction with well seismic cooperation is realized Layer prediction. The application of seismic waveform indication inversion technology in thin interbedded reservoir prediction of Bohai A oilfield shows that the coincidence rate of single well reservoir prediction is more than 85%, and the coincidence rate of plane prediction is 78%, which has achieved good results. The research results provide technical support for the implementation of development wells and the understanding of injection production connection.

A New Viewpoint to Vine-type Shallow-water Delta of the Lower Member of Minghuazhen Formation in Laibei Low Uplift

Dalin Zhao[1], Shaopeng Wang[1*], Pengfei Mu[1], Qiongyuan Wu[1], Chen Qian[1]
1. Bohai Oilfield Research Institute, Tianjin Branch of CNOOC (China), Tianjin, CHINA
E-mail: 464296745@qq.com

Keywords: Laibei Low Uplift, the Lower Member of Minghuazhen Formation, vine-type Shallow-water Delta,growth pattern.

In order to clarify the sedimentary model and characteristics of the dendritic shallow water delta in the lake basin during the shrinking period of the Bohai Bay Basin, based on core observation, thin section identification, particle size analysis, logging and seismic attribute analysis, and combined with palaeogeomorphology characteristics, a comprehensive analysis of the low-level shallow-water delta in the lower segment of the Minghuazhen Formation in the Laibei low uplift was carried out. The study shows that:(1) The river-controlled shallow water delta front deposits formed by meandering river entering the lake are developed in the study area. The growth pattern of the front skeleton sand body is mainly divided into three types : superposition type, interweave type and oscillating type.(2) The superposition type sandstones developed underwater distributary channel and estuary sandbar sequentially in the early stage, with poor channel stability and easy breakage, and developed isolated narrow channel sandstones in the late stage; Underwater distributary channel of the interweave type sandstones is reticulate and interwoven on the plane; The oscillating type sandstones have weak channel stability and are easy to cut and divert.(3)The study area was steadily tectonically subsided and filled by sediments during the shrinking period of the lake basin, resulting in an open lake surface and extremely gentle topographic slope during the deposition of the Minghuazhen Formation, which provided a geomorphic basis for the development of skeletal sandstonesDuring the deposition period of the low-level domain, there was sufficient supply of provenance and shallow water bodies in the lake basin, and the interaction process of river and lake deposition caused frequent river diversions and cross-cutting superposition, forming a large area of superimposed sandstones with vine-type distribution. The research results can be useful for oil and gas exploration and development in shallow water delta reservoirs.

Reservoir characteristics of wandering braided river in Guantao Formation of Nanpu 1-29 Area

Xueqian Pang[1], Yanshu Yin[1*]
1. School of GeoSciences, Yangtze University, Wuhan, Hubei Province, CHINA
E-mail: yys@yangtzeu.edu.cn

Keywords: Nanpu 1-29 Area, Guantao Formation, Reservoir characteristics

Based on the core and logging data of the study area, this study on the reservoir characteristics of the wandering braided river in Guantao Formation of Nanpu 1-29 Area was mainly carried out from four aspects, including reservoir petrology, pore structure, reservoir physical property and reservoir heterogeneity. The results showed that the reservoir lithology of Guantao Formation in Nanpu 1-29 Area was mainly fine-medium sandstone, pebbly sandstone and glutenite. The pore types of reservoir were mainly intergranular pores, the pore throat radius varies greatly, and the maturity of sediment composition and structure was low, which was characterized by rapid deposition near source and short channel. The physical properties of different reservoirs were different, and the main reservoirs had better physical properties, especially the two small reservoirs NgIV3-1 and NgIV3-2. The reservoir heterogeneity in the study area was strong, and it's mainly explained from the aspects of intra-layer heterogeneity, interlayer heterogeneity and plane heterogeneity.

Source Analysis of the Multi-Water Sedimentary Pattern in the Upper Part of the Huagang Formation in the North-Central Part of the X Depression of the East China Sea Basin

xiao guang xiao[1*]
1. research institute, Shanghai Branch of CNOOC Ltd, Shanghai, CHINA
E-mail: xiaoxg@cnooc.com.cn

Keywords: Xihu Sag,Huagang Formation,Source Analysis,U-Pb

The Huagang Formation of the Oligocene in the X Depression of the East China Sea Basin is in the stage of depressional evolution, with variable source systems and few analogous contemporaneous outcrops in the surrounding area. The source type and direction have been controversial, which poses a challenge to the understanding of sandstone genesis and type, and reservoir in the depression. In this paper, based on previous studies, the source type and direction of the north-central X depression are investigated by integrating principal component analysis and cluster analysis, in addition to comprehensive analyses using lithological features, heavy minerals, zircon U-Pb dating, clay mineral combs, FMI and seismic, and other multi-information tools[1-4].

The study shows that the East China Sea Basin is a metamorphic crystalline basement in the Yuan Dynasty, and a set of Yanshanian igneous rocks was developed in the X Depression and the surrounding local superposition under the influence of Yanshanian volcanic activity. The heavy mineral assemblage garnet-titanite-zircon-magnetite in the upper part of the flower section is characterized by a high percentage of zircon U-Pb in the metasedimentary period. The source of the QQ and EE tectonics in the eastern part of the X depression is self-contained, mainly from the eastern Diaoyu Island uplift zone and the source is farther away from the western slope and the YQ tectonics. The West Sub-Ambient WW structure is influenced by the short-axis sea reef uplift in the west and the long-axis tiger reef uplift in the north, and the long-axis source is dominant in the north of the structure, while the short-axis source is dominant in the south. The long-axis source affects the YQ structure from north to south, but the eastern source is dominant in this structure.

The comprehensive source analysis suggests that the source-sink pattern of "three-way source supply and axial convergence" is developed in the upper part of the north-central Hanhua depressionFig.1. In the context of the basin depression, the western slope and the eastern slope develop multi-point sources with short axes. In the middle of the depression, the small and medium-sized braided river and curved river sedimentary water system carries to the middle of the depression, and then converges with the large axial braided river system in the north and transports from north to south[5]. This forms a regionally widespread thick-layered sandstone. The large sandstone reservoir collective in the upper part of the flower developed in this source-sink mode has good parent rock type, coarse grain size, adequate elution and strong resistance to compression, forming a better sandstone reservoir. It provides a good basis for improving the exploration and development effect of X depression.

Study on reservoir prediction of thin interbed in middle deep layer based on crosswell seismic technology

Cheng Guo[1*], Lan Zhang[1], Shaopeng Wang[1], Longtao Cui[1], Hebing Tang[1]
1. Bohai Oilfield Research Institute, Tianjin Branch of CNOOC Ltd, Tianjin, CHINA
E-mail: guocheng@cnooc.com.cn

Keywords: Bohai Bay,corss well seismic,thin inter-bedded layer,sandbody distribution

The middle-deep buried reservoir occupies an important position in Bohai Bay, which is characterized by deep buring(buried depth is greater than 2500m), low seismic resolution, and thin interbedded, making it difficult for quantitatively description. In this paper, taking the A oilfield in East Bohai uplift as the target area, a new method is conducted to study the thin interbed of sandstone and mudstone between wells by using seismic data. In order to improve the quality and accuracy of the processing parameters, the ground seismic high resolution amplitude preserved processing is carried out.Based on which,reservoir prediction is established by using high resolution crosswell seismic data.With the combination of crosswell seismic data and geological model, the discontinuous boundary of reservoir is revealed,making it better for understanding of reservoir structure and connectivity relationship. In comparison with conventiona method,this method make it possible to predict the distribution and connectivity of sand bodies, and provides a new way for quantitative prediction and research of reservoirs in middle deep buried reservoir. Besides,it effectively lower the risk of reservoir prediction and improve the prediction accuracy,which provide guidance for well location and highly efficient development of the middle-deep buried reservoir in Bohai Bay.

Evolution from shallow-water deltas to fluvial fans in lacustrine basins

Tian Yang[1*], Xiaofang Li[1], Laixing Cai[1]
1. Institute of sedimenttary geology, Chengdu University of Technology, Chengdu, Sichuan, CHINA
E-mail: tianyang9645@gmail.com

Keywords: Architecture, shallow-water delta, fluvial fan, Shaximiao Formation, Sichuan Basin

The deposition of shallow-water deltas and fluvial fans in lacustrine basins is closely related to the tectonic activities and climate changes. Therefore, these sediments are ideal archives that can elucidate allogenic processes. However, distinguishing between shallow-water deltas and fluvial fans in lacustrine basins with subsurface conditions is difficult. A case study of the Middle Jurassic Shaximiao Formation (J2s) in the central Sichuan Basin was taken to make these points, based on core observations, seismic analyses, petrology analyses, and geochemical analyses. Fifteen sedimentary facies and eight facies associations were established, corresponding to fluvial channelized depositions, fluvial non-channelized depositions, and shallow-water delta depositions. Shallow-water deltas and fluvial fans are characterised by different characteristics, sediments in the first member of the Shaximiao Formation (J2s1) and the first sub-member of the second member of the Shaximiao Formation (J2s21) are dominated by shallow-water delta deposits. Conversely, sediments between the second and fourth sub-members of the second member of the Shaximiao Formation (J2s22 to J2s24) are primarily fluvial fan deposits. The channel widths in the shallow-water delta deposits are broader than those of the fluvial fan deposits and the opposite of channel-body density. The increased uplift of the Dabashan Mountains controls the paleocurrent direction and promotes the evolution from a shallow-water delta to a fluvial fan. Shallow-water deltas are developed in relatively humid environments, while fluvial fans are produced in a relatively arid climate. Highly frequent channel-width variations are controlled by short cycle climate fluctuation. Regarding both shallow-water deltas and fluvial fans, the channel width in the relatively humid environments are wider than those in arid environments. It is likely that sedimentary evolutions from shallow-water deltas to fluvial fans are relatively common in lacustrine basins in relatively arid climates with wide and gentle geological backgrounds.

A study on fine description and well pattern infilling of braided river tight sandstone reservoirs —Take Block T of Sulige[1*] gas field as an example

Feiyang Wang1,2, Xiucheng Tan2, Jinku Liu1, Yang Hu1, Mingjie Deng1, Yi Wu1, Zhou Li1, Quan Tan1
1.Geological Exploration and Development Research Institute of CNPC Chuanqing Drilling Engineering Company Limited, Chengdu, Sichuan, 610051, 2.Southwest Petroleum University,Chengdu, Sichuan, 610500,China
E-mail: 1947631552@qq.com

Keywords: Braided river deposition, Sulige gas field, tight sandstone gas reservoir, fine reservoir description, distribution law of residual gas

Block T is located in the southern part of the middle district of the Sulige gas field. The main horizon of Block T is the lower sub member of 8th Member of Middle Permian Shihezi Formation, which belongs to braided river deposition dominated by strong hydrodynamic conditions. The river channels in He8 member migrate frequently. The sedimentary sandbodies have strong heterogeneity and continuously developed in a large area on the plane, and show the characteristics of multi-stage channels cutting and overlapping by each other. In order to solve the problems of complex distribution law of effective sandbodies and difficult stable production of the block, we comprehensively utilize the rich drilling and logging data, three-dimensional seismic data and test production data in the area to carry out fine reservoir description for the main horizon of the whole block. By clarifying the characteristics and distribution law of effective reservoirs, the reservoir production, the development law of river channels and favorable residual gas distribution area, to provide reliable geological targets for the deployment of infill wells. At the same time, the effect of infill wells in the test area is analyzed and evaluated in combination with geological model, numerical simulation and production performance data in the infill test area. The results show that there is an obvious early pressure drop before the test infill wells are put into production. But the test production is relatively normal, the casing pressure remains good after putting into production, and the reduction of daily gas production is small, so it is considered to have economic benefits. By monitoring the production performance of adjacent wells of the test infill wells. It is considered that the infill deployment of class I reservoir area should avoid the high permeability layers with good connectivity and maintain a well spacing of at least 450m, which will have little impact on the production of adjacent wells. The well spacing requirements for class II and III reservoir areas or reservoirs with obvious interlayer sealing can be reduced to 350m. In order to maximize the utilization of the whole reserves in the process of well location, we should determine the reasonable well type according to the effective reservoir types and the well patterns. Therefore, the research results provide a practical and reliable basis for the next step of infill well location deployment in the block.

Sedimentary characteristics of shallow water delta in seismic complex imaging area of BZ29 block

Long Cao[1*], Shaopeng Wang[1], Pengyu Gao[1], Yanhui Zhang[1], Pengzhi Zhang[1]
1. Bohai Oil Research Institute, CNOOC (China) Co.,Ltd.Tianjin Branch, Tianjin, CHINA
E-mail: caolong2@126.com.cn

Keywords: Huanghekou sag, Shallow water delta, Material supply, Paleotopography, Sedimentary model

Affected by gas cloud area and complex seismic imaging the study of reservoir distribution and connectivity is restricted, to the lower Minghuazhen Formation in block BZ29 block of Huanghekou sag in Bohai Bay. Systematically studied sand body genesis based on the regional sedimentary background, combined with the data of logging, core, logging facies, and seismic facies. The coupling between palaeotopography, transportation distance, and sand enrichment in a shallow-water deltaic depositional environment is explored.

The study shows that the paleomorphology of the Minghuazhen Formation is relatively gentle, and the seismic phase exhibits a planar dispersion of lobe shape. Through core observation, typical anti-rhythmic estuarine dam features and freshwater lake mesocosm paleontological fossils were found, and the mudstone color is mainly gray-green. All of these micron sedimentary features are indicative of a submerged depositional environment at the leading edge of the shallow water delta. Through the thickness statistics of the drilled wells, the thickness of sandstone gradually thins from the source area to the study area, and it is clear that the study area is a shallow water delta front end submerged sediment under the weak source supply condition. The paleotopography of the depositional area was recovered by using the impression method, and three pale grooves mainly exist in the study area, with locally uplifted. The ancient trench is the main accumulation area of sediments, Forming a distributary channel and sand dam, the thickness of the sand body is 8~14m, the uplift area forms a rapid distributary channel and Inter-Channel Bay deposits, the thickness of the sand body is 3~8m. The above research results have been successfully applied in the development evaluation project of the BZ29 block, The complex sedimentary phenomena in the gas cloud area are reasonably explained, The proved reserves have increased by 10 times compared with that before evaluation by the implementation of evaluation wells in the low potential area of paleotopography, and 10 adjustment wells have been deployed in high-quality reservoir areas, At present, five wells have been put into operation, with a daily oil production capacity of more than 100 m^3.

Keywords: Detrltal zircon U-Pb dating, Yangtze River, East China Sea Shelf Basin, Xihu Depression, Pinghu Formation

A key piece of evidence to verify the birth of the Yangtze River during the Eocene is tracing its provenance. However, few people can reveal the major sources area of the Yangtze River and its impact on the sedimentary filling of the East China Sea Shelf Basin. We compared the newly acquired detrital zircon chronological data of the Xihu Depression and compile the published detrital zircon U-Pb ages of the upper, middle, and lower Yangtze River and other potential source areas, then reproduced the provenance changes of sediments in the Xihu Depression of the East China Sea Shelf Basin during the key period of Eocene Pinghu Formation. Results showed that 446 zircons from 6 samples revealed the detrital zircon U-Pb age distribution of lower, middle and upper Pinghu Formation in the Xihu Depression is very wide that ranging from 36.1±0.7 Ma to 2954.0±30.2 Ma, and the age range is roughly similar with major age clusters at 100-200 Ma, 200-300 Ma, and 1700-2100 Ma and minor groups of 400-500 Ma, 700-1000 Ma, 2400-2600 Ma ages. However, the zircon age peaks of the lower Pinghu Formation is more monotonous, which are dominant in100-200 Ma, the population of 200-300 Ma, 400-500 Ma and 700-1000 Ma are significantly smaller than that of the middle and upper Pinghu Formation. Compiled zircon ages of the potential source areas showed the age peaks of the Yangtze River and the Subei-Yellow Sea Basin were similar to the Xihu Depression but the age population of 700-1000 Ma is relatively increased, the age group of other potential source areas including the North China plate, west Cathaysian plate, and Peral River Estuary were different from it. Detrital zircon U-Pb age non-negative matrix factorization of potential sources areas and Xihu Depression revealed that the lower Pinghu Formation is less related to the East Asia continent provenance, it may be supplied by local uplifts. While in the middle and upper Pinghu Formation, the relative contribution of the middle Yangtze River increased to approximately 90%, indicating the major provenance was mainly from the middle Yangtze River catchment during Eocene, which may be related to the complete connection of the modern Yangtze River. However, the U-Pb dating age peaks of the middle Yangtze River are similar to the northern of the Xihu Depression with relatively high 400-500 Ma and 700-1000 Ma clusters, but the small peaks of the two age groups in the middle and southern Xihu Depression showed it very different from the middle Yangtze River, indicating that the influence area of provenance from the Yangtze River is relatively limited. The Eocene significant but limited provenance of the middle Yangtze River catchment to the Xihu Depression indicated that the birth of the Yangtze River may occur during the sedimentary period of the middle Pinghu Formation.

The impact of floodplain heterogeneities on the morphodynamic evolution of coastal meandering rivers: insights from the Medieval Brenta River (NE, Italy)

Elena Bellizia[1*], Jacopo Boaga[1], Paolo Mozzi[1], Giorgio Cassiani[1], Andrea D'Alpaos[1], Massimiliano Ghinassi[1]
1. Department of Geosciences, University of Padova, Padova, PD, ITALY
E-mail: elena.bellizia@studenti.unipd.it

Keywords: coastal meandering rivers, fluvial sedimentology, channel morphometry, floodplain heterogeneity

Coastal plains developed through interaction between fluvial and marine systems that allowed the accumulation of a variety of morpho-sedimentary bodies. These bodies can strongly differ in terms of geometry and grain size, and contribute to forming complex and heterogeneous sedimentary successions, which are, in turn, carved by new river channels. The impact of substrate heterogeneities on morpho-sedimentary processes of channels draining these areas has been poorly investigated, and little is known about the fluvial response to topographic variability triggered by substrate differential compaction.

The present study contributes to filling this knowledge gap by analysing morphometry and sedimentology of a 14 km long Medieval-channel belt of the southern Venetian Plain (northeast Italy). In this area, paleochannel belts are clearly visible from satellite and aerial images, and they are easily accessible for investigation. The study belt is sited at about 8 km from the modern coastline of the Adriatic Sea, which is characterised by a microtidal range (i.e., +/- 1.0 m around mean sea level). The paleo-channel belt was almost 200 m-wide, shows a sinuous pattern and flowed within the backwater zone. The proximal and distal parts of the study portion of the belt overlay alluvial mud and sandy beach ridges, respectively. Morphometric analyses reveal that the bends of the channel belt experienced significant morphological changes moving from the proximal, cohesive, self-compacting alluvial substrate to the distal, cohesionless, poorly compactable beach ridges. Closely spaced sinuous bends developed on the muddy substrate, whereas bends are less sinuous and wider on the sandy beach ridges. Differently, from a sedimentological point of view, no relevant change in point-bar sedimentary features was observed moving downstream along the belt. Sedimentological analyses reveal that point-bar deposits of the study channel belt are homogenously made of sand, with rare muddy layers at the bar top. Additionally, these bars show poorly expressed vertical and downstream fining of the grain size. Results from this study reveal that downstream changes in channel substrate impacted mainly channel-bend morphometries, whereas no relevant variations occurred in terms of sediment transport capability of the river. The overall paucity of mud deposits in the distal part of the system could be explained in terms of a limited impact of tidal forcing on riverine transport processes.

Keywords: Peak discharge variance, Meandering rivers, Planform analysis, Meander migration

Despite considerable advances due to the development of recent approaches, the study of river deposits through sedimentary facies models based on channel planform is facing a certain scepticism in fluvial sedimentology. The ability of these models to predict the geometry, internal structure, and grain size of alluvial sediment bodies preserved in the rock record has been questioned, and recent works highlighted that these models neglect the control exerted by hydrological variability on river depositional dynamics and accumulation of related deposits. In the midst of this discussion, a novel approach based on the categorization of rivers according to their variance in peak discharge was proposed by Fielding et al. (2018 - Sedimentary Geology), which turned out to be an effective and reliable basis for classifying the alluvial rock record. Although the latter study shed light on the importance of hydrological regime in fluvial processes and accumulation of related sedimentary bodies, knowledge is still missing on how precisely peak discharge variability influences river morphodynamics.

We investigated the role of interannual peak discharge variance (PDV), defined as the ratio between the standard deviation and the mean of annual peak discharges, to understand the impact of variable hydrological regimes on the evolution of meandering channels. We assembled a dataset of more than 5000 meanders from a suite of 27 long-term gauged, meandering rivers in different locations around the globe. Their PDV values range from 0.04 (very low) to 1.61 (very high) and were derived from continuous discharge data spanning at least 20 years. Digitization of river banks along selected reaches, from past and present freely distributed satellite imagery, allowed us to extract meander bend morphometric features (i.e. width, radius of curvature, sinuosity, amplitude, skewness and asymmetry). Migration rates and different types of cut-off processes were also monitored and assessed within the time interval between available satellite images by quantifying the displacement of both past and current channel centerlines. A joint analysis of these features was performed to unravel the fingerprint of hydrological unsteadiness on planform behaviour, and it is expected to contribute to the development of a new generation of facies models based on the signatures of flow discharge and its variability over time.

Preliminary results highlight that a difference in planform morphometry is provided by differing variability of peak discharge. Low PDV rivers, displaying a greater discharge stability, are characterized by greater sinuosity, curvature radius and asimmetry when compared to high PDV ones. Additionally, high discharge values experienced by high PDV rivers could be recognized as a cause of varying migration rates and development of different types of cutoffs, with respect to their low PDV counterparts.

Scaling relationships in fluvial systems and their application to the rock record

Adrian Hartley[1*]
1. Geology & Geophysics, University of Aberdeen, Aberdeen, City of Aberden, UNITED KINGDOM
E-mail: a.hartley@abdn.ac.uk

Keywords: fluvial, DFS, scaling

Present day fluvial systems display well established scaling relationships between channel width to depth, channel belt width to depth and point bar width to channel depth. These relationships are important as they provide a potential mechanism for predicting channel body dimensions from one dimensional subsurface datasets such as wireline logs or core. Scaling relationships can also aid in reducing uncertainty associated with estimating fluvial channel body width in the rock record, which, for a given thickness can vary by between 2 and 5 orders of magnitude.

Here we report point bar, channel and channel belt width and depth data from fluvial systems in present day basins to establish dimensional trends for fluvial systems developed in distributive, axial and alluvial valley settings. We use these data to establish generic relationships applicable to all fluvial systems and which should also apply to the rock record. We also illustrate that simple linear relationships between channel width and depth and channel belt width and depth as reported previously are at odds with our data and that an exponential relationship is more appropriate.

Linking present day channel and channel belt dimensions to preserved channel belt sandstone bodies is difficult, as preserved channel belt stacking patterns are not easily observed in modern day basins. Stacking patterns are related to spatial location in basins and the type of fluvial depositional systems (distributive, axial or valley). We present preliminary dimensional data that allow distinction between these different fluvial systems types and place increased constraints on channel body dimensions for use in subsurface studies. Whilst dimensional data from modern day channels and channel belts are not directly transferable to the preserved rock record, this approach does provide generic relationships that could potentially form the basis for more accurately predicting sandstone body dimensions for subsurface fluid extraction and/or storage.

Sedimentary characteristics of arid shallow water delta in the Qaidam Basin: A case study of the Xiayoushashan Formation in Youshashan Oilfield, Qinghai

pei zhang[1*]
1. Oilfield Development Department, Research Institute of Exploration and Development of Qinghai Oilfield Branch,CNPC, Dunhuang City, Gansu Province, Gansu Province, CHINA
E-mail: zhangpeiyjyqh@petrochina.com.cn

Keywords: the Youshashan outcrop,arid climate,shallow water delta,modern deposition

Based on the Youshashan outcrop in Qinghai, comprehensive core, logging and modern sedimentary of Lake Gasku in Qinghai, many studies have confirmed that:The delta deposits in the Youshashan area of western Qaidam Basin were formed in a swollen and shrinking lake basin under arid climate conditions.research shows:Shallow lake basin supported by lake water in arid climate,It has the characteristics of widening water flow and low flow velocity,The sediments are mainly brown-red,Mainly controlled by the main river channel,A large number of detrital materials are deposited in the crevice channel, underwater distributary channel, and mouth bar area to form multiple composite channel-mouth bar lobes,Affected by the dry environment, the compound lobe has a small development scale and a wide distribution range.This type of delta consists of delta plains, frontal margins, and predeltaic subfacies,On the plain subphase, there are obvious divergent water channels in the composite buds;The front subfacies is the most active accumulation area of the regional delta, and the main channel frequently branches into multiple branch channels,The branch channels extend independently and overlap with each other, finally forming a composite channel-estuarine bar combination with a divergent distribution and local contiguousness.The regional pre-delta subfacies belt is very narrow and underdeveloped, and it is transformed by the effects of lake wave tossing, etc., and the shallow lake sheet sand mixed with it, and it is difficult to distinguish the interaction with the shallow lake subfacies.For this reason, the main channel and composite channel-mouth-bar tuft assemblages are the most important oil and gas reservoirs in regional deltas.

A study on the Sequence Architecture and Paleohydraulics of the Upper Member of Bhuj Formation, Kutch Basin, India

Rajarshi Banerjee[1], Anudeb Mandal[1*]
1. Geology, Presidency University, Kolkata, West Bengal, INDIA
E-mail: anudeb.geol@presiuniv.ac.in

Keywords: Bhuj Formation, Kutch Basin, Fluvial Architecture, Paleohydrological parameters

The Early Cretaceous Bhuj Formation, which is the youngest formation of the Kutch Mainland stratigraphic sequence, consists predominantly of three stratigraphic intervals from bottom to top- a Lower Terrestrial Member, a thin Marine Member which pinches out towards the eastern part of the basin and an Upper Terrestrial Member. The Upper Terrestrial Member is a dominantly fluvial succession, which consists of the following characteristic architectural elements- Channel Element(CHE), Downstream Accretion Element(DAE), Lateral Accretion Element(LAE), Abandoned Channel Fill Element(ACE) and Overbank Fines including Levee Deposits(LV), Crevasse Splay Deposits(CS) and Floodplain Fines(FF). The channel elements can be further classified into several channel belts(characterized by concave-up base and flat top), depending on the hierarchy of the bounding surface. Overall the Upper Terrestrial Member can be sub-divided into five channel belts, stacked vertically from bottom to top. Each channel belt consists of several lenticular trough cross sets. A total of 463 trough cross-set thicknesses were measured from all the channel belts. Using these data, several paleo-hydrological parameters such as mean paleo-channel depth, mean paleo-channel width, mean annual discharge, paleoslope, bankfull channel discharge, drainage area, principal stream length, stream velocity, unit stream power etc. were calculated using established formulae. Graphs drawn to analyse the temporal variation of these paleo-hydrological parameters across the vertically stacked channel belts indicate gradual narrowing(decrease in bankfull width) and shallowing(decrease in bankfull depth) of the channels through time. The overall decrease in discharge rate, bankfull width and depth indicate that the entire fluvial system dried-up through time. This drying-up trend is also corroborated by the transition of fluvial channel deposits to a thick aeolian succession, especially at the topmost part of the third channel belt. The aeolian succession is marked by distinct dune and interdune fields. This drying-up trend could be due to the effect of either paleo-climatic variations or tectonism or an interplay of both.

Description of braided bar reservoir based on the integration of braided river sedimentary numerical simulation and spectral-decomposed and fused seismic attributes

Jianmin YANG[1*], Yanlai LI[1], Shaopeng WANG[1], Honglin YUE[1], Hanqing ZHAO[1]
1. Bohai Oilfield Research Institute, Tianjin Branch of CNOOC Ltd., Tianjin, CHINA
E-mail: yangjm15@cnooc.com.cn

Keywords: Delft3d,Braided river deposits,Numerical simulation,Frequency division fusion,Reservoir description

The Guansan oil formation reservoir of Caofeidian C structure located in the east of Shaleitian uplift belongs to typical sandy braided river deposition. The reservoir changes rapidly and the structure is complex. Because there are few drilled wells in the study area, it is difficult to accurately describe the shape of braided bar and reservoir;

This paper creatively applies the combination of sedimentary numerical simulation and frequency division RGB fusion technology to the fine anatomy of braided bar reservoir. Firstly, based on the sediment hydrodynamics of the Dleft3D platform, this paper uses sedimentary numerical simulation technology to realize the dynamic numerical simulation of braided river sediments, sedimentary phenomena and evolution, clarify the evolution and transformation process of each micro phase of braided river, and summarize the development and evolution process of braided bar and the formation mechanism of braided bar from the mechanism, Furthermore, the quantitative parameters such as the scale and style of the braided bar in the study area are obtained; Then, the frequency division RGB fusion technology is used to identify the sedimentary microfacies of braided bar in the form of stratigraphic slices. Combined with the parameters such as sedimentary scale and style of numerical simulation, the reservoir of braided bar is finely characterized.

This method provides a new method and idea for the exploration and development of similar oilfields and fine reservoir evaluation.

Sequence stratigraphy and seismic geomorphology of Mid-Miocene fluvial systems in the northern shelf of South China Sea: Implication for climatic control

Li'e Lin[1], Haiteng Zhuo[1*], Ming Su[1], Jin Feng[2], Zhigao Li[2], Lin Ding[2], Jiayuan Du[2], Zhixuan Lin[1], Rongnan Yang[1]
1. School of Marine Science, Sun Yat-Sen University, zhuhai citry, Guangdong Province, CHINA
2. CNOOC, ShenZhen.Ltd, Shenzhen, Guangdong Province, CHINA
E-mail: zhuoht3@mail.sysu.edu.cn

Keywords: fluvial systems, sequence stratigraphy, seismic geomorphology, climate change

The development of fluvial systems, whether incised or unincised, has been proved to be regulated by the interaction of various forcing factors, including sea-level change, tectonics, and evolution of drainage basins. Recently, climatic control on fluvial systems has been a hotly-debated topic, while the coupling relationship between them hasn't been fully revealed.

Using vast 3D seismic data on the northern shelf of the South China Sea, this study identified multiple stages of widely-distributed fluvial systems within the Middle Miocene successions. According to core descriptions, well-log motifs, and seismic geomorphology, the fluvial systems can be categorized into braided or meandering types, which also correspond well with the subdivision of systems tracts. Furthermore, from cluster analysis of heavy minerals in a few wells, we found that there were two main trunk channels of the ancient Pearl River since 23Ma, which controlled the major depositional pattern of the entire Pearl River Delta.

Sequence stratigraphic analysis, combined with a systematic mapping of fluvial systems of various stages, indicated that their distributive pattern had changed significantly across a key sequence boundary, i.e., the SB17.1 with a geological age of ca. 17Ma. Beyond this surface, the fluvial systems displayed widespread pattern and very high efficiency of sediment delivery to the shelf margin. Previous studies have confirmed that climate change can significantly influence fluvial styles by controlling the fluvial discharge and vegetation cover beside. In this study, we attributed this dramatic change in fluvial systems to be mainly the upstream control, i.e., being climatically driven rather than sea-level change, which coincided with Mid Miocene Climate Optimum (MMCO: 17.2~15.5 Ma). The warm and humid weather during MMCO increased the fluvial discharge and the drainage areal extent might have significantly contributed to the dramatic increase in the distribution of fluvial systems across the northern shelf of the South China Sea.

Fluvial succession from the distal Lower Freshwater Molasse (LFM) in the Northern foreland basin of the Alps (Bern Area, Switzerland)

Guilhem Amin Douillet [1*], Ahathian Manikkapoody[1], Daniela Van den Heuvel[1], Déborah Harlet[1], Fritz Schlunegger[1], Larryn W. Diamond[1]
1. Institut für Geologie, Universität Bern, Bern, SWITZERLAND
E-mail: guilhem.douillet@geo.unibe.ch

Keywords: fluvial, meander, belt, molasse, foreland

The Swiss Molasse is formed by Tertiary sediments recording the evolution of the Northern Foreland Basin of the European Alps. The Lower Freshwater Molasse (LFM, Chattian to Aquitanian, ca. 30-20 Ma) is a thick group of alluvial to fluvial sediments. It contains conglomerates in the proximal zones near the Alps that evolve into a meandering fluvial system in the lowlands. Here, focus is put on deciphering the architecture and paleoflow directions of this fluvial meandering system in the region of Bern (Switzerland).

Field exposures are investigated from quarries and recent fluvial incisions in the upper part of the LFM (Early Miocene). They allow to depict the variety of sedimentary structures within coarse-sand fluvial channels, silt-dominated overbank levees, and weathered marl-dominated paleosoils. Drone-based photogrammetric reconstructions also enable to visualize the lateral and vertical stacking patterns of larger-scale fluvial channel belts. These surface outcrops depict sharp and unpredictable lateral changes in lithofacies associations, and the dominant lateral amalgamation of sandstone beds as meander belts. The apparent orientations of cross-bedding patterns are coherent within narrow zones (100's m), yet become contradictory at a larger scale. They thus seem to indicate local orientations of the meanders rather than any larger-scale trend.

A collection of >350 publicly available borehole logs, covering an area of ca. 20 x 20 km2, was analyzed in order to give insights into the 3D organization of the LFM. This reveals heterogeneous proportions of sandstone beds in the subsurface, including zones where sandstones are overrepresented on a lateral horizon, as well as narrow zones with a higher proportion of sandstone beds stacked vertically. Within the shallow subsurface, there seems to be a preferential W-E strip of sandstone beds throughout the investigated zone, although any interpretation is impeded by the interference of Quaternary glacial incisions. This trend would however align with the regional draining direction of the LFM. Furthermore, a shallow, laterally spreading cluster of coarse grained sandstone is identified in the uppermost part of the LFM within the city center of Bern. Vertically, two narrow areas with a very high proportion of sandstones over more than 150 m of thickness are identified, yet the data do not allow these clusters to be followed laterally or to be assigned any orientation. This suggests, however, that at least some fluvial channels are very stable over time and do not undergo lateral switching over extensive periods.

Scarce high quality boreholes down to >200 m depth did not allow to infer any vertical (time) evolution in the sedimentation dynamics. Instead, these boreholes depict relatively stable and regular heterogeneity with alternating sandstones, overbank levees, and paleosoils.

An attempt is currently underway to identify variations within the mineralogical and chemical signature of the paleosoils. This might yield a proxy for the degree of stability of channels, and/or a proxy for the proximal-distal situation at a given time.

E-mail: sabin.rotaru@geoecomar.ro

Keywords: river incision, bathymetry, bank erosion, sediment balance

Danube River is one of the largest fluvial systems in Europe in terms of length, drainage area, discharge and sediment load. Multiple anthropogenic pressures in the Danube River Basin have led to evident hydromorphological alterations, amongst which the most heavily disturbed component is the sediment regime. Like many temperate zone rivers, the sediment load of the Danube River has been substantially reduced due to the combined impact of flood protection, navigation and hydropower measures applied over a long period of time.

In this study, annual changes in riverbed morphology were analysed for a period of ten years (2010-2020) using various data recorded from single-beam bathymetry, river discharge and sediment load measurements. We investigated five reaches located downstream of the Iron Gates I and II Dams, displaying various representative landscapes for the Lower Danube sector such as wide sections with large or small islets, narrow sections or large meanders. The analyses revealed an accelerated riverbed incision compared to previous trends (i.e. 1985-2005 interval) which is discussed in relation to anthropogenic interventions such as dredging for ensuring optimal navigable conditions, floodplain embankment and hydropower generation.

Sedimentary characteristics of near provenance braided river delta in the upper 3rd Member of Shahejie Formation of KL A oilfield

Hanqing Zhao[1*], Shaopeng Wang[1], Cheng Guo[1], Bo Zhang[1], Pengfei Mu[1]
1. Bohai Oilfield Research Institute, Tianjin Branch of CNOOC Ltd., Tianjin, CHINA
E-mail: zhaohq17@cnooc.com.cn

Keywords: Bohai Bay basin,Near provenance braided river delta,sedimentary characteristics,sequence stratigraphy

The upper 3rd Member of Eocene Shahejie Formation ($E_2S_3^U$) is the main oil bearing zone in KL-A oilfiled of Laizhou Bay sag ,Bohai Bay basin, East China. In order to revealing the $E_2S_3^U$ sedimentary characteristics and patterns in the study area, using seismic, core, grain size, casting thin section and logging data, the sedimentary facies types and distribution under the sequence framework in the $E_2S_3^U$ are summarized. The results show:(1) A typical near-source braided river delta sedimentary system in $E_2S_3^U$ of KL A oilfield was deposited which has the typical characteristics of progradational seismic reflectance signatures, incised channel and collapse deformation structures in core, as well as the low structural maturity and compositional maturity.(2)Based core and logging facies, three kinds of subfacies are recognized: braided river delta plain, braided river delta front and pro- braided river delta. Furthermore, it can divided into the following six sedimentary microfacies: braided channel, flooding plain, underwater distributary channel, underwater distributary interchannel, mouth bar and sheet sand.(3)Using sequence stratigraphy, divided $E_2S_3^U$ into a set of third-order sequence, the lowstand systems tract (LST) was deposited by thick sandstones of underwater distributary channel, and the transgressive systems tract (TST) and highstand systems tract (HST) were deposited by thin sandstones. (4) The sandstone thickness and distribution scale of different systems tracts are controlled by the elevation of the lake level and the rate of sediment supply rate. This rule provides an reference for the evaluation of sandstone reservoir in the gentle-slope zone of a faulted lacustrine basin.

Prediction of braided river delta front based on target processing and frequency division inversion

Yang Li[1*], Hebing Tang[1], Chao Li[1], Cheng Guo[1], Qiongyuan Wu[1]
1. Bohai Oilfield Research Institute, Tianjin Branch of CNOOC Ltd, Tianjin, CHINA
E-mail: liyang51@cnooc.com.cn

Keywords: progradation,braided river delta front,multiples,generalized S-transform,sedimentary framework,frequency divisiong inversion

A oilfield in Bohai Bay belongs to river controlled braided river delta deposit, and the favorable reservoir is progradation in braided river delta front. The single stage progradars have the characteristics of thick thickness, high filling degree and limited distribution. The typical "small and fat" is the key direction of potential exploitation in oil fields. In order to describe the plane range of the precursor, the residual multiple wave suppression technology based on amplitude fitting and signal matching reconstruction is used to solve the problem of residual multiple waves in the near-channel. The extension technology based on generalized S transform is used to expand the low-frequency and high-frequency signals of earthquakes at the same time to obtain the real wide-frequency seismic signals. Based on the seismic data processed by the target, the single stage progradars are explained carefully under the constraints of geological model, and the fine vertical sedimentary framework and plane distribution form are established. Finally, the high resolution inversion density data body is obtained by using the frequency division nonlinear inversion and the formation frame of the single stage precursor is used to constrain the inversion density data body, and the accurate prediction and description of the plane distribution and thickness of the single stage precursor are realized. The prediction accuracy of reservoir is up to 90% by the new drilling development well, which effectively guides the implementation and rolling evaluation of the development well in the oilfield, and provides technical reference for other geological reservoir conditions, seismic data quality and similar buried depth.

The Influences of Authigenic Minerals on the Quality of Nubian Sandstone Reservoirs

Mohamed Mabrouk Rahoma[1*]
1. Sedimentology, Libyan Petroleum Institute, Tripoli, LIBYA
E-mail: m.rahoma@lpilibya.com

Keywords: facies, Authigenic mineralogy, reservoirs quality

This paper presents the results of my sedimentological and petrographical study of Nubian Formation in north Gialo area in Sirte basin in Libya that used for identifying and recognizing the facies type and their changes through the studied interval. It also helped me to interpret the depositional processes and the depositional environments and describe the textural characteristics, detrital mineralogy, Authigenic mineralogy and porosity characteristics of the rocks within the cored interval, thus we can identify the principle controls on porosity and permeability within the reservoir sections for the studied interval.

To achieve this study, I described the cores of studied well and marked the all features that representing in color, grain size, lithology, and sedimentary structures and used them to identify the facies. Then, I chose a number of samples according to noticeable change in the facies through the interval for microscopic investigation.

The results of the microscopic investigation showed that the the authigenic clays and the authigenic cements have an important influence on the reservoir quality by converting intergranular macro pores to micro porosity and reducing permeability.

It is recommended to give these authigenic minerals more investigation in future studies since they have an essential influence on the potential of sandstones reservoirs.

Research on the genesis of reservoir dissimilarity based on differences in petrology, physical properties, and diagenesis—A case study of Chang 82 reservoir in Jiyuan Oilfield, Ordos Basin

Qiang Tong[1], Jixin Huang[1*], Qiang Luo[1]
1. Inter American Institute, Research Institute of Petroleum Exploration and Development, Beijing, CHINA
E-mail: huangjixin@petrochina.com.cn

Keywords: genetic differences of reservoirs, petrology, physical properties of reservoirs, diagenesis, diagenetic facies, Jiyuan Oilfield

There are significant differences between the eastern and western reservoirs of Yanchang Formation in Jiyuan Oilfield, Ordos Basin. Up to now, there is still a lack of specific analysis on the genetic differences of reservoirs. A large number of existing studies usually have not noticed the differences of reservoir characteristics between the east and the west caused by bidirectional provenance, resulting in the relatively poor guiding effect of reservoir research results on production and development. Therefore, based on the comparison of differences in petrology, physical properties and diagenesis, this paper studies the origin of the difference between the eastern and western reservoirs of Chang 8_2 in Jiyuan Oilfield through experimental means such as core properties, Graphic granularity analysis, Casting sheet image, SEM, cathodoluminescence and XRD. The differences of reservoir basic characteristics are carefully compared, and then the causes of reservoir dissimilarity are analyzed through diagenesis analysis, reservoir pore evolution, diagenetic facies division and reservoir formation mechanism discussion. The research results show that the clastic assemblage and rock structure characteristics reflect the difference in provenance supply between the east and the west. The content of interstitials in the west is slightly higher than that in the east, but the overall development of the reservoir space is better, and the surface porosity is also larger. The physical properties of the reservoirs in the west are much higher than those in the east. XRD shows that the content of clay minerals is significantly related to the physical properties. The reason for the deterioration of the physical properties in the east is that the pores are filled with kaolinite and chlorite. The western reservoir is poorly sorted and relatively more compacted, but the primary intergranular pores are well preserved under the action of chlorite film, and the eastern part has a higher degree of dissolution, but the ability to improve the reservoir is limited. And the middle and late cementation further led to a significant decrease in the porosity of the eastern reservoir. Because the number of residual intergranular pore facies on the chlorite lining far exceeds that in the east, the composition of diagenetic facies in the west is better than that in the east. Sedimentation is the basis for the development of higher-quality reservoirs in the west. Good mineral content composition and higher-quality diagenetic transformation are the reasons for the better quality of the reservoirs in the west and the east. This study is expected to provide a theoretical basis for deepening the subsequent exploration and development of Chang 8_2 reservoir in Jiyuan Oilfield.

Study on seismic geomorphology of the second member of Jurassic Shaximiao Formation in Wubaochang area, Northeast Sichuan

rui fang[1*]
1. School of Earth Science and technology, Southwest Petroleum University, Chengdu, Sichuan, Sichuan, CHINA
E-mail: 342645160@qq.com

Keywords: Fluvial facies, Base level cycle, Stratal slicing, Seismic landform

Fluvial reservoir is an important reservoir type in continental basin. Due to its fast phase transition and strong heterogeneity, there are many problems to be solved on how to accurately characterize the distribution characteristics of fluvial sand body and study its reservoir distribution law. Taking the second member of Shaximiao Formation in Wubaochang area of Northeast Sichuan as an example, using the principle of base level cycle change, combined with drilling, logging curves and seismic reflection characteristics, this paper identifies that the study interval mainly develops one third-order and three fourth-order base level cycles; According to the characteristics of field outcrop, sedimentary structure and sedimentary sequence, the sedimentary facies of Sha2 member is studied. It is considered that braided river sedimentary system and meandering river sedimentary system are developed in the study area; Using seismic stratigraphic slicing technology, the distribution characteristics of sand bodies and facies belts in different periods in the longitudinal direction of Sha2 member are finely described, and the transformation law of "braid meander" in the fluvial facies strata of Sha2 member is revealed from bottom to top. Its specific characteristics are as follows: under the low accommodation space, the sand bodies are distributed in a large area to form mutually superimposed braided river channels; When the base level rises rapidly, the accommodation space increases and a relatively isolated meandering river channel is formed. The sedimentary characteristics and seismic geomorphic response changes of braided rivers and meandering rivers developed in the study area are the comprehensive response of base level cycle changes of accommodation space and sediment supply ratio (A / s) in the process of fluvial facies sedimentary evolution. A / S is mainly affected by tectonic movement and climate change factors.

5. Département de géologie, Université de N'Gaoundéré, N'Gaoundéré, CAMEROON

E-mail: fosso.menkem@gmail.com

Keywords: Mayo Oulo-Lere, Bambalo Formation, sedimentary sequence, electrical resistivity tomography.

The Mayo-Oulo-Lere Basin is located in the northern Cameroon between the western extension of the Doba basin (Chad) and eastern edge of the Benue trough (Nigeria) in Africa. This study maps the depth and spatial development of Bambalo sedimentary sequences at the Mayo Oulo-Lere Basin. The depositional sequences present an exposure of crocodile fossils and plants evidenced by superficial alteration. The Bambalo Formation was described in terms of lithostratigraphy, vertical electrical sounding (VES) and electrical resistivity tomography (ERT) in order to bring out a better understanding of stratigraphic evolution and setting conditions during sedimentation. Sedimentary deposits in the Mayo Oulo-Lere basin are mainly fluvio-lacustrine deposits consisting of alternating claystone, siltstone and limestone. Lithostratigraphic log of Bambalo for the subsurface geology up to 25 m show three main depositional sequences (S1, S2 and S3). The sedimentary sequences are dominated by retrogradational depositional trends that describe short sequences of fining-upwards successions, as sediment supply fills the available accommodation space after each tectonic phase or/and rise of lake level.

The ERT image results obtained from geophysical analysis using Res2Dinv display local features associated with folding in the aforementioned sedimentary thickness. Additionally, the VES analyses using ipi2win software show that the upper 78 m part of the Bambalo formations is composed of four layers (L1, L2, L3 and L4) distinct by resistivity. L4 Layer correlated with the top of lithostratigraphic log S3, while L3 is a semi-resistive set of 78 ohm.m layering S1 and S2 lithostratigraphy sequences. Layer L2 corresponds to a conductive set with resistivity of approximately 27 ohm.m above the lower layer L1, a resistive sequence with resistivity greater than 1000 ohm.m.

The results of this study demonstrate that the combination of ERT and lithostratigraphic analysis is a powerful tool for a better understanding of the Bambalo sedimentary process and basin evolution. The lateral and vertical evolution of the layers being proven, a future deep excavation will certainly make it possible to bring to light new types of fossils from these deposits and in the neighbouring basins.

Depositional Environment of the Barren Measures Formation, Gondwana Supergroup, Damodar Valley Basins, Eastern India

Joydip Mukhopadhyay[1*], Gobinda Nandi[1]
1. Geology, Presidency University, Kolkata, Kolkata, West Bengal, INDIA
E-mail: Joydip17@gmail.com

Keywords: Gondwana, Fluvial, Deltaic, Damodar Valley

The Gondwana succession in India records a long span of time from Carboniferous (~350 Ma) to end Cretaceous (~60 Ma). During this time span of about 300 million years the Indian peninsula recorded passage from high southern latitude to low norther latitude during which the entire Gondwana rocks were deposited. The Gondwanas characteristically include two major cycles of coal formation separated by a barren interval. The voyage of peninsular India across a wide latitudinal range witnessed major changes in climatic regime. Besides eustatic changes play an important role in the development of different depositional settings ranging from marginal marine to continental fluvial (Casshyap and Tewari, 1984, 1991; Veevers and Tewari 1995). In generalized stratigraphic classification, Indian Gondwana succession from the eastern Indian Damodar Valley Coalfields is classified into six formations, namely in ascending order, Talchir, Barakar, Barren Measures, Raniganj, Panchet and Suprapanchet Formations. The lowermost Talchir Formation record Permo-carboniferous glaciation event. Barakar and Ranigunj Formations are coal-bearing and represent predominantly fluvial depositional environment. Both these coal-bearing formations are sand-dominated and show multi-storey fining-upward cycles. In contrast, Barren Measures Formation is mud-dominated and includes mudstone and mudstone-sandstone heterolithics. The Barren Measures suggest deposition in a much quieter environment than the coal-bearing Barakar and Raniganj Formations. Overall facies sequence indicates deposition in a delta plain setting. The tectonics, as well as climatic factor, is likely to be important for such transformation.

Acknowledgment: The research is supported by the WBDST project (No 283-ST/S&T/10G-26/2017).

Discrimination different sediment of rivers by using heavy and light minerals

Fouad Al-Kaabi[1*], Manal Al-Obaydi[1], Esraa Muhammad Ali[1]
1. Research and Development, Iraq Geological Survey, Baghdad, IRAQ
E-mail: fouadsaleem77@yahoo.com

Keywords: heavy minerals, light minerals, fluvial sediments, Tigris River, Diyala River, Iraq

Quaternary sediments in the center of Iraq are weathered from igneous-metamorphic complex in the north and northeast of Iraq, northwest of Iran and southeast of Turkey. Different types of minerals and rock fragments from this complex are transporting by rivers in these areas downstream.

Twenty-one of sediment samples were taken from Tigris and Diyala rivers in Tikrit, Diyala, Baghdad, and Wassit governorates along the of Tigris and Diyala river sediments in the center of Iraq. The main focus in these samples was the change in mineralogical composition across two rivers in the studied area, and their valuables. Thus, this study focuses on identification the light and heavy mineral assemblages and their spatial distributions, maturity, provenance in the collected samples.

Examination of the heavy mineral content shows that most samples are dominated by opaque minerals (33.97% – 69.66%). In addition to this group, various percentages of heavy minerals such as amphiboles, pyroxenes, mica and garnet, with a few amounts of zircon, tourmaline and rutile were presented in the studied samples.

The light minerals composed of quartz, feldspar, and rock fragments which derived from sedimentary, igneous, and metamorphic rock fragments.

The large amount of unstable heavy minerals compared to ultrastable minerals was referred to immature sediments, arid- semiarid climate, and mechanical weathering in the source area. These immature sediments found to be contain quartz and feldspar together, comparing with mature sediments, that were recognized in south of the study area, were involved only quartz.

The studied samples showed a noticeable amount of amphibole, pyroxenes and micas along the Tigris River at the studied sites, may indicate a continuous transport in spite of being unstable minerals. Furthermore, the results from heavy minerals demonstrated that no evidence of reduction in these minerals diversity downstream.

Studying heavy minerals also can suggest that Diyala River sediments was weathered from igneous- rocks from Iran with minor input from metamorphic rocks, whereas, Tigris River sediments probable came from metamorphic rocks with igneous contributed. Therefore, this study demonstrates that using light minerals in addition to heavy is great benefit in provenance studies

The influence of global warming on channel planform morphology and sediment reworking of the Earth's highest meandering belts

Zhipeng Lin[1,2*], Zhongpeng Han[1,2], Yalige Bai[1,2], Chengshan Wang[1,2]
1. State Key Laboratory of Biogeology and Environmental Geology, China University of Geosciences (Beijing), Beijing, CHINA
2. School of Earth Sciences and Resources, China University of Geosciences (Beijing), Beijing, CHINA
E-mail: linzhipeng@cugb.edu.cn

Keywords: Climate change, Global warming, Yarlung Tsangpo River, Meander, River morphology

Meander planform morphodynamics plays a vital role in rendering planetary surfaces(Seybold Hansjoerg et al.; Willett et al., 2014; Ielpi & Lapôtre, 2019) and regulating climate and carbon cycle (Repasch et al., 2021; Ielpi et al., 2022). The upstream of Yarlung Tsangpo River flowing over the Himalayan highlands develops the Earth's highest meandering belts. Rapid planform changes in the meandering channels within the pristine systems are largely free from human interference. Yet we know little about how the pronounced climate changes in Himalayan regions have impacted the meandering morphology and morphodynamics. Here we show that meander migration and sediment reworking have been accelerated over the past 40 years. Our results are based on the 5200 planform changes of meander bends since the 1980s, integrating geo-referenced high–resolution remote sensing imagery with GIS analysis. Faster migration of frozen outer riverbanks was comparable to the increases in temperature, glacier, and permafrost degradation. Further analysis of controlling factors reveals a consistently positive response between changes in climate and channel planforms. We find that the nearly two-fold increase in meandering channel mobility and sediment reworking was not controlled by autogenic processes or externally imposed noise like active faults. Results indicate that global warming may exert a first control on the upland river morphodynamics and accelerate the fluvial biogeochemical cycle, which further may increase the downstream risk involved with riverbank retreat and planform changes. Our finds improve the understanding of the evolution of upland meandering channels in a warming world and reveal the impacts on sediment reworking of glacier retreat and permafrost thaw.

Study on Gas - Water Distribution of Shan 1 - He 8 Member in Su 59 Well Area

Lian Zhihua[1*], He Jiang[1]
1. School of Geoscience and Technology, southwest petroleum university, Chengdu, Sichuan, CHINA
E-mail: 2359722670@qq.com

Keywords: Su 59,hydrocarbon generation conditions,sand body,reservoir,air-water distribution

The problem of gas-water co-production has always been the key to limit the stable production and production in the western region of Sulige. Su 59 block is in the area of weak hydrocarbon generation intensity in Sulige area on the plane. The lack of hydrocarbon generation power and the low degree of natural gas filling have led to the widespread water cut of the Shihezi-Shanxi Formation gas reservoir in Su 59 block. Based on core and logging data, this paper mainly analyzes the main control factors of natural gas enrichment in He 8 and Shan 1, the main gas producing horizons. The results show that the regional hydrocarbon generation conditions determine that the gas content of Shan 1 reservoir is relatively high, while the water content of He 8 reservoir far from Shan 2 and Taiyuan Formation source rocks is generally high despite the superposition and development. The gas-water distribution in Block Su59 is affected by the local high point of the structure, sand body distribution, reservoir physical properties and other factors. The gas source in the lower part moves upward, which will be preferentially filled into the channel sand body with high porosity and permeability, and then the gas-water difference will be generated under the control of local structure, namely, the ‘ three-determined ’ gas-water distribution mode of ‘ determining the trend of source rock + determining the pattern of high permeability sand body + determining the gas-water difference in single sand body ’ by micro-structure.

Keywords: Stratigraphic forward modeling, Susceptibility mapping, Canyon evolution, Upslope model

The debate on the submarine canyon origin between the upslope erosion model dominated by retrogressive mass failures and the downslope erosion model controlled by gravity flows has not been fully settled. However, this debate is critical for explaining submarine canyon evolution. This study combines susceptibility mapping and stratigraphic forward modeling (SFM) to examine the origin and evolution of submarine canyons under various fluvial discharge and morphologies. The SFM work consists of dozens of hypothetical numerical experiments based on typical passive margin bathymetry with half bathymetry occupied by an incipient canyon and associated river mouth topography, and another half bathymetry by steep slopes without canyons. Evolution characteristics in both plan and cross-section views are analyzed, and the impacts of fluvial and morphological features on canyon evolution are tested.

The results indicate that submarine canyons can be divided into four types according to their morphological features, locations, and origins: blind canyons, shelf-incising canyons, step-trigger gullies, and the incipient canyon and its dendritic tributaries. Submarine canyons retreat landward, tributaries develop on the canyon outer banks, and blind canyons grow landward to capture small gullies and form shelf-incising canyons. There are three types of canyon networks: linear canyons with regular spacing, straight main-stem canyons with dendritic tributaries, and sinuous main-stem canyons with tributaries on the canyon outer banks.The upslope pattern is dominant regardless of changes in fluvial discharge and morphologies. The locations of tiny gullies on steep slopes determine the distribution and growth direction of submarine canyons, whereas fluvial conditions and morphology parameters affect the canyon dimensions. High fluvial discharge and high canyon sidewall slope angle promote tributary development and canyon erosion. High canyon sinuosity leads to an asymmetrical distribution of tributaries on canyon outer banks whereas high regional slope angle increases the canyon length and decreases the canyon spacing. There are three critical questions for analyzing canyon evolution: whether canyons are affected by long-term erosive flows, the relative importance of gravity flows and mass movement, and differentiation between main-stem canyons and tributaries. The distance component parallel to the shelf break between rivers and canyon mouths may be more important than the distance component perpendicular to the shelf break.

This study settles the debate between the upslope and downslope erosion models. In addition, it refines the upslope model by highlighting the importance of small-scale gullies and testing the influence of fluvial and morphological conditions on canyon evolution. The conclusions could promote the understanding of submarine canyons and assist in reservoir exploration and hazards prevention.

Stratigraphic Cycles in Turbidite Sand Sheet Systems----Implications for Progradation/Retrogradation Cycles

JIANAN WU[1*]
1. Offshore Petroleum Exploration, Petrochina Hangzhou Research Institute of Petroleum Geology, HANGZHOU, ZHEJIANG, CHINA
E-mail: 642837124@qq.com

Keywords: sand sheet systems, stratigraphic cycles, turbidite, progradation, retrogradation

Attempts have been made in the past to link stratigraphic cycles in turbidite sequences to progradation (i.e. thickening and coarsening upward) and retrogradation (thinning and fining upward). However, if the sedimentary system is laterally unconfined or shows much compensational stacking, the relationship between stratigraphic cycles and such vertical sequences may be more complex or stochastic. Meanwhile, progradation and retrogradation imply a basinward or landward shift in deposition respectively, but few 2D outcrop sections along depositional dip have been studied sufficiently to establish the longitudinal variations in stratigraphic cycles. In this study, two Cretaceous turbidite sand sheet systems, referred to as Pehoe Member B and Paine Member A (abbreviated here to Pehoe B and Paine A) are compared, to investigate the longitudinal stratigraphic variation and possible implications.

With a logging scale of 1:10, statistical methods such as runs tests, moving average, and correspondence tests are used to detect stratigraphic cycles. Combined with facies and thickness analysis, Pehoe B and Paine A sand sheet systems are both interpreted to be laterally confined with dominantly vertical stacking overall. Along depositional dip, stratigraphic cycles of thickening and coarsening upward then thinning and fining upward, where present, are asymmetrical in proximal areas but appear to be more symmetrical in distal areas. The longitudinal variation of stratigraphic cycles is generally consistent with that of maximum thickness of amalgamated beds and total counts or counts/meter of all bypass features. Turbidite vertical sequences of both Pehoe B and Paine A reflect a general progradation then retrogradation process, with superimposed small scale fluctuations, which may infer allogenic variations in sediment supply (3rd to 4th order sequences).

Upper Pliocene deep-water sedimentary system in a block of Rakhine Basin, Bay of Bengal

Hui Sun[1*]

1. Institute of Offshore Oil and Gas Geology, Hangzhou Research Institute of GeologyPetroChina, Hangzhou, Zhejiang, CHINA
E-mail: sunh_hz@petrochina.com.cn

Keywords: reservoir, sequence, sedimentary, deep-water, Rakhine Basin

In recent years, gas discoveries have been made in the deep water area of the Rakhine Basin in the northeastern part of the Bay of Bengal Basin. The Pliocene deep-water sediments in this area frequently migrate and overlap, and the unconformity is particularly developed. Reasonable sequence stratigraphic analysis methods can guide the identification of favorable target formations and the interpretation of deep-water sediments. Using logging and seismic data, and the sequence stratigraphic framework was established under the guidance of a reasonable deep-water sedimentary sequence model. The sequence boundary was interpreted in the whole area, by identifying the top boundary of the condensation section and the bottom boundary of mass transport depositions. It is clear that the Upper Pliocene, the main target layer in this study area, is controlled by dual provenances in the north and northeast. The sediments from the north are distributed in a small range, which is distributed in a near-north-south direction, and mainly develops small channel-lobe complexes. The sediments from the wider distribution range and greater thickness of the sediments in the northeast, which are distributed in the northeast-southwest, and are mainly composed of large-scale channel complexes. Drilling revealed that the sediments of the northern provenance are finer in grain size, and the sediments of the eastern provenance are coarser. The eastern part of the study area has more developed reservoirs. Affected by the development of sedimentary inheritance, late sedimentation is more likely to erode the early thin hemipelagic mudstone caprock, which makes the overall preservation conditions in the eastern part relatively poor and the trap effectiveness decreases. Although the northern reservoir is small in scale, under certain structural background conditions, it is easier to form small lithologic hydrocarbon reservoir with sand lens.

IDENTIFICATION AND CONTROLLING FACTOR OF CHANNELS IN HUANGLIU FORMATION OF THE LEDONG SAG IN THE QIONGDONGNAN BASIN

quanyuan luo[1*], xiangyan jiao[1], Xiaohu he[1], lifeng wang[1], kun liu[1]
1. South China Sea Western Petroleum Research Institute , Hainan Branch of CNOOC(China) Limited, haikou, hainan, CHINA
E-mail: luoqy7@cnooc.com.cn

Keywords: the Qiongdongn basin,Huangliu Formation,channel,sedimentary model,controlling factor

The Ledong Sag is located in the western part of the Qiongdongnan Basin in the northern South China Sea. It is connected to the Lingshui Sag, the Lingnan Lower Uplift in the south, the Yinggehai Basin in the west by the F1 fault, and the Yanan Lower Uplift in the north. In recent years, the Miocene lithological traps in the Ledong Sag have become hotspots for exploration in the South China Sea. Many medium and large-scale gas fields have been discovered. The discovered gas fields are all closely related to submarine fans and gravity flow channels. For more oil and gas discoveries to increase the success rate of lithological trap exploration, it is necessary to strengthen the identification of channels and the study of control factor.

On the basis of 3D seismic data, drilled cores, wall cores, logging, FMI logging and analytical tests, the seismic facies, litho-electric facies and sedimentation of the channels are analyzed. The structure and sedimentary characteristics and their controlling factors have been comprehensively studied. The results achieved are as follows: 1)On the basis of the sequence stratigraphic framework, techniques such as heavy minerals, petrology, seismic stratigraphic interpretation, and paleo-geomorphic restoration are used to clarify the provenance and controlling factor of sediments in the channel. 2) The Huangliu Formation in the Ledong Sag developes two phases of channel, which mainly developes five types of sedimentary microfacies: main channels, overflow-natural dike, landslide mud, inter-channel and continental slope mud. 3) The formation and evolution of the two-phase channels and the direction of the main provenance are mainly controlled by sea level changes, paleomorphology and tectonic activities.4) The early channels in the Huangliu Formation are mainly developed in the Yingqiong junction, which are characterized by a large number, small scale, strong branching, and braided features. The late channels are restricted to the central canyon in the Ledong Sag, which are a characteristic of single-branch axial restricted channel and multi-stage development in the longitudinal direction.5)The physical properties of late channels are mainly medium porosity and high permeability, which are mainly distributed in deep water areas, and the reservoirs are buried in shallow depths. It is the key exploration direction in the channel field of the Huangliu Formation. The main channel is the most favorable sedimentary unit of the channel.

Hybrid event bed characteristics, distribution, and its role in high-frequency change of the Upper Triassic submarine fan succession in the West Qinling Orogen Belt, Northeastern Margin of Tibet Plateau

Mingxuan Tan[1*], Haonan Sun[1]
1. Department of Marine Geology &Geophysics, Hohai University, Nanjing, Jiangsu, CHINA
E-mail: mxtan@hhu.edu.cn

Keywords: Submarine fan, Bed type, Hybrid even bed, Mudclast, Allogenic, Autogenic

Hybrid event beds (HEBs) record the disequilibrium of the submarine fan evolution via the mud-forced dampening turbulence, which could be caused by allogenic and autogenic forcings in either proximal or distal segment of the lobe-dominant submarine fan within several timescales. Detailed field investigation (over 550 m in total) together with petrographic and mineralogical analysis of selected outcrop sandstone and mudstone samples show that the Upper Triassic submarine fan succession (mostly the Nalu Formation) is composed mainly of turbidites, HEBs, and mass-transport deposits (MTDs) in the West Qinling Orogen Belt, Northeastern Margin of Tibet Plateau. Five types of HEBs (i.e., HEB-1 to HEB-5) ranging from 0.094 m to 3.40 m are recognized based on their thicknesses, sedimentary structures, and textures. Bed by bed description and measurement (1142 beds in total) show that these HEBs are mainly distributed within various facies associations of the lobe-dominant submarine fan succession, including the dominance of HEB-1 and HEB-2 beds (~71.50%) within distributary channel to lobe off-axis settings (FA1~FA3) and the significant ratio of HEB-3 to HEB-5 beds (~54.22%) within the lobe fringe to lobe distal fringe settings (FA4~FA5). Different petrographic and shapes of mudclasts from their microscopic perspectives, particularly MC-1~MC-3 type, suggest erosional bulking and disaggregation of heterolithic, homogenous mudclasts within H1b and H3 interval of HEBs, which could play different roles in the longitudinal mud-driven flow transformation between turbulent and laminar flow behaviors. By contrast, the MC-4 type of mudclast mainly comprising non-cohesive carbonaceous materials and platy detriatal minerals has less contribution to the flow stratification. The vertical distributions of the HEB-prone succession are characterized by four types of depositional scenarios in the studied localities, which has yielded significant allogenic and autogenic information combined with the recognition of the dominant HEB types and the thickening- or thinning-upward trend of vertically stacked submarine lobes according to the process-based sedimentological interpretation. The study has enhanced our understandings of the HEBs distribution of the submarine fan succession in the east margin of Palaeo-Tethys Ocean based on most undiscovered deep-water outcrops, particularly in the Upper Triassic Nalu Formation, and it also shows that the development of HEBs contribute to the initiation, gradual switching, and avulsion of the high-frequency submarine fan evolution due to the alternation between disequilibrium and equilibrium.

A turbidite sedimentation is discontinuous due to autogenic flow fluctuations associated with interface instability

Keywords: Turbidite, deepwater, Kelvin-Helmholtz waves, flow fluctuation, CFD simulation

Turbidite systems are responsible for transporting a significant amount of sediments into deepwater basins and preserving important environmental and sedimentological signals from the shallow water areas. The deposition of turbidite is generally thought to occur during the waning stage of a turbidity current as the flow energy gradually decreases and sediment accretion increases. With a high-resolution CFD (computational fluid dynamics) method and grain-size data from the field, we simulated a natural scale turbidity current releasing from a relatively steep slope to a flat basin. Our results show that the flow accelerated along the steep slope with little deposition but quickly shifted to depositional mode once it arrived at the flat plain. As the flow adjusted itself along the slope, the turbidity current developed Kelvin-Helmholtz (KH) waves between its upper flow boundary and the ambient fluid, with a wavelength of 15 m to 50 m and amplitude of 5–10 m. The KH waves had a direct impact on the sediment concentration and flow velocity profile, effectively causing the flow to fluctuate between supercritical and subcritical status. Consequently, the sedimentary processes within the flow also alternated among deposition, bypassing and erosion. During the simulation, the flow only used 26 % to 33 % of its total running time on depositing sediments and had a similar amount of time for erosion. In the remaining time, the flow was mostly bypassing the observational area. Contrasting to the traditional view that a turbidite is the result of a continuous depositional process forming characteristic Bouma sequences, our study suggests that the flow power and associated sediment transportation in a turbidity current are inherently fluctuating and alternating due to the autogenic KH instability. Our study has important implications for understanding the depositional processes of turbidite sedimentations and interpreting various information contained within such deepwater deposits.

Sedimentary characteristics and genetic significance of Late Triassic deep-water fine-grained gravity flow in Dayugou area, West Qinling

1*

1. , , , , CHINA
E-mail: 211311040017@hhu.edu.cn

Keywords: Density current,Fine turbidity current,Sedimentary characteristics, Genetic mechanism

Deep water fine-grained gravity flow deposition has important paleoenvironment and paleoclimate indicators, but the deposition process is more complex than coarse-grained sediment gravity flow. The detailed outcrop anatomy shows that the Upper Triassic Kache Formation in the Dayugou area of the West Qinling was deposited by slope fan and and hemipelagic deposition, and the fine-grained sediment gravity flow deposits (fine-grained hyperpycanal flow, hypopycnal flow and fine-grained turbidite) are widely developed. Among them, the fine-grained densified current deposits are mainly siltstone and argillaceous siltstone with suspended load (individual stage sediment thickness is 0.05-0.60 m). The normal flowing water ripple and transitional argillaceous ripple appear alternately vertically, showing overlapping characteristics of multi stage positive rhythm and composite rhythm. The lithologic combination of the hypopycnal flow deposits is characterized by thin interbedings of centimeter-scale sand and mud, which can be roughly divided into two types (Mutti, 2019). The sediment of hypopycnal flow I develop incomplete sand current ripples and the sedimentof hypopycnal flow II contain deformation and development of soft sediments. Fine-grained turbidites are also developed in the stratigraphy (thickness of individual stage is 0.05-0.2 m), which is characterized by Ta-Tb or Ta-Tc of Bauma sequence as a whole. Bi-directional cross bedding (lenticular bedding and herringbone cross-Bedding) developed in the target strata in the study area, indicating that the fine-grained turbidite may be affected by internal waves and tides. The paleocurrent analysis shows that the study area may be transformed by the underflow perpendicular to the continental slope at the same time, which further complicates the deep-water sedimentary process. Around Carnian period of Late Triassic, multi-stage heavy rainfall provided favorable climatic conditions for the formation of hyperpycanal flow in Qinling residual ocean basin. However, the extensive development of fine-grained sediment gravity flow deposition shows that the supply capacity of river sediments in its source area is relatively low, which provides an opportunity for deep-water underflow reconstruction in the eastern margin of the paleoTethys ocean in the Late Triassic.

Identification and Geological Significance of Shallow Sea Gravity Flow Sedimentary Microfacies of Dongfang A Area in Yinggehai Basin, Northwest South China Sea

Jinlai Huan[1,2*], Yu Wang[2], Zhi Qi[2], Yongnian Gan[2]
1. Department of Earth Sciences, Northeast Petroleum University, Daqing, Heilongjiang, CHINA
2. Nanhai West Petroleum Research Institute, CNOOC China Limited, Hainan Branch, Zhanjiang, Guangdong, CHINA
E-mail: huanjl@cnooc.com.cn

Keywords: shallow sea gravity flow, sedimentary microfacies, lithofacies, logging facies, seismic facies, depositional model

In recent years, more and more submarine fan reservoirs have been discovered, and the research scope of submarine fan is increasingly broad, but there is no unified conclusion on the division of sedimentary microfacies of submarine fan in the academic circle. In 2011, Cummings et al. studied the Bacchus Basin in northern Spain and divided the sedimentary microfacies into main channel, branch channel, composite lobes and composite lobes edge. In 2012, Li Shengli et al. studied the Zhujiang Formation in Liwan 3-1 area, Baiyun Sag, and divided a complete deep-water fan into four subfacies, mainly composed of gravity flow channel, natural dike and slump body deposits. In 2016, Picot et al. studied the Congo fan in late Quaternary and made it clear that large submarine fan was mainly composed of multiple sub-submarine fan lobes and main channels. The characteristics of sedimentary reservoirs of Dongfang A area in Yinggehai Basin, northwest South China Sea have undergone multiple rounds of studies, including exploration, evaluation, and reserves. Currently, the reservoirs within the gas field are believed to be of shallow sea gravity flow deposits origin. There is still a lot of controversy in the understanding of the composition and characteristics of the sedimentary microfacies, which greatly restricts the research accuracy of the sand body distribution law and the heterogeneity within the reservoir, and affects the process of gas field exploration and development.

Through in-depth and systematic analysis of the comprehensive characteristics of lithofacies, logging facies and seismic facies of Dongfang A area, a division scheme of the sedimentary microfacies of shallow sea gravity flow deposits suitable for area A is established upon the known classifications of submarine fan depositional systems both domestic and abroad in addition to the geological background of the target area.Various sedimentary microfacies such as erosion channel, channel side edge, distributary channel and lobes are identified. Based on the above researches, the author proposed an identification plate for sedimentary microfacies of shallow sea gravity flow deposits. The sedimentary microfacies were finely characterized and the plane distribution of sedimentary microfacies was recognized under the control of shallow sea gravity flow deposits model. The second gas formation is controlled by the erosion - filling- overflow sedimentary model of the restricted gravity flow in pre formed depression, and mainly develops sedimentary microfacies such as erosion channel, erosion channel side edge, distributary channel and lobes. The first gas formation is controlled by the unrestricted overflow sedimentary model in gentle slope, and develops sedimentary microfacies such as distributary channel and channelized lobes. This identification method can be widely used in reservoir evaluation, prediction and fine characterization of the similar oil and gas fields to guide the exploration and development.

Keywords: Density-current deposits, Sedimentary sorting processes, Geochemical variations, Southern Mariana Trench

Sediments in the Mariana Trench provide an excellent opportunity to characterize sedimentary processes and their role in determining geographic and stratigraphic variations in the geochemical composition of subducted sediments. Sediments analysed for this study are from the southern slope of the Challenger Deep in the southern Mariana Trench, and were retrieved using box samplers during the 2016TS01 Expedition aboard R/V Tan Suo Yi Hao, led by the Institute of Deep-Sea Science and Engineering, Chinese Academy of Sciences. The box cores were subsampled using a push core with a diameter of 10 cm and a length of 70 cm. Each core consists of ~60 cm of sediment from below the sediment-water interface. Analytical results show that sediments in the cores mainly comprise diatom fragments (e.g., Ethmodiscus rex), clay and silt-grade minerals (e.g., plagioclase, serpentine and volcanic glass). According to grain-size variation, particle composition and sedimentary structures, a number of depositional units can be identified in the cores. Each of the depositional units consist of a lower interval that is coarser-grained and bioclast-rich, and an upper interval that is finer-grained and relatively clay-rich. Within a depositional unit, alternation of structureless and laminated intervals, and subtle grain-size and compositional changes are best interpreted to reflect pulsed variations in current flow velocity and sediment flux, rather than being the products of separate flow events. The combination of overall mud-rich grain size, a lower laminated division with nested graded intervals, and an upper graded, but otherwise structureless division, within each depositional unit resembles the structure of mud densite. Consequently, the depositional units are interpreted to be the products of mud sediment density flows. They are not deep-sea oozes deposited from pelagic settling, which are not characterized by either current-formed laminations or grain-size sorting. The depositional units, which were defined from variations from mineral composition and grain-size, help explain geochemical data. For example. bioclast-rich samples in laminated intervals are typically marked by higher SiO_2 but lower Al_2O_3, MgO, TiO_2 and ΣREE contents compared to those of clay-rich sediments in graded intervals. Particularly, ΣREE contents systematically increase upwards within depositional units, which is clearly caused by sedimentary sorting during density-current deposition that readily disperses finer, clay-rich components to deep water depths in the trench. Overall, along a trench, therefore, what is subducted depends on the proportion of resedimented versus pelagic sediments. A sedimentary pile dominated by clays would have a different geochemical signature to those dominated by diatoms and radiolarians, with the clay component being either arc-derived or of pelagic origin with secondary growth of Fe-Mn minerals. We suggest that sorting process, and thereby a geographic and stratigraphic variation in sedimentary components during transporting to the trench, can further complicate the geochemical composition of subducted sediments, as well as of arc magmas related to sediment-derived components.

Keywords: turbidity current, numerical modeling, bedforms, deep-water, cyclic step

Seafloor topography is known to have a major influence on deep-water gravity flows by affecting their flow behavior and depositional style. Previous investigations suggest that normal faults can control the hydraulic status of a turbidity current and form characteristic bedforms. However, how a normal fault triggers the flow transition and how such a transition controls the bedforms formation remain poorly quantified. In this study, advanced computational fluids dynamics numerical simulations are used to investigate the behavior of turbidity currents when flowing across the escarpment generated by a normal fault. We systematically assess how variations of fault dip angles, fault displacements, and initial flow velocities control the hydraulics of turbidity currents and associated depositional processes. Results show that the normal fault topography exerts a fundamental control on the flow hydraulic behavior by accelerating the flow. The influences of the initial flow velocity and sediment concentration on a turbidity current are generally secondary but also affect the bedform formation by changing the erosion and depositional styles. Such a complex control mechanism may explain the synchronous existence of antidunes and cyclic steps observed in deep-water fans. This research bears important implications in predicting turbidity current hydraulics and resulting deposits in tectonically active basins where the normal faults reach the seafloor.

Keywords: turbidity current, numerical modeling, deep-water, fold and thrust belt

Deep-water fold and thrust belts are generally composed of networks of folds that have a major influence on the pathways and deposition of turbidite systems. However, the detailed hydraulic responses and associated depositional patterns of a turbidity current within such fold networks, particularly segmented fold topography have not been well understood. This study combines structural modelling of fault-related folds and computational fluid dynamic simulations of turbidity currents, to reveal the hydraulic and sedimentological behaviours of an unconfined turbidity current interacting with two en echelon fold segments. A natural scale turbidity current is released upslope of a variety of two-segment-fold scenarios, in which the strike of the structures is orthogonal to the dip direction of the slope and the front of the flow. The results show that the lateral growth and linkage of individual fold segments, as well as the separation and overlap distance of fold segments strongly influence the style of turbidite sedimentation. For two unlinked folds, the turbidity current flows across the overlapping area of the folds while also diverting sideways along the upslope fold limbs. In contrast, where the two-fold segments are structurally linked to form an elevated overlapping zone, the main body of the turbidity current is diverted around the folds to spread downslope. The separation distance between the two folds has a critical influence on the amount of flow diverted sideways. The overlapping distance of the fold segments determines the relative thickness of sediment accumulated in the front of the downslope fold limbs. The results of the study have implications for turbiditic slope-fan models and the prediction of sand distribution in deep-water fold and thrust belts.

A new insight into the genetic mechanism of the Miocene sediment mounds in the Qiongdongnan Basin, northern South China Sea

Litao Xu[1*]
1. School of Earth Resources, China University of Geosciences, Wuhan, Hubei, CHINA
E-mail: 1521352413@qq.com

Keywords: Qiongdongnan basin, Meishan Formation, Mounds, Gravitational gliding, Detachment faults, Genetic mechanism

The mounded stratigraphy at the top of the Miocene Meishan Formation (Fm.) in the southern slope zone of Qiongdongnan Basin attracted extensive attention. The mounds were interpreted to result from various controversial geneses such as reefs, contourite mounds, sediment waves, and incised canyons. In this study, the newly collected seismic data were used to characterize the mounds, and a relatively reasonable genetic mechanism was proposed. The seismic profiles revealed that the mounds alternated with “V”-shaped troughs, forming a mounded topography at the top of the Meishan Fm., which showed regular sinusoidal fluctuations in the cross-sections. The lateral distribution of the mounds and troughs is characterized by the alternating distribution of E-W trending narrow ridges and gullies. The current mainstream interpretations of the origin of the mounds in this area can be divided into two categories: reefs and channel erosion. However, the latest drilling revealed that the mounds were mainly composed of bathyal mudstones instead of reefs. On the other hand, it is doubtful whether the seafloor could be sculptured by erosion to form a mounded topography that showed regular sinusoidal fluctuations. Many previous studies show that the formation of topographic relief in deep water probably originated from one kind of soft-sediment deformation caused by slope instability, which provides enlightenment for this study. The analysis of tectonic evolution showed that the southern slope became steeper abruptly resulting from accelerated subsidence since the late period of the Meishan Fm. deposition (10.5Ma). Meanwhile, frequent earthquakes induced by the re-activated faulting and intense magmatism caused strong vibration. These factors were highly likely to cause slope instability and gravitational gliding. In this case, the unconsolidated plastic layer near the sea-bed slipped along a detachment surface the detachment surface presents as a strong reflecting surface on seismic sections, which drove the formation of a series of small N-dipping listric detachment faults above the detachment surface. The plastic layer was cut into multiple tilted fault blocks. Since then, the troughs between fault blocks controlled the distribution of the submarine channels and were finally filled by sandstones and bathyal mudstones. The erosion capacity of the submarine channels was limited, otherwise, most of the mounds in the whole area would be likely to be destroyed beyond recognition. The fault blocks and the infillings in troughs were eventually compacted to form a typical phenomenon of regular topographic relief. The genetic model of the mounds proposed here is novel and can provide a reference for the interpretation of similar phenomena in other regions.

Sedimentation across structurally complex deep-water slopes: Neogene to Recent stratigraphic evolution of the Hikurangi subduction margin, New Zealand

Keywords: Deep-water, slope, seismic, subduction, turbidite

Deep-water sedimentation on active margins involves complex sediment pathways through interaction with structures. Descriptions of sediment distribution in such settings are often and necessarily simplified into models, such as‘fill and spill’or‘tortuous corridors’. Understanding the distribution of sediment across slopes has implications for resource exploration, understanding geohazard likelihood, and predicting the potential fate of pollutants in the deep-sea. Here we document Neogene to recent sedimentation patterns of the Hikurangi subduction margin, offshore eastern New Zealand to characterise depositional systems across a deep-water fold-and-thrust belt.

A series of thrust-bound structures bound intra-slope basins, each tens of kilometres long by kilometres wide, have been diachronously forming, filling, and deforming over the past 25 Ma. In the offshore, actively building portion of the subduction wedge bathymetric, 2D and 3D seismic, and well data analysis constrain large scale sedimentation patterns. 15,344 km^2 of 3D seismic across this margin allow structural and reflector sequence interpretation, with mapping of sedimentary systems describing the evolving sediment-structure interaction. Deep-marine sediments include (hemi-) pelagites, turbidites, mass-transport deposits (MTDs) and contourites. Five sedimentary systems delivered sediment across nine slope basins, with channels variably running axially and transverse to the slope along their profile. The run-out lengths of the channels vary spatially and temporally. Coarse grained sediment was captured across a range of slope accommodation zones, whose fill varies along strike of individual depocentres. At times sediment was trapped in upper-slope basins, but at other times was ducted to base-of-slope basins or even bypassed the slope entirely. Cannibalisation of previously filled basins via mass wasting is common. Variably-active sediment inputs, bypass conditions and structure development resulted in the development of complex depositional systems, often with similar styles of sedimentation occurring contemporaneously in proximal and distal basins, contrary to simple fill and spill models.

Fundamentally, sediment supply and distribution is governed by external controls, e.g., tectonic evolution of the margin, sediment flux, and climate. However, at basin scale local forcing such as growth of bounding structures, emplacement of MTDs, or breach of structures by sediment conduits dictates sedimentary system style. At the smallest scale, autogenic regulation of the sedimentary system, e.g., flow stripping at sills and channel avulsions contribute to the spatiotemporal variation in sediment distribution. Constraining the interaction of this hierarchy of controls helps determine if basins were filling, spilling or a combination of these end members at any point in their evolution.

Characteristics of deep-water gravity-flow deposits under the background of salt tectonic activities: A case study of the Miocene in block A, Lower Congo-Congo Fan Basin

HUA CHEN[1*]
1. Department of Middle East, Research Institute of Petroleum Exploration and Development, PetroChina, Beijing, CHINA
E-mail: chenhua0630@163.com

Keywords: salt structures, gravity flow deposition, interactions, Miocene, Lower Congo-Congo Fan basin

The Lower Congo-Congo Fan Basin is a typical saline passive continental margin basin located on the east coast of the South Atlantic Ocean. Its complex salt tectonic activities have an important impact on the spatial distribution of the slope channel-lobe system, which controls the hydrocarbon accumulations. Understanding the relationship between salt structures and deep-water gravity-flow deposition is the key to making breakthroughs in deep-water petroleum exploration in the study area, and has important research significance. Based on the seismic - logging curves interpretation and seismic attribute analysis, the process and characteristics of gravity-flow deposition under the background of salt tectonic activity of the Miocene in block A of the Lower Congo-Congo fan basin are revealed. The results show that the deposition center and sand-rich position during the early filling-overflow stage and the late passing-erosion stage in the minibasins are different. The angle between gravity flow direction and axial direction of minibasin is inversely proportional to the size of lobe in the minibasin. The interaction relationships between salt structures and channels include seven types: redirection, restriction, blocking, migration, erosion, uplift and truncation. When the salt tectonics activity is weak and the capacity of provenance supply is strong, the sediments tend to be transported to a distant place to form lobes; otherwise, most of the sediments are blocked by salt tectonics and develop lobes.

Turbidite system dominated by normal faults growth and linkage on a slope belt of rift basin: Bonan Sag, Bohai Bay Basin, China

Rongheng Tian[1], Benzhong Xian[1,2*], Qianran Wu[1], Wenmiao Zhang[1], Baizhi Yang[1]
1. College of Geosciences, China University of Petroleum, Beijing, CHINA
2. State Key Laboratory of Petroleum Resources and Prospecting, China University of Petroleum, Beijing, CHINA
E-mail: xianbzh@cup.edu.cn

Keywords: Fault linkage and growth, Turbidite system, Paleo-geomorphology restoration, Lacustrine rift basin, Bohai bay basin

The complex fault system has great influence on the deposition pathways and filling process of sediment in the slope belt of rift basin. We use 3D seismic data and drilling cores to study the influence of faults growth and linkage on turbidity current flow process and dispersal pattern in the kenxi gentle slope belt in the south of Bonan Subsag, Bohai Bay Basin. Two typical palaeo-geomorphologys of the fault growth process were identified, including fault-terraced type and slope type, and 5 faults linkage styles controlling the direction of turbidity current. 13 lithofacies , including two pebbly sandstone facies, 9 sandstone facies and one mudstone facies are identified, which were interpreted as turbidity current deposition. According to the degree of erosion and deposition, and the types of lithofacies associations, it can be divided into 6 deep-water depositional artchitecture units: erosional channel, transitional channel, depsitional channel, channelized lobe, depositional lobe and sheet-like sandbody. Two types of turbidity flow process under the control of fault activity were elucidated, including weakly confined gentle slope type flow process and confined fault-terraced type flow process. In addition, five types of sediment dispersal patterns under the control of faults linkage were established. Tectonic movements are considered to be the major factor controlling the generation and deposition of turbidity current in slope belt of rift basin. Fault activity controls the confinement degree of palaeo-geomorphology, and then affects the difference of flow types and depositional artchitecture units. Channel-lobe system is more likely to develop in weakly confined palaeo-geomorphology formed by weak tectonic activity, and channel system is more likely to develop in confined palaeo-geomorphology by strong tectonic activity. For another, the faults linkage types will lead to the diversity of turbidity dispersal patterns, turbidity current dispersal patterns of the complex slope belts of the faults system are controlled by the geometric characteristics and the evolution degree of the relay rampes.

Sedimentary evolution of the transitional sequence of the 5th Member of Zhujiang Formation in Baiyun deep-water area, Pearl River Mouth Basin

Penglin Song[1*]

1. East South China Sea Petroleum Research Institute, CNOOC, Shenzhen, Guangdong, CHINA

E-mail: spl_alan@163.com

Keywords: the shelf slope break belt,gravity flow sedimentary system,system tract,sequence

The 5th Member of Zhujiang Formation (23.03Ma to 21Ma) is one of the main target strata in Baiyun deep-water area of Pearl River Mouth Basin, but the origin and evolution model of its sand bodies are not clear. As a result, in this study we make a comprehensive analysis of the dynamic coupling relationship during the period of 23.03 Ma to 21 Ma, between the shelf slope break belt and gravity flow sedimentary system. Seismic and drilling data from Baiyun sag and Liwan sag are used, as well as published papers on the tectonic evolution of the Pearl River Mouth Basin and the slope break belt. Results show that the transitional sequence of the 5th Member of Zhujiang Formation in Baiyun deep-water area is characterized by forced regressive systems tract, and the transition of the shelf slope break zone during this period controlled the development of the gravity flow depositional system. A sequence evolution model was built for the 5th-4th member of Zhujiang Formation in Baiyun sag and Liwan Sag which suggests the formation mechanisms of LW13-3 sand bodies and BY5-3 sand bodies. Generally, this evolution model may help determine favorable natural gas targets in the 5th member of Zhujiang Formation in this area, guiding future exploration and exploitation activities.

New insight of sedimentary facies of Miocene to Pliocene Agbada Formation , offshore Niger Delta Basin

YUFANG XIAO[1], HONGLIANG WANG[1*]
1. SCHOOL OF ENERGY RESOURCES, CHINA UNIVERSITY OF GEOSCIENCES, BEIJING, CHINA
E-mail: whliang@cugb.edu.cn

Keywords: Gravity flow, Sedimentary facies, Agbada Formation, Offshore, Niger Delta Basin

OML 123 block is located in the shallow water (2m-45m water depth) of the south-eastern Niger Delta Basin. The Agbada Formation is the main oil productive reservoir in the study area. Predecessors did a lot of research on sedimentary facies and believed that the area belongs to deltaic facies. This paper, based on comprehensive analysis of rock core, well-logging and seismic data, suggested that the Agbada Formation in the study area developed not only deltaic facies , but also gravity-flow deposits. Sedimentary background analysis proved that the study area has the basic conditions for forming gravity flow deposit. A large number of sediments generated under strong hydrodynamic conditions, such as pebbly sandstones and massive sandstones, were observed through the examination of nearly 800m of conventional core. Furthermore, some sedimentary features that would only formed in the case of gravity flow were identified, such as deformation structure, convolute bedding, sluicing structure, Bouma sequence, and the graded bedding, which is the best representative of gravity flow. Alternatively, the detailed well-logging analysis recognised GR logging shapes associated with gravity-flow depositional facies. In wireline logs, gravity flow sand bodies exhibited cylindrical, coarsening-up, fining-up, and serrated motifs. Moreover, seismic facies showed both sheet-like and mounded external forms (geometries), and parallel/continuous as well as chaotic/hummocky internal reflections. Furthermore, well profile analysis determined the distribution of gravity flow in lowstand systems tracts of sequences, and the delta-gravity flow deposition model suitable for Agbada Formation in the study area was established. The discovery of gravity flow may be of great significance for further lithologic exploration.

Genesis of gravity flow channel in Ledong area, Yinggehai Basin, South China Sea

Qiyang Zhang[1], Hua Wang[1*], Si Chen[1]
1. School of Earth Resources, China University of Geosciences(Wuhan), Wuhan, Hubei, CHINA
E-mail: wanghua@cug.edu.cn

Keywords: Gravity flow channel,Yinggehai Basin, Ledong area,sedimentary characteristics,genetic analysis

The Huangliu Formation (11.6Ma5.7 Ma) in the Yinggehai Basin develops large-scale gravity flow channels(reach to 140 Km in length) in the Yingdong slope belt , which is the key target of oil and gas exploration. This study comprehensively analyzes the sedimentary characteristics and control factors of the gravity flow channel in the Ledong district using 3D seismic, cores, drilling, and logging data. The gravity flow channel is mainly developed in the lowstand system tract of the second member of the Huangliu Formation. The typical gravity flow sedimentary characteristics include deformation structure and scouring surface identified from the core; The particle size curves reveal that the sorting of sediments is poor. And the projection analysis of the C-M diagram shows the characteristics parallel to the baseline, which is in line with the transition type of high-density turbidity current to low-density turbidity current. Based on the core facies and logging facies, the gravity flow channel deposition can be divided into five depositional elements: erosional channel, main channel, secondary channel, channel edge, and marine mud. The erosional channel is marked by a high amplitude box-shape curve; the main channel is marked by a high amplitude straight box curve and high amplitude weakly toothed box; and the channel edge is dominated by finger type, micro amplitude finger type, and interbedded bell type. Based on the seismic facies and superposition model in the seismic section, the spatial and temporal analysis of gravity channel deposition is carried out. The results can be divided into three stage. In the initial stages, the furcate area shows weak amplitude and chaotic reflectors in seismic data; weak to moderate amplitude and discontinuous reflectors dominate the edom channel during development stage; the extinction stage is characterized by medium-high amplitude and continuous reflection.The gravity flow channel during the deposition of Huangliu formation in the Yinggehai basin was formed under the coupling action of five factors: the sharp decline of relative sea-level (max decline is more than 150m), the short distance from provenance, large-scale sediment supply for the delta, the inherited incised valley that provides sand transport pathway for channel infilling, and the influence of underlying fault weak zone, within which, the weak fault zone is the main controlling factor.

E-mail: zhyf@swpu.edu.cn

Keywords: Well NK-1,Gravity flow deposition, Reef-building, MJ island reef,South China Sea

MJ island reef is an atoll build on the base of volcanic eruption. The drilling of well NK-1 showed that the deposition of thick gravity flow during 25.8-25.1Ma caused the water to become shallow rapidly, which laid an important environmental foundation for the growth and development of reefs. The gravity flow deposition thickness of this section is 127.6 m, which can be divided into two sections from bottom to top. The lower section is 30.3 m thick, which is a clastic flow deposition. The rock types of gravel include dacite, basalt, tuff, coral reef block, etc; The gravels psephicity are fine, poorly sorted (10-350mm), and the content is 50-65%. Gravels are mixed and piled up, and are distributed in various forms such as horizontal, inclined and upright, Intergravels are filled with plaster and fine reef debris. The high roundness of gravel indicates that it may be transported from coastal sediments to slope sediments by gravity flow.The upper section is 84.6m thick, deposited by granular flow, and the particles type is mainly bivalve shells, a few coral reef blocks and small volcanic gravels. The particles have a certain sorting property, are stacked at medium high angles, have a certain orientation, and the upward particle size becomes coarser. The volcanic gravel is significantly thinner than that in the lower section, and is mainly distributed in the lower part of the section, and gradually disappears upward, which may be related to the decrease or disappearance of volcanic rock provenance caused by the growth of reefs in the provenance area. The water above the gravity flow deposition in this section became shallower, and the reef began to be builded, eventually forming the atoll landform of MJ island.

How do old submarine landslides influence future mass failure processes?

Nan Wu[1*]
1. School of Ocean and Earth Science, Tongji University , Shanghai, CHINA
E-mail: nanwu@tongji.edu.cn

Keywords: Submarine landslides, Exmouth Plateau, Geohazard prevention

Submarine landslides represent a potential geohazard as they can generate tsunamis, and damage subsea cables and coastline infrastructure. Previous studies have revealed that old landslides can modify and affect the morphology and routing directions of subsequent turbidite systems. However, the role of submarine landslides in dictating where and why subsequent landslides deposition will occur is still an important problem to address. This work aims to reveal how old landslides influence the younger landslides by interpreting five landslides in Exmouth Plateau, NW Australia. We indicate that the location, nature, geometry, and hazard potential of future mass failure events are profoundly affected by the presence of old buried landslides. We show that previous failures can : i) provide the lithological control for the future landslide's basal failure zone; ii) provide bathymetric constraints to the subsequent landslide; iii) switch the direction of the subsequent failure, which is key for understanding tsunami hazard; iv) and enhance the erosive ability of the future failure events. More importantly, we indicate that the thickness distribution pattern of old landslides can provide a mechanism for predicting future landslide's location and depocentre. Therefore, our study could provide a useful case study in offshore geohazard study (e.g. tsunami prediction) as our results can be used to predict future landslides transport direction, depocentre and location.

Seismic recognition of supercritical turbidity-current bedforms

Guangfa Zhong[1*]
1. State Key Laboratory of Marine Geology, Tongji University, Shanghai, CHINA
E-mail: gfz@tongji.edu.cn

Keywords: supercritical flow bedforms, turbidity currents, seismic recognition, antidunes, chutes-and-pools, cyclic steps

Compared with open channel flow, turbidity current is more easily transformed into supercritical flow due to its lower reduced density. Submarine investigations have shown that upslope-migrating sediment waves and/or supercritical-flow bottoms are ubiquitous in modern turbidity-current environments, including shallow delta front slopes, submarine canyons and channels, levee backslopes, channel-lobe transition zones, fan lobes, and even abyssal plains. Recognized supercritical turbidity-current bedforms include antidunes, chutes-and-pools, and cyclic steps. Most of these bedforms are identified by their morphological characteristics revealed by bathymetric measurements, together with seismic profiles and bottom samples. Nevertheless, the relevant seismic evidence has not increased much, aside from the well-known upslope/upstream migration, backsets, and undulations with backsets and/or foresets. It remains unclear how to distinguish various supercritical-flow bedforms by seismic data. On the other hand, recent discoveries in flume experiments and numerical simulations have greatly improved our understanding of the formation and evolution of various supercritical-flow bedforms. Here we attempt to combine these findings with the practice of seismic identification of various types of supercritical-flow bedforms. Our seismic recognition and interpretation are largely built on the analysis of external morphology and internal architecture of different bedforms.

Morphological analysis reveals the size (wavelength and wave height), aspect ratio (wavelength to wave height ratio), symmetry (symmetrical, upslope asymmetrical, and downslope asymmetrical), and upslope migration of the waveforms. In general, antidunes present symmetrical to weakly asymmetrical sinusoidal streamwise profiles, with relatively small wavelength and aspect ratio, while cyclic steps are mostly upslope or downslope asymmetrical, with large wavelength and aspect ratio. All supercritical-flow bedforms migrate upslope.

The analysis of internal architecture reflects the types and characteristics of stratification observed in seismic profiles. Four general types of seismic-based beddings are defined, which are undulations with backsets and foresets, planar upslope-dipping backsets, concave-upward backsets, concave- to convex-upward backsets, and alternating concave- and convex-upward backsets, respectively. The first type of seismic beddings can correspond to antidunes or fully depositional cyclic steps depending on their symmetry; the second and third types may reflect the partially depositional to partially erosional cyclic steps, or fully depositional cyclic steps with different degrees of late erosion at their downstream end, and the last one may represent antidunes superimposed on the chutes-and-pools bedforms.

This work was funded by the National Natural Science Foundation of China (grants 41876049 and 41676029).

Calciclastic and siliciclastic gravity flow deposits in a tectonically active setting, West Qinling, central China

Pan Li[1*], Ben Kneller[2], Victoria Valdez Buso[2]
1. Research Institute of Petroleum Exploration and Development, PetroChina, Beijing, CHINA
2. School of Geosciences, University of Aberdeen, Aberdeen, Scotland, UNITED KINGDOM
E-mail: lipanccc@126.com

Keywords: turbidity current, debris flow, gravity flow transformation, hydrocarbon exploration

Siliciclastic gravity flow deposits have been well documented in outcrop, in the subsurface, and from modern systems. In contrast, mixed siliciclastic and calciclastic (carbonate) gravity flows deposits have been relatively understudied. Here, we report such an outcropping system from the Lower Triassic of the northern West Qinling (Qinghai province, central China) - an active continental margin during that period, with a focus on deep-water carbonate breccia-rich beds and associated deposits. Based on grain size, fabric, bed thickness and vertical sequence, two basic types of breccia-rich beds are recognized in the study area. Type I beds are characterized by very large (pebble to boulder size), subangular to subrounded carbonate (ooid grainstones/packstones), igneous and intraformational rip-up clasts that are disorganized, matrix-supported or clast-supported. Type I beds form the thickest beds (3 to 15 m) in the area, one of which shows an irregular, sharp top surface with protruding megaclasts and ponding sediments. In contrast, Type II beds comprise two-layer units, with the lower division resembling type I beds except for overall finer-grained (sand to cobble) clasts and thinner bed thickness (typically <3 m), and the upper division showing Bouma-like (Ta-Te) sequences. The boundary between the lower and upper parts of type II beds is typically gradational.

The above characteristics suggest that a type I bed was deposited by a subaqueous debris flow alone, whereas a type II bed was deposited by a subaqueous debris flow (the lower debrite division) and a co-genetic turbidity current (the upper turbidite division) due to transformation of debris flow during a single flow event. The thicker and coarser-grained type I beds (debrites) lack linked turbidites at the outcrop, probably due to limited mixing of these larger debris flows with ambient waters or more likely bypassing of co-genetic turbidity currents down-slope. Transport of large lithoclasts of ooid grainstones/packstones and other non-carbonate clasts/blocks, and a tectonically active setting with inferred significant faulting, indicate that these breccia-rich beds were probably caused by the catastrophic collapse of a shallow-water clastic shelf and carbonate platform margin due to fault-related earthquakes. Taken together, the investigated calciclastic and siliciclastic gravity flow deposits suggest a down-slope flow transformation trend from slumps/slides to debris flow and then to turbidity currents, as suggested from other siliciclastic systems. From a hydrocarbon exploration perspective, type II breccia-rich beds themselves tend to show a higher reservoir potential (especially at its upper turbidite division) than type I breccia-rich beds. However, the presence of the latter might suggest significant volumes of reservoir sands bypassed downstream by co-genetic turbidity currents.

Ponded turbidites: field and textural expression of flow ponding processes of mud-rich turbidity currents (Szczawa, Oligocene, Polish Outer Carpathians)

Piotr Siwek[1*], Anna Waśkowska[1], Marek Wendorff[1]
1. Faculty of Geology, Geophysics and Environmental Protection, AGH University of Science and Technology, Kraków, Lesser Poland, POLAND
E-mail: psiwek@agh.edu.pl

Keywords: ponded turbidites, ponded flow evolution, banded sandstone, combined-flow bedforms, normal grading, mineralogical sorting

Sedimentary succession at Szczawa, Fore-Magura Tectonic Unit of the Polish Outer Carpathian Orogen, is composed of deep-water turbidites. The studied section is mud-predominated, with several thick to very thick turbidite beds comprising well-developed basal laminated sandstones. The sedimentary features show widespread evidence for confinement and ponding of the depositing turbidity currents, probably in structurally-controlled intraslope mini-basin. The vertical sequence of bed-forming sedimentary structures can be interpreted according to the results of an experimental study of flow ponding conducted by Patacci *et al.* (2015). Several sequences begin with cross-laminated divisions which show paleocurrent direction opposite to the upper part of the bed. This can express the first flow reflection off a confining slope. Lower parts of sandstone beds show heterolithic light-dark (sand-sandy mud) parallel lamination and banding. This type of mud-rich tractional structures was probably formed under decelerating basal transitional mud-laden flows (*sensu* Baas *et al.*, 2009). The banded division is often followed by cleaner sandstone with well-developed combined-flow structures, e.g. hummocky cross-stratification-like structures, sigmoidal-cross lamination, biconvex ripplemarks and inclined synsedimentary folds. These structures are evidence of interactions of oscillatory and unidirectional flow components. The former is provided by the propagation of internal waves, generated at the internal concentration interface in stratified ponded suspension. At the boundary between co-genetic sandstone and mudstone, some centimetre thick silty division occurs frequently. This was deposited probably when the input flow started to decline. Graded, abnormally thick mudstone caps terminate such beds suggesting the collapse of static and presumably inflated muddy clouds after basal flow decline.

Basal sandy-to-silty divisions show normal grain-size grading typical of turbidite beds. Normal distribution grading applies to sand-sized and coarse silt grains. Different depositional intervals vary in terms of matrix content and degree of grain-size and compositional segregation at the scale of laminae. Banded divisions are composed of alternating matrix-rich and/or matrix-supported sandstones/coarse siltstones, or sandy mudstones with sand laminae. The process of mud-fractionation seems to be hindered, and mud-rich tractional structures were probably formed under transitional flows with near-base turbulence at least partly damped. In contrast to mud-rich banded divisions, combined-flow structures are composed of cleaner sandstone. This may testify to better fractionation of cohesive fraction to muddy cloud at the subsequent stage of basal flow evolution, as a consequence of an increase in flow velocity and flow turbulence. Laminae-scale compositional and grain-size sorting is best visible in siliciclastic-bioclastic sandstones. Namely, there is a tendency of these two grain populations to separate into lower siliciclastic and upper bioclastic layers. Grading in mudstone caps is associated with mineral sorting. Lower parts of mudstone divisions are enriched in quartz, feldspars and clay minerals, at the expense of carbonate micrite. This regularity can be the evidence of preferential fallout of silt-sized quartz grains and flocculated clay particles. It would also prove that the muddy suspended cloud was of density low enough to enable gravitational segregation of particles that differ in size and mineral composition.

Sediment dynamics of submarine landslides by grain-resolving simulations

Rui Zhu[1], Zhiguo He[1*]
1. Ocean Engineering, Zhejiang University Ocean college, Zhoushan, Zhejiang, CHINA
E-mail: hezhiguo@zju.edu.cn

Keywords: Granular Collapse, Runout Distance, Cohesive force

Many turbidity and debris currents are associated with large-scale submarine landslides, which are important transporting agents for oceanic sediments. We investigate the sediment dynamics of submarine landslides via grain-resolving direct numerical simulations. The landslide process is simplified as the submerged collapse of weakly polydisperse, loosely packed cohesive granular columns. The cohesive forces act to prevent the detachment of individual particles from the main body of the collapsing column, reduce its front velocity, and yield a shorter and thicker final deposit. The cohesive forces significantly reduce the amount of available potential energy released by the particles. Computational particle tracking indicates that the cohesive forces reduce the mixing of particles within the collapsing column, and it identifies the regions of origin of those particles that travel the farthest. The simulations demonstrate that cohesion promotes aggregation and the formation of aggregates. They furthermore provide complete information on the temporally and spatially evolving network of cohesive and direct contact force bonds. While the normal contact forces are primarily aligned in the vertical direction, the cohesive bonds adjust their preferred spatial orientation throughout the collapse. They result in a net macroscopic stress that counteracts deformation and slows the spreading of the advancing particle front.

RESEARCH ON SEQUENCE STRATIGRAPHIC FRAMEWORK AND SEDIMENTARY MODE OF LOWER CONGO BASIN

YUFANG XIAO[1], HONGLIANG WANG[1*]
1. SCHOOL OF ENERGY RESOURCES, CHINA UNIVERSITY OF GEOSCIENCES, BEIJING, CHINA
E-mail: whliang@cugb.edu.cn

Keywords: Lower Congo Basin,sequence stratigraphic framework, sedimentary facies mode

The Lower Congo Basin is a passive continental margin salt-bearing basin developed since the Oligocene. It has multiple sets of oil and gas systems and superior oil and gas accumulation conditions. However, there are insufficient studies on the basin-scale sequence stratigraphy and the development and evolution of gravity flow in the sequence framework. In this paper, the sequence stratigraphic framework and sedimentary facies mode of key strata in the basin were systematically studied using a large number of drilling, logging and seismic data. The research results show that 12 large-scale sequence interfaces have been identified in the target interval, including 7 sequences in the Tertiary and 4 sequences in the Cretaceous. They are named SSQ1-SSQ11 from top to bottom. The deposition of the submarine fan in the Lower Congo Basin can be divided into two stages: Oligocene-Miocene and Pliocene-present. The Oligocene-Miocene developed two deposition centers in southeast and northwest areas, with large deposition thickness; the Pliocene-present day has only one deposition center, and the stratum is relatively thin, which is located on the side of the salt boundary basin. Four types of sedimentary facies were identified, including gravity flow channels, embankments, flowering bodies, and deep-semi-deep muddy sediments. Finally, the gravity flow deposition mode of the slope-deep sea plain was established. The gravity flow deposition type is greatly influenced by the terrain slope, and the slope part is mainly developed by canyon channels. As the slope of the terrain becomes slower, restrictive waterways, weakly restricted waterways-natural embankment systems, flowering bodies and deep-semi-deep sea muddy deposits are developed in sequence.

3. College of Earth Science and Engineering, Shandong University of Science and Technology, Shandong, CHINA
E-mail: b.menzoul@doctoral.uj.edu.pl

Keywords: Numidian Formation, turbidities, deep-sea sediments, SSDS, Algeria

The Numidian Formation (upper Oligocene – lower Miocene) in the Ouarsenis Mountains (NW Algeria) is well exposed in the areas around the towns of Theniet El Haad and Ouled Ben Abdelkader; Four well-exposed sections are described in detail, including three sections and one section respectively from the mentioned areas. The Numidian Formation here consists mainly of siliciclastic turbidites and other sediment gravity flow deposits intercalated between hemipelagic mudstones. The sediments show numerous types of sedimentary structures, including a wide range of soft-sediment deformation structures (SSDS). These are not distributed in a more or less haphazard way but are related to the lithofacies of the sediments. The four sections comprise eight lithofacies (F1-F8). Lithofacies F1 (concentrated density flows) consists of massive sandstones with SSDS caused by liquefaction (load casts) and fluidization (fluid-escape structures: pillars and dish structures). Lithofacies F2 (concentrated density flows) consists of normally-graded, medium- to very coarse-grained sandstones with primary depositional structures such as parallel lamination, ripple cross-lamination, and abundant erosional structures such as gutter casts, flute casts, mud ripples, groove casts and scour structures around obstacles, and still more or less enigmatic structures such as longitudinal ridges and furrows, and frondescent marks. SSDS due to liquefaction (convolute lamination) and fluidization (fluid-escape structures) are rare. Lithofacies F3 (hyper-concentrated density flows) is represented by inversely-graded pebbly sandstones to parallel stratified sandstones with some climbing ripples, and groove casts Lithofacies F4 (low-concentration turbidity current) consists of medium- to fine-grained parallel-laminated sandstones with abundant convolute lamination and rare load casts. Lithofacies F5 (debris-flows and mudflow) occur as conglomerates with mudstone clasts and as folded sandstones; both convolute lamination and ball-and-pillow structures are fairly common. Lithofacies F6 (slumps) consist of sandstones and siltstones that were strongly deformed while still in an unlithified state; the beds show centimeter-scale convolute lamination, as well as slump folding, commonly as isolated masses within F8. Lithofacies F7 (low-concentration turbidity current with hemipelagites) consists of alternations of mudstones, siltstones, and sandstones which do not show specific structures apart from parallel lamination. The last lithofacies, F8 (autochthonous sediment), contains only marly mudstones without sedimentary structures that are visible in the field.

E-mail: qianyu.nju@gmail.com

Keywords: Gravity-driven sediment flows, High concentration layer, Sediment transport, Muddy open coast, Coastal erosion, Jiangsu coast

Wave and/or current supported gravity-driven sediment flows (GDSFs) cause substantial sediment movement across the continental shelf, contributing to morphological evolution in many regions worldwide. However, they appear to occur episodically and ephemerally and, therefore, it remains a challenge to document them in detail with *in situ* measurements. Here we present solid evidence of frequent generation of such flows over the shallow sea floor of a muddy open coast. They were triggered by wave resuspension and/or sediment settling from the overlying water column, maintained by wave- and/or current-induced bed stress, and terminated due to upward spreading of bottom sediment within the high concentration layer. Randomly selected GDSF events were analyzed to realize parameterization with a buoyancy-friction model; the resultant bed drag coefficient for two of the cases is higher than the value of 0.003, which is attributed to the additional drag at the interface between the overlying flow and the moving GDSFs. Although short-lived, the observed GDSF events in the three different seasons indicate that they occur more frequently than previously thought.

Holocene shallow-marine hybrid event beds from the East China Sea

Xin Shan[1*], Xuefa Shi[1], Lina Jin[1], Shuqing Qiao[1]
1. Department of Marine Geology, First Institute of Oceanography, Qingdao, Shandong, CHINA
E-mail: xshan@fio.org.cn

Keywords: Sediment gravity flow, Hybrid event bed, Turbidite, Debrite, Shallow-marine deposit

Many sediment gravity flow deposits that developed in deep marine settings fit into neither the typical Bouma nor the matrix-supported debrite classification schemes and instead show hybrid character (comprising both turbidite and debrite features). Our studies of shallow-marine deposits have documented the presence of such mixed flow deposits in the river-dominated deltas and wide shelves. AMS 14C dating, grain size analysis and measurements of stable isotopic composition of organic matter were conducted to delineate the depositional process of the recognized hybrid beds. The internal subdivisions of the hybrid event beds, including H1, H3a, H3b and H5 divisions, were differentiated mainly based on sedimentary textures, including cohesive mud content, sand content and sorting. The data indicate that hybrid sediment gravity flow deposits were sourced from intra-shelf failures and/or hyperpycnal flows, and subsequently transformed and deposited as hybrid event beds. The occurrence of hybrid event beds in modern shallow delta front/shelf settings is an important novelty, implying that flow transformations are perhaps widespread and not only limited to deep marine systems.

E-mail: gustavolobato@petrobras.com.br

Keywords: turbidites, sedimentation rates, repeat bathymetry, erosion rates, turbidity currents

Turbidites form some of the largest sedimentary deposits on earth. These deposits often form the final sink of a sediment routing system and hence the sedimentation rates control their long-term storage of sediments, nutrients, carbon and pollutants. Measurements of short term ($<10^3$ yrs) sedimentation rates in turbidite systems are rare, especially below 100 years due to dating limitations. Yet these short-term rates have a strong control on depositional patterns as they record high-frequency palaeo-climate changes and control the fine-scale sedimentary heterogeneities in the stratigraphic record. Here we use decadal bathymetric difference maps, cores and flow monitoring data to show how sedimentation rates vary from source to sink in two distinct modern turbidite systems (Bute Inlet and Congo Fan). We quantify the sedimentation rates in different fan regions (e.g., canyon, mid-fan, lower-fan), turbidite environments (e.g., channel, channel-lobe transition, lobes) and sub-environments (e.g., channel-axis, channel-margin, proximal-lobe). Additionally, we provide the first systematic measurements of erosion rates in turbidite systems. The results show the expected Sadler's effect (i.e., negative power-law relationship) between sedimentation rates against time span. We found sedimentation rate variability shows distinct signatures depending on the turbidite environments and sub-environments. From proximal to distal, we identified two sedimentation rate regimes that appear in the fan region, environment and sub-environment scales: (i) regressive downstream erosion, and (ii) progressive downstream erosion. These regimes correspond to a transition from regular low-magnitude events to infrequent high-magnitude events. Our results are compared with direct flow monitoring data to show changes in the process-product relationship at different timescales are related to contrasting turbidity current characteristics/frequencies. Furthermore, the use of time-lapse maps enables us to also highlight the important role of erosion rates on the dynamics of turbidite deposits, which provide an important guide to interpreting short-term turbidite depositional cycles in the rock record.

Can mica play a role in forming hybrid beds of submarine lobe systems?

Liu Qun[1*], Ben Kneller[1], VIKI VALDEZ[1], xiumian hu[1]
1. School of Environment and Science, Nanjing xiaozhuang university, Nanjing , jiangsu, CHINA
E-mail: Qunliu2019@hotmail.com

Keywords: submarine lobes, hybrid beds, flow transformation, mica

Hybrid beds deposited by transitional flows are found to be more and more common in submarine lobe systems, and various ways of promoting flow transformation have been proposed. Clay concentration, especially clay flocculation has been regarded as the main reason for the increase of flow cohesiveness, and in recent years, microbial bioforms has also been revealed to play an important role. Mica is a phyllosilicate mineral which is structurally similar to clay mineral, its widely electrostatic force at mica surface has been widely used in medical area, but seems to be overlooked in geoscience area to have played a role in promoting flow transformation. In this study, a well-exposed submarine lobe complex with hybrid beds developed at its frontal fringed which are exceptionally mica rich are introduced to discuss the possible role of mica in promoting flow transformation. The lobe complex is composed of twelve lobe elements, the first three lobe elements are aggradational stacked, preserving axis to the frontal fringe deposits; the rest eight lobe elements are compensational stacked, preserving axis to lateral fringe deposits. Only frontal fringe of the first three lobe elements are hybrid beds prevalent, occupying 80% of the interval. Mineralogy and grain size analysis have been undertaken to compare the mineralogical difference between the axis to lateral turbidite beds and frontal fringe hybrid beds. The results show that the samples are all composed of quartz, mica and feldspar, and frontal fringe contains three times as much mica than the lateral fringe, with an average of 60%. Mica in the hybrid beds range from silt to medium sand in size and the um scale biotite and muscovite flocculate to form flocs, which are common in hybrid beds. The clay mineral and organic matter is very little in the sampled beds and clay mineral flocculation is hardly detected. This study reveals that mica may play an important role in the flow transformation process.

Effect of submarine sediment landslides on the redistribution of manganese nodules

Wang Haiyu[1], He Zhiguo[1*]
1. Ocean College, Zhejiang University, Zhoushan, Zhejiang, CHINA
E-mail: hezhiguo@zju.edu.cn

Keywords: Manganese nodules,three-dimensional DNS-DEM coupling,Lagrangian particle tracking model,The cohesive forces

Manganese nodules, also known as polymetallic nodules, are widely distributed in the deep-sea plains of the global oceans and are a potential source of key metals such as copper, nickel and cobalt. The nodule distribution has both spatial aggregation and heterogeneity, which may be related to the inundation and collapse process of the surrounding sediments.In this study, sediments are abstracted as weakly polydispersed and loosely packed viscous particle cones. Through a three-dimensional DNS-DEM coupling model based on immersion boundary method and considering cohesion, the effects of cone shape, particle size and cohesion on the flooding and collapse process of accumulated sediments in stratified environment are studied, and the dynamic characteristics of sediment flooding and collapse are analyzed. The movement model of manganese nodule particles under the condition of sediment landslide is constructed by using Lagrangian particle tracking model.The simulation results show that the larger the slope is, the longer the transport distance of sediment particles is, the more manganese nodules are covered; the smaller the particle size is, the more uniform the distribution is, which leads to the cover of manganese nodules; cohesion significantly reduces the available potential energy released by particles, promotes the formation of aggregates and aggregates, slows the diffusion of advancing particles, and reduces the farthest movement distance of particles, which often leads to manganese nodules being covered.

E-mail: ypeng@cup.edu.cn

Keywords: Paleovalley, low-accommodation foreland basin, meandering channel-belt deposit, delta, tidal channel and bar, strandplain/shoreface

The McMurray Formation and Wabiskaw Member in Alberta, Canada record a paleovalley system developed under the influence of a continental-scale river that longitudinally transported and debouched sediment into the southward-transgressing Boreal Sea in the distal, low-accommodation Western Canada Foreland Basin (WCFB). In this study, we present a high-resolution stratigraphic framework for the paleovalley fill in the McMurray-Wabiskaw interval, which was deposited during a long-term transgression. Using wireline logs from >20,000 wells and more than 500 cores, regional mapping focused on resolving stratigraphic relationships and the distribution of depositional environments across approximately 60,000 km^2 in the Athabasca Oil Sands Region of northeastern Alberta. The studied stratigraphic interval is part of a third-order sequence: the McMurray Formation developed during a period of relative sea-level fall, lowstand, and early transgression, while the overlying Wabiskaw Member was deposited during late transgression. Within the McMurray Formation, superimposed fourth-order sea-level fluctuations in this low accommodation setting created a complex amalgam of deltaic strata vertically and laterally juxtaposed with valley-fill deposits. Relative sea-level rises resulted in rapid transgressions in which the shorelines migrated >400 km landward. Thin (5-15 m thick), widespread deltaic parasequence sets were deposited during subsequent sea-level highstands. During relative sea-level falls, fluvial meandering channel belts developed in downcutting paleovalleys, with associated shorelines dramatically prograding basinward. In the Wabiskaw Member, continued sea-level rise coupled with potentially decreasing sediment supply resulted in the development of tide-influenced/dominated channels and bars in estuaries. The final phase of the third-order transgression was marked by a regional transgressive ravinement event and several southwestward backstepping wave-dominated shorefaces/strandplains. This paleovalley fill in the low-accommodation foreland basin demonstrates a transition from deposition in continental fluvial and marginal-marine settings subject to high-frequency eustatic changes, to open-marine conditions over a long-term transgression.

Morphology of river channels and surface runoff of the northern Campania Plain (Italy) during LGM

Daniela Ruberti[1*], Carla Buffardi[1], Marco Sacchi[2], Marco Vigliotti[1]
1. Department of Engineering, University of Campania "L. Vanvitelli", Aversa, Caserta, ITALY
2. Istituto di Scienze Marine (ISMAR), Consiglio Nazionale delle Ricerche (CNR), Naples, NA, ITALY
E-mail: daniela.ruberti@unicampania.it

Keywords: LGM, Campania Grey Tuff, Incised Valley, palaeomorphology

The Campania Plain, southern Italy, formed as a large graben or half-graben filled with thousands of meters of Quaternary sediments. Of particular interest is the recognition of an important stratigraphic marker, the Campania Grey Tuff (CGT) deposits (39 ka B.P.) during one of the last explosive eruptions of the Campi Flegrei, a complex volcanic system along the Tyrrhenian margin of the plain. The CGT blanketed the whole area and filled morphological depressions, dipping gently towards the central region of the plain, giving origin to a thick, laterally continuous, volcaniclastic unit that covered previous marine-transitional settings, whose landforms controlled the facies distribution and post-depositional settings of the CGT deposits. Since 39 ky, most of the Campania Plain became a land area. Following the eustatic regression associated with the LGM sea-level drop, a seaward shift of the shoreline and the forced regression of paralic-shallow marine depositional systems concurrently occurred, while the rivers flowing in the inner plain likely started fluvial downcutting with formation of a major incised valley. The surface underlying the regressive phase associated to the sea level drop is clearly recognizable across the plain as it is cut in the ignimbrite deposits. The reconstruction of this surface was based on geological and geophysical data, including stratigraphic well logs and high-resolution single channel reflection profiles to image the stratigraphic pattern of the continental shelf. The 3D representation has shown the morphology of the palaeovalley developed during the LGM. The valley is characterized by a complex structure likely related to channel entrenchment and aggradation. Two main downcuttings occur in correspondence of the modern Volturno River course and the Regi Lagni Channel (formerly Clanio River). The Volturno river likely flowed almost in the present location and received the waters of the Agnena Canal (formerly the Cales River, to north) before the deepest part of the incision located close to the present-day delta area. The Clanio River came from the east, conditioned by an older volcanic dome, and created a wide bend in the plain, entering the deep incision south of the mouth of the current Volturno River. The reconstructed surface actually suggests the occurrence of a complex network of incisions that supports the reconstruction of a channel entrenchment on the plain and especially towards the coastline, which at that time was located ca. 13 km offshore. Above this surface, large remobilization of volcaniclastic material took place during the re-establishment of the fluvial system, witnessed by the abundance of reworked pyroclastic ash and clasts recognized in the alluvial deposits of the medium-upper part of the valley fill. Previous radiocarbon dating indicated that the valley started to form at ca. 37 ka B.P. The onset of the LGM renewed fluvial downcutting leaving the previously formed terraces ca. 10 m above the valley floor. These deposits occur in the subsurface below the present delta plain and have their offshore equivalent in the thick succession of upper Pleistocene prograding units deposited during the Falling Stage of the sea level, bounded at the top by the erosional surface.

A millennial-scale record of Late Pleistocene and Holocene glacio-eustatic events: evidence from the Pescara paleovalley system (Central Italy)

Bruno Campo[1*], Giulia Baribieri[1], Andrea Di Martino[1], Wan Hong[2], Daniele Scarponi[1], Stefano Claudio Vaiani[1], Alessandro Amorosi[1]

1. Biological, Geological and Environmental Sciences, University of Bologna, Bologna, Emilia Romagna, ITALY

E-mail: bruno.campo@unibo.it

Keywords: Paleovalley system, integrated facies analysis, parasequence architecture, glacio eustasy, melt water pulse, Po-Adriatic basin

A buried paleovalley system, about 50 m deep and 2 km wide, was identified beneath the Pescara coastal plain (Central Adriatic) through combined stratigraphic, sedimentological, paleontological and geotechnical data. Detailed analysis of a 52 m-long-core recovered from the paleovalley depocenter allowed the high-resolution facies architecture reconstruction of the paleovalley fill (PVF) above the incised Early Pleistocene bedrock. Seventeen closely-spaced radiocarbon dates provide a high-resolution chronological framework for the cored succession.

A 13 m-thick fluvial gravel body, which mostly accumulated during the Last Glacial Maximum (30-19 ky BP), forms the lowermost PVF. This deposit is interpreted as the lowstand systems tract (LST) and shows an erosional and time-transgressive basal surface representing the sequence boundary. Above the LST, the cored succession (11.3-8.0 cal ky BP) displays a deepening-upward trend, from poorly-drained/inner-estuarine to lagoonal/outer-estuarine facies associations. These soft, organic-rich silty clays represent the transgressive systems tract (TST) and are linked to the post-glacial sea-level rise that caused the progressively drowning of the Pescara paleovalley and the formation of an estuary. The maximum flooding surface (about 8.0 cal ky BP) marks the onset of coastal progradation, and defines the base of the highstand systems tract (HST). This latter is characterized by a shallowing-upward tendency from paludal clays to fluvial gravels, with transition to coastal sands in the distal sector.

Within the Holocene (TST+HST) strata, seven millennial-scale depositional cycles bounded by flooding surfaces (parasequences or Ps) were recognized. Transgressive parasequences (Ps 1-3) exhibit a distinctive retrogradational stacking pattern that records the drowning of the valley and estuary formation, in response to rapid, stepwise sea-level rise likely driven by Melt Water Pulses (MWPs) 1B and 1C. MWP 1D likely triggered the maximum landward migration of the shoreline at the peak of the Holocene transgression, around 8.0 ky BP. As sea-level stabilized, between 8-7 ky BP, coastal progradation started and the estuary was progressively filled with freshwater organic-rich deposits (Ps 4), which in turn were replaced by more drained coastal-plain facies (Ps 5-7). In the last 5.2 ky BP (Ps 6-7), further coastal progradation took place and a wave-dominated fluvio-deltaic system developed. Hence, highstand parasequences (Ps 4-7) show a particular aggradational to progradational stacking pattern.

Very low accumulation rates assessed for LST (0.7 mm/y) suggest almost complete sediment bypass between 30-11.3 ky BP. On the other hand, TST parasequences testify rapid aggradation with the highest accumulation rates (up to 9.4 mm/y), whereas HST deposits show a mean value of 2.9 mm/y. During the Holocene, the study site evolved from a laterally confined region of sediment storage (the paleovalley, between 11.3-8.0 cal ky BP), to an unconfined sector where sedimentation took place patchily according to complex mechanisms of coastal plain progradation (last 8.0 ky).

This study documents for the first time the onshore development of a paleovalley system in front of the Mid-Adriatic Depression and provides new stratigraphic evidence for MWP 1B and poorly documented MWPs 1C and 1D.

E-mail: chenhua0630@163.com

Keywords: gravity flow deposits, sedimentary evolution, source supply, continental margin morphology, Miocene, Lower Congo Basin

Research about sedimentary evolution and its response to source supply and continental margin morphology of the gravity flow deposits is the key to hydrocarbon exploration breakthrough in the deep-water. Based on integral analysis of seismic, logging and core samples in block X of the Lower Congo Basin in the West Africa, the Miocene sequence framework is redefined and the sedimentary units of the Miocene gravity flow deposits are fully identified. The sedimentary evolution of the gravity flow deposits is systematically revealed, and its response to source supply and continental margin morphology is discussed. The Miocene in the study area can be divided into four 3rd order sequences, referred to as SQ1 (Lower Miocene), SQ2 (Lower part of Middle Miocene), SQ3 (Upper part of Middle Miocene) and SQ4 (Upper Miocene). Four major types of deep-water sedimentary units are identified, namely MTD, gravity flow channel (including erosional bypassing channel, restricted erosional channel, weakly restricted erosional- aggradational channel and unrestricted aggradational channel), levee and lobe. In SQ1, the gravity flow deposits were mainly developed in the stretching zone of block X with NW-SE extension, and the dominant sedimentary unit was lobes or unrestricted aggradational channels. During SQ2, the gravity flow deposits were widely distributed (NW-SE trending), and weakly restricted erosional-aggradational channels were dominant. In SQ3, the gravity flow deposits developed in the north of the study area with NWW-SEE extension, and restricted erosional channels were widely recognized. In SQ4, the gravity flow deposits developed in the whole study area (E-W trending) with erosional bypassing channels being dominant. SQ1-SQ4, the gravity flow deposits were generally characterized by progradation. That the Congo River delivered abundant source supply to the deep-water caused by tectonic uplift, climate cooling and sea level fall was the overriding factor for the progradation of the gravity flow deposits. The continental margin morphology (tilting shelf and wide slope) and the gradient change of the slope caused by salt structures and faults controlled the sedimentary dispersion process and the sand body distribution.

Morphology of canyon-fan system and its effects on oil reservoir in Crawford Skipper Basin, North Sea

Shenghan ZHANG[1*]
1. Northwest Center of Geophysical Support, Sinopec Geophysical Research Institut, NanJing, JiangSu Province, CHINA
E-mail: zhangshenghan1995@163.com

Keywords: canyon-fan system, gas chimney, offshore oil reservoir

Inspired by exploration wells in Mariner Oil Field (located in Crawford Skipper Basin, North Sea), we find that canyon-fan system is able to play a significant role in the formation of offshore oil reservoir. In the study area, a large canyon-fan system was found through multiple seismic profile analysis, and deep-water system develops a characteristic pattern of depositional architecture from slope canyon and channels to lobes on the basin floor during Palaeocene. The analysis of cores obtained from exploration wells shows that in the deep part of the basin, mudstone is extremely fine grained with irregular fracture surface, while in the upper part, there exists un-bedded mudstone along with moderately fossils and claystone. The canyon is full of chaotic low amplitude reflectors with some discontinuous high amplitude reflectors at the base, which probably indicate slumps and slides. The canyon-fan system formed during the depositional progress exerts enormous influence on the distribution of reservoirs (migration or trap of oil and gas). The branch channels deposited with strong tidal currents benefit for lateral migration of hydrocarbon, while faults beneath basin floor provide vertical migration paths, which is key for canyon-fan system reservoir. According to the volume attribute, there are gas chimneys through sediments, indicating the leakage of hydrocarbon (natural gas and clean oil) during or after the establishment of reservoir. The research results show that the canyon-fan system deposited under specific sedimentary environment is potential to form large oil and gas reservoir.

Quaternary Deep-water Sedimentary Characteristics and Their Relationship with the Gas Hydrate Accumulations in the Qiongdongnan Basin, Northwest South China Sea

Miaomiao Meng[1*]
1. Gas Hydrate Engineering Technology Center, Guangzhou Marine Geological Survey, Guangzhou, Guangdong, CHINA
E-mail: 18811309981@126.com

Keywords: Channel-levee facies, Mass transport deposits, Qiongdongnan Basin, Gas hydrates

Recent geological investigations and offshore drillings have revealed the great prospects of the gas hydrate resources in the Quaternary sediments of the Qiongdongnan Basin (QDNB). Pore-filling gas hydrates were first discovered in the sand layers during the 2019 gas hydrate drilling expedition (GMGS6) in the QDNB. Logging data, 2D/3D seismic data, recovered cores, and grain size analysis were used to study the sedimentary facies and their relationships with the gas hydrates. It was found that the Quaternary sediments are hemipelagic deposits, mass transport deposits (MTDs), and channel-levee facies. The MTDs are characterized by vertical superposition and transverse migration. Both fracture-filling (in vein, massive, and nodular occurrences) and pore-filling (disseminated) gas hydrates were identified. The fracture-filling gas hydrates mainly occur in the muds. The pore-filling gas hydrates mainly occur in the sand layers of the channel-levee facies, which can provide reservoir spaces for the gas hydrates. It is speculated that the MTDs could be a favorable seal for the accumulation of gas hydrates. Multi-stage gas charging may have caused the multi-layer distribution of the gas hydrates. Under the premise of sufficient gas sources, the combination of channel-levee facies and overlying MTDs is conducive to the enrichment and preservation of pore-filling gas hydrates, which could be an exploration target. This study provides a reference for gas hydrate prediction and exploration in the QDNB and other prospecting areas with similar geological settings around the world.

Slope-gully to slope-fan deposits constrained by slope gradient and relative sea level changes; Insights from the Pearl River Mouth Basin,northern South China Sea

Hongxun Tian[1*], Changsong Lin[2], Lin Li[1], Zhongtao Zhang[3], Taotao Yang[1], Zhili Yang[1], Jianan Wu[1]

Keywords: slope-gully to slope-fan deposits, slope gradient, relative sea level changes, South China Sea

Submarine canyons, slope channels and gullies have been well known as long strip-shaped negative landforms and long-term conduits for transfer of sediments from continental shelf slope to abyssal plain, and the slope-gully to slope-fan deposits play an important role in revealing the early growth process of continental shelf margins. Up to now, studies on slope gully deposits have mainly focused on the steep slope regions in West Africa, New Zealand, Antarctic continent, North America, Mars and some inland lake basins. Different from submarine canyons and slope channels, the slope gullies have the following universal rules: (1) generally developed in steep slope area; (2) often linear in planform, relatively straight and shallow; (3) mainly confined and erosional; (4) small scale compared with submarine canyons and channels.

In the Pearl River Mouth basin, northern South China Sea, a set of unique slope-gully to slope-fan deposits was developed along the continental slope during the period of Early-Middle Miocene. The slope-gully to slope-fan deposits were obviously zoned constrained by slope gradient: the slope gullies were mainly discovered on the upper slope and didn't cut off the shelf slope break; while the slope fans were developed on the middle to lower slope area, a single slope fan was stripe-shaped and multiple slope fans converged to form a slope fan group. Based on high-resolution 3D seismic data, 23 slope gullies were divided into three types: erosional-depositional, depositional and sediment bypassed. A comprehensive analysis of cores and well logs uncovered that the slope-gully to slope-fan deposits were fine grained turbidite deposits supported by the ancient Pearl River. According to the plane distribution characteristics of the slope-gully to slope-fan deposits revealed by seismic slices of root-mean-square amplitude, the slope-gully to slope-fan deposits were mainly developed in the low systems tract to the early transgressive systems tract, and then were gradually disappeared accompanying the rise of the relative sea level.

In general, the slope-gully to slope-fan deposits were fine grained turbidite deposits, obviously zoned constrained by slope gradient (the gradient of upper slope is from 2° to 3.5°, and the gradient of middle to lower slope is changed from 0.8° to 1.5°) in the plane distribution, and mainly controlled by relative sea level changes in vertical evolution.

Submarine canyons can transport large volumes of terrigenous material from the continent to the deep-sea environment and are the primary conduits of source-to-sink systems. The large-scale morphologic features of canyons have been well studied using seismic reflection and the bathymetry data. However, detailed analyses of the small-scale elements of canyon morphology are relatively few because of the limited resolution of traditional field investigations. In this paper, the multi-scaled geomorphology of a bended submarine canyon (canyon C4) located in Wanhu Seamount region (northern South China Sea) is described and discussed based on the in-situ high-definition video data, high-precision near-bottom acoustic data, and push-cores obtained using the manned submersible vehicle. The NNW-trending submarine canyon diverted to 122.5° at the foot of Wanhu Seamount, and the fresh erosional surfaces were recorded using the video data at the canyon axis bend. A total of eight sediment waves were generated at the overbank of the bending region. These waves contain wavelengths and wave heights decreasing in an upslope direction from the canyon axis towards the Wanhu Seamount. The C-M pattern (coarsest one percentile grain size versus median grain size values), grain cumulative probability curves, and grain size gradations derived from the sediment cores suggested that these sediment waves were induced by a turbidity current. The bending of the canyon resulted from the deflection and reflection of the turbidity currents, which were constrained by Wanhu Seamount. The abnormal geomorphologies of some sediment waves were related to the back-squeezed underflow of the turbidity currents. The turbidity current behavior was compared and found to be in agreement with the experimental and modeling simulation results mentioned in the literature. However, the morphologic setting in the natural case was more complex than that observed from the experiments, with the flow behaviors being more complicated. Future studies are required for more detailed comparison between the natural case and simulations to better understand the turbidity current behavior in a bended submarine canyon.

Variations and controls of asymmetry and stacking pattern for unidirectionally migrating deep-water channels

Chenglin Gong[1*]

1. College of Geosciences of China University of Petroleum (Beijing), College of Geosciences of China University of Petroleum (Beijing), Beijing, CHINA

E-mail: chenglingong@cup.edu.cn

Keywords: Unidirectionally downstream-migrating channels, unidirectionally upstream-migrating channels, channel cross-sectional asymmetry, latitudinal variations, Ekman spiral

This study is the first documentation of a global variation in channel morphology and stacking pattern, evident from a global database of 60 channels that are migrating sideways. The chosen channel examples migrated both parallel to and against the dominant contour-current direction (i.e., unidirectionally downstream-migrating versus upstream-migrating channels). Downstream-migrating channels differ from their upstream-migrating counterparts in that they are confined totally by incisions rather than by overbank levees or sediment drifts developed downstream of contour currents. All channels display an asymmetrical cross-section with their steep flank located towards the channel migration direction. An Ekman spiral varying with latitude is proposed to account for the observed (latitudinal) variation in channel asymmetry and stacking pattern. Analogous to wind-driven ocean currents, submarine channel turbidity currents, impacted by the friction force of contour currents, result in Ekman transport. This causes net cross-stream sediment transport, thereby forcing successive channels to migrate unilaterally.

Left-sided asymmetry of Neocomian submarine fans of West-Siberian interior sea (Russia)

Alena V. Khramtsova[1*], Konstantin V. Zverev[2]
1. Geological Exploration Department, Tyumen Oil Research Cente, Tyumen, RUSSIA
2. Department of planning and support of geological exploration, GAZPROMNEFT STC, St. Petersburg, Leningradskaya oblast, RUSSIA

Keywords: Achimov Formation, morphology, asymmetric submarine fan, channels, avulsion, mud/sand turbidite systems

During the Berriasian - Early Valanginian time, an asymmetric submeridional interior deep marine basin existed within the bounds of West Siberia which in the north was connected with boreal seas. As a result of avalanche sedimentation from the east (Siberian Platform) and south-east (Altai-Sayan folded region), partly from the west, clastic material was transported into the deep-sea basin to form Achimov fans. The Achimov Formation has a clinoform structure and is confined to the Neocomian base, overlying the Bazhenov argillaceo-siliceous source-rock, being a promising target for HC resource potential. Most of the discoveries have produced significant oil and gas condensate flows.

The results of sedimentological analysis of cores collected from 50 wells in various West-Siberian fields show that Achimov reservoir are composed mainly of fine-grained to medium-fine-grained sandstones and siltstones with poor reservoir properties. The rock structures are similar to those of the Stow (1) and Bouma (2) sequences described for clayey and sandy turbidites. The deposits also contain hybrid beds represented by debris siltstones with clayey intaclasts and sandstones with massive and fluid structures. The deposits distinctively feature the presence of carbonaceous debris which indicates their being transported by deltaic or river channels (hyperpycnal genesis of turbidites). Architectural elements of submarine fans in the Achimov Formation have been identified based on integrated core, well-logs and seismic data. Turbidite channels and lobes represent main targets to study submarine fans. Slope channels have slightly meandering shape. Distributary channels become more meandering at a longer distance from the bottom of the slope. Achimov submarine fans feature various morphologies, from radial to elongated shapes, and usually have a few feeder channels. The fan morphology depends on submarine slope dip, grain-size distribution and sediment volume. On average, unconfined submarine fans are 20-50 km long, 20-50 m thick, and 15-30 km wide.

Based on the research results, the authors identified morphological similarity between Achimov submarine fans of West Siberia and modern oceanic fans of the Amazon and Congo rivers (3) associated with mud and mud/sand turbidite systems (4) and found out a left-sided asymmetry of Achimov submarine fans. The preferential development of distributary channels and lobes in the left part of the main feeder channel is attributed to radial avulsion and asymmetric growth of levees. This allows to predict predominant development of sand reservoirs (and much higher NTGs) in the left side of asymmetric fans, and vice versa, lower NTGs in its right side.

The formation and development of avulsions and splays of submarine channel systems: Insights from 3D seismic data from northeastern Bengal Fan

Kun Qi[1], Chenglin Gong[1*], Ronald Steel[2], Dali Shao[3], Liangbo Ding[3], Hongxia Ma[3]
1. College of Geosciences, China University of Petroleum (Beijing), Beijing, CHINA

E-mail: chenglingong@cup.edu.cn

Keywords: Submarine channel systems, Avulsions; Splays, Channel evolution, Bengal Fan

Avulsions and splays of submarine channels are important autogenic responses affecting sediment distribution in deep-water areas; however, their formation and development are still not well understood. Using high-resolution 3D seismic data and spectral decomposition red-green-blue (RGB) color blends, two seismically well-imaged submarine channel systems (SCS1 and SCS2) on the northeastern Bengal Fan are used to document the formation and development of avulsions and splays. The results suggest that avulsions occurred mainly during the early evolution stage of submarine channel systems. SCS1 and SCS2 were respectively accompanied by one and four avulsions and accordingly produced two and five independent submarine channels. During this early phase, these channels collectively incised into the underlying stratigraphy but lacked levee deposits. Splays, in contrast, developed consistently during the late evolution stage of the submarine channel systems. Three crevasse splays and three overbank splays developed on the overbank areas of SCS1 and SCS2. During that late stage, channel and levee deposits built over the site of former erosion, thus forming the aggradational phase of channel evolution. Crevasse and overbank splays are two different types of splay observed on this part of the Bengal Fan. The former were created by flow breaching of the adjacent levees, producing large-scale elongated shapes; they were related to relatively stable sediment gravity flows, a high-degree of channel instability, and steep levee topography. Overbank splays, however, were created by flow overtopping adjacent levees and produced small-scale, fan-like shapes; they were related to gradually-weaking sediment gravity flows, a low-degree channel unstability, and gentle levee topography.

Evolution of the Pleistocene Aggradational Channels in Offshore Myanmar

Xiaoyong Xu[1*], Ying Zhang[1], Yintao Lu[1], Hongxia Ma[1], Dali Shao[1], Hui Sun[1], Liangbo Ding[1]
1. Offshore Research Center, PetroChina Hangzhou Research Institute of Geology , Hangzhou, Zhejiang, CHINA
E-mail: xuxy_hz@petrochina.com.cn

Keywords: Myanmar, Pleistocene, Deep-water, Channel centerline, Channel evolution

Recentlythe proportion of incremental reserves from deep-water increased year by year and exceeded 50% since 2010. Deepwater exploration has become the key area of future oil and gas exploration. As one of the main reservoir for deep-water oil and gas explorationdeep-water channels have attracted more and more attention. Based on high-resolution40 Hz3D seismic datathis study carried out a detailed description of an aggradational channel-levee complex in offshore Myanmar. The centerlines of the different channels in the complex were recognized from bottom to top. The overall width of this channel-levee complex is 25~30 km. The width of the single-channel is about 300 mand the thickness is estimated to be 10 m. The channels' centerlines in this complex show an organized evolution. The channel was relatively straight with low curvature at the beginning of aggradationand the curvature gradually increase over time. During aggradationthe deep-water channels not only swing but also sweep downstream. Predecessors believed that downstream sweep is very rare in deep-water channelshoweverour research shows that this phenomenon does exit in the study area.

Morphological and architectural evolution from inception to abandonment of submarine channels: An example from the Pleistocene Bengal Fan

Dongwei Li[1], Chenglin Gong[1*]
1. College of Geosciences, China University of Petroleum (Beijing), Beijing, CHINA
E-mail: chenglingong@cup.edu.cn

Keywords: Submarine channels, channel inception, morphological and architectural evolution, end-member types of channel belt, Bengal Fan

3D seismic data from the Bengal Fan along with spectral decomposition and RGB color blending techniques allows the exploration of morphological and architectural evolution of a Pleistocene submarine channel, from its inception to abandonment. Five main architectural elements of the Bengal channels were recognized: feeder and trunk channels, oxbows, levees, channelized and unchannelized crevasse splays, and lobe complexes. Four end-member types of channel-complex sets (CCSs) were identified: (1) straight to low-sinuosity, non-leveed (immature CCS1), (2) moderate-sinuosity, non-leveed (submature CCS2), (3) high-sinuosity, leveed (mature CCS3), and (4) high-sinuosity, leveed CCSs (supermature CCS4-5). Channelization commenced with the erosion of straight to low-sinuosity, non-leveed CCSs from an initially featureless slope, and evolves from immature through supermature CCS stages with a spatiotemporal increase in channel sinuosity (Si). A statistical analysis of channel width (W), thickness (T), and cross-sectional area (Ca) suggests that W, T, and Ca progressively increase from immature CCS1 and submature CCS2, upward to supermature CCS4 and CCS5, and to mature CCS3. Architecturally, mature and supermature CCSs have overbank levees, crevasse splays and oxbows, but immature and submature CCSs don't. Immature, submature, mature CCSs have abrupt lateral offset of channel fairways, but supermature CCSs don't.

How do tectonics influence the initiation and evolution of submarine canyons? A case study from the Otway Basin, SE Australia

Nan Wu[1*]
1. School of Ocean and Earth Science, Tongji University , Shanghai, CHINA
E-mail: nanwu@tongji.edu.cn

Keywords: Submarine buried canyons, Mass wasting processes, Canyon-fill, Tectonic activity

The architecture of canyon-fills can provide a valuable record of the link between tectonics, sedimentation, and depositional processes in submarine settings. In this study, we investigate the role of plate tectonics in the initiation and evolution of submarine canyons. We demonstrate that plate tectonic-scale events (i.e. continental breakup and shortening) have a first-order influence on submarine canyon initiation and development. Initially, the Late Cretaceous (c.65 Ma) separation of Australia and Antarctica resulted in extensional fault systems, which then formed a steep stair-shaped paleo-seabed. Subsequently, the Late Miocene (c.5 Ma) collision of Australia and Eurasia has resulted in substantial uplift and exhumation in the SE Australian continental margin. These tectonic events have resulted in elevated seismicity that ultimately gave rise to the gravity-driven processes (i.e. turbidity currents and mass wasting processes) and formed the canyon base. The inherited stair-shaped topography then facilitated gravity-driven processes which established a mature sediment conduit extending from the shallow marine shelf to the abyssal plain. We indicate that the canyon stratigraphic architecture can be used as an archive to record tectonic movements. Moreover, the factors which preconditioned and triggered gravity-driven processes can also induce canyon initiation and facilitate canyon development.

Morphologic and depositional transformations of deep-water channels in the Rakhine continental margin since late Miocene and their responses to the route-shifting of the Brahmaputra River

Yijie Zhu[1], Chenglin Gong[1*], Kun Qi[1]
1. College of Geosciences, China University of Petroleum (Beijing), Beijing, CHINA
E-mail: chenglingong@hotmail.com

Keywords: Deep water channels, morphological characteristics, sedimentary constitution, sedimentary transformation, Brahmaputra River

The response of the evolution of deep-water depositional system to the shifting of sediment routing is an important topic of the current source-to-sink study. In this paper, three-dimensional seismic data and detrital zircon age spectrum data are used to reveal the transformations of deep-water channels in morphology (W = width, T = depth, C_a = cross-sectional area) and sedimentary constitution (channel development degree (C_d) = ratio of channel cumulative cross-sectional area to coincident profile area) and their responses to the changes of sediment-routing systems of Brahmaputra River. Morphologically, deep-water channels occurred in late Miocene are wide ($1837 < W < 11271$ m) and deep ($180 < T < 936$ m), with relatively larger cross-sectional areas ($0.298 < C_a < 6.252$ km^2). However, channels occurred in Quaternary are narrow ($357 < W < 1629$ m) and shallow ($31 < T < 159$ m), with relatively smaller cross-sectional areas ($0.008 < C_a < 0.167$ km^2). As for Pliocene channels, their values of widths ($858 < W < 4490$ m), depths ($77 < T < 283$ m), and cross-sectional areas ($0.049 < C_a < 0.942$ km^2) are between above-mentioned two end members. For the sedimentary constitution of deep-water channels, late-Miocene ones are absent in levees and thus, are named non-leveed channels, corresponding to high degree of development (C_d = 0.18%). On the contrary, Quaternary channels are flanked by levees and hence named leveed channels, corresponding to low degree of development (C_d = 0.015%). As for channels occurred in Pliocene, they consist of both levee ones and non-leveed ones and correspond to moderate degree of development (C_d = 0.035%). The detrital zircon core density statistics from the 362 cruise of International Ocean Drilling Program (IODP) present that the characteristic age spectrum (0-60 Ma core density age) of the Paleo-brahmaputra river has decreased gradually since the late Miocene (5.35%→4.75%→4.58%). Such fact suggests the influence of sediment-routing systems of paleo-Brahmaputra river on the northwestern margin of Bangladesh was gradually decreasing since late Miocene and accordingly, less and less sediments from Himalaya-Tibet Plateau were accumulated in the study area. Above all, it could be concluded that it was the gradual decreasing in sediment supply of the catchment (paleo-Brahmaputra river) that drived the decreases in widths, depths, and cross-sectional areas, and the degree of development of deep-water channels.

Numerical study on suspended sediment in Dongtou Archipelago areas

Jianchen Wang[1*]
1. Ocean College, Zhengjiang University, Zhoushan, Zhengjiang, CHINA
E-mail: 22034207@zju.edu.cn

Keywords: Dongtou archipelago, SSC, tides, temporal and spatial variation

Estuaries are key areas of land-sea interaction. Suspended sediment concentration (SSC) and its transportation play an important role in the ecological environment and geomorphology evolution. In this paper, a modeling study with high resolution for the Oujiang Estuary and Dongtou archipelago using a three-dimensional unstructured-grid finite-volume coastal ocean model (FVCOM) has been established and well-calibrated. Combined with the observed data, the spatial and temporal variation of SSC in the estuarine waters around the Dongtou archipelago is analyzed. The hydrodynamic model is validated with observed velocity and direction data over spring and neap tides. The results show that the tides are asymmetric in spatial and temporal distribution. The SSC peaks occur after the peaks of current velocity in the Dongtou archipelago. SSC at the bottom is more than 2 times that at the surface and the SSC during the spring tide is higher than that during the neap tide. There is lateral residual circulation between the channels of Damen Island and Xiaomen Island.

LES-DEM numerical investigation on particle suspension mechanism in turbidity currents

Jiafeng Xie[1*], Peng Hu[1], Chenlin Zhu[2], Thomas Pähtz[1]

1. Ocean College, Zhejiang University, Institute of Port, Coastal and Offshore Engineering, Zhoushan, Zhejiang Province, CHINA

2. China Jiliang University, School of Mechanical Engineering, Hangzhou, Zhejiang Province, CHINA

E-mail: xiejf@zju.edu.cn

Keywords: turbidity current, particle suspension, coherent vortical structure, force analysis

Turbidity currents are a natural phenomenon that extensively happens in deep-water environment. They are essentially a fluid-particle coupled motion process. Particle suspension mechanism is the key to the evolution of turbidity currents, which affects the shape maintenance and transport distance of the currents during their propagating along the continental shelf. Nowadays, we employed the LES-DEM model to simulate the small-scale lock-exchange turbidity currents over an inclined fixed slope, with the variation of terrain slope and initial particle concentration. The advantage of this method is that it can accurately track the trajectories of individual particles and analyze their force processes while characterizing the hydrodynamics of the current. In our study, the initial particle concentration is set to 1-2%, and the terrain slope angle varies between 1/20 and 1/5. The simulation results indicate that particle suspension in turbidity currents occurs mainly near the current head, and the number of the suspension particles increases first and then decreases, closely related to the fluid vorticity. The uplift of these particles is associated with the presence of a large-scale transverse coherent vortical structure that accompanies the local low-pressure core. By force analysis , it is the bed-normal total force that determines the patterns of particles entering and exiting the suspension state. The increase in particle concentration gives rise to a significant increase in the positive bed-parallel and bed-normal total forces. This implies that not only does the advance speed increase, but also the particle suspension level of the current is enhanced. The increase of the slope angle makes the advance speed of the turbidity current along the slope slightly increase, however, the particle suspension does not depend on the variation of the slope angle under the small slope angle condition.

Deepwater Channel Characteristics and Hydrocarbon Accumulation in xisha Area

ZHILI YANG[1*], hongxun tian[1], li li[1], lin li[1], taotao yang[1], hongxia ma[1], dong li[1]
1. Institute of offshore oil and gas geology, PetroChina Hangzhou Research Institute of Geology, hangzhou, zhejiang, CHINA
E-mail: yangzl_hz@petrochina.com.cn

Keywords: Xisha area,deepwater channel,seismic reflection, hydrocarbon accumulation

The xisha area is located in the northern part of the South China Sea . The seabed topography is complex . The water depth reaches 1000-3000m . Since Miocene, the xisha area was in a stable subsidence period, and its tectonic activity was not active. After the Miocene, it entered the deep-water depositional environment of the continental slope. Based on 2D seismic data, a terrigenous deepwater channel was identified in the study area. During the sedimentary period of the Upper Miocene Huangliu Formation, deep-water channel deposits with terrigenous clasts as provenance developed in the west of Huaguang Sag, Qiongdongnan Basin. Controlled by sea level, the Huangliu Formation developed three stages of deepwater channel. In the early stage of the Huangliu Formation, the development of channel was in the low sea level stage, and the developed channel were U/V downward incised channel, which had strong limitations. In the early stage, the upstream part of the channel was composed of several independent branch channels, and the downstream part of the channel converged into a composite channel system and cut each other. In the middle period of the Huangliu Formation, the development of the channel is a period of rapid sea level rise, and the channel is characterized by channel complex, which is highly restrictive. In the middle stage, there are many restricted branch channels upstream, and many independent channels downstream converge to form a channel complex. In the later stage, the early channel is cut and moved in plane. The late stage of channel development is in the high sea level period, which is characterized by channelize-lobe with weak restriction. In this period, the upstream part of the channel is a single swing channel, the middle part is a complex of several swing channels, and the downstream part is a channelize-lobe.

The three-stage Deepwater Channel is controlled by sea level changes. From the early stage to the late stage of the channel , the sea level changes from the low stage to the high stage. The restriction of the developed deepwater channel gradually weakens. The Channel develops from a single channel with strong restriction in the early stage to a channel complex with multiple channel cutting and migrating each other in the middle stage, and then transits to a channel complex and a channelize-lobe in the late stage.

The first deep-water gas field of in China has been found in the deep-water channel of the central canyon. According to the analysis of hydrocarbon source conditions, the study area has a good organic matter generation and preservation system. At the same time, the Deepwater Channel developed in the deep-water sedimentary environment of the continental slope, developed huge thick marine mudstones of Huangliu Formation, and had better sealing conditions. The sediments filled in the deepwater channel are presumed to be clastic rock ; The channel develops in the depression, and the oil and gas generated in the lower part can migrate upward along the faults controlling the depression to form reservoirs in the channel.

Geomorphological and sedimentary characteristics of the Pearl River submarine canyon - fan system, northern South China Sea

Ke Huang[1*], Guangfa Zhong[1], Liaoliang Wang[2], Benduo Zhu[2], Huodai Zhang[1,2]
1. State Key Laboratory of Marine Geology, Tongji Univerisity, Shanghai, CHINA
2. Guangzhou Marine Geological Survey, China Geological Survey, Guangzhou, Guangdong, CHINA
E-mail: kehuang@tongji.edu.cn

Keywords: Submarine canyon, Submarine fan, Turbidity currents, Mass transport deposits, Tectonics, South China Sea

The Pearl River submarine canyon - fan system (PRCF) comprises one of the most important sediment source to sink systems in the northern continental margin of the South China Sea (SCS). The system is of significant implications for understanding the sedimentary evolution of the host continental margin and for deep-water hydrocarbon and gas hydrate exploration in the same margin. Previous research on the PRCF has mainly focused on its morphological characteristics and associated sub-bottom submarine landslides, with little attention paid to the sedimentary infillings. Here we used two-dimensional seismic profiles, combined with multibeam bathymetric and scientific ocean drilling data, to investigate the geomorphological and sedimentary characteristics of the canyon-fan system.

The multibeam bathymetrical data reveal that modern PRCF extends more than 300 km from the shelf break off the paleo-Pearl River Delta in the north, via the continental slope, to the deep sea basin in the south. The system consists of the Pearl River submarine canyon in the continental margin and its connecting submarine fan at the toe of the margin. The canyon can be further subdivided into four segments, which are a head area consisting of about 19 NNW-SSE-trending submarine tributaries, a nearly E-W-oriented upper reach, a NWW-SEE-striking middle reach, and a NW-SE-trending lower reach. Overall, the canyon gradually narrows downstream. Our seismic sequence analysis indicates that the PRCF began in the late Middle Miocene. Thickness of the system is the thickest in the upper reach and the thinnest in the middle reach. Seismic facies analysis reveals that the canyon - fan system has dominantly been filled by coarse-grained turbidites and mass transport deposits, with the mass transport deposits increased upward. Little lateral swinging is observed during the development of the PRCF. Formation and evolution of the canyon - fan system are predominantly controlled by tectonics. Other factors, including sea level changes and sediment supply, may also play an important role.

Evolution of cyclic steps and related flow process at canyon mouth on slope of the Rovuma Basin, offshore Mozambique

Yuhang Chen[1*]
1. School of Earth Sciences and Engineering, Xi'an Shiyou University, Xi'an, Shaanxi, CHINA
E-mail: cyh@xsyu.edu.cn

Keywords: Cyclic steps, Morphology, Bottom current, Slope break, Flow process, Rovuma Basin

Cyclic steps, as a typical submarine bedform, have been intensively recorded at canyon mouth in submarine environment around world. Previous studies documented the morphology and sedimentary feature of the cyclic step and determine its formation mechanism, flow dynamic features, to reveal its downslope flow process evolution. However, the alongslope flow process under the influence of seafloor topography and ocean circulation was not taken into account fully, leading to a general lack of consensus on the spatial flow process at canyon mouth. 3D seismic data were used to depict the morphology and internal architecture of cyclic steps at the canyon mouth in slope of the Rovuma Basin (offshore Mozambique), to determine the sedimentary features of the cyclic steps and reveal its spatial flow process evolution of and related controls. The result shows that turbidity current interacts with northward flowing bottom current, resulting in northward deflection deposition of turbidity current. Sandy part of turbidity current flows along the axial direction of canyon mouth, forming a linear series of crescent-shape net-erosional cyclic steps. These cyclic steps are characterized by short steep stoss side and long gentle lee side. Muddy part of turbidity currents is deflected towards to north flank of canyon mouth by the bottom current, and deposited as undulating net-depositional cyclic steps, showing long gentle stoss side and short steep lee side, which are orthogonal to axial direction of canyon mouth and thin out away from canyon mouth. However, local slope breaks at seafloor increase the velocity of downslope turbidity current, thus enhance the erosion of flow on cyclic steps, which results in the formation of net-erosion cyclic step, making the stoss side become short and gentle, and lee side become steep.

Quantitatively parameterizing slope channel system in Taranaki Basin, New Zealand using seismic geomorphology

Erman Haizal Kamaruzaman[1*], Andrew David La Croix[1], Peter JJ Kamp[1]
1. Earth and Environmental Sciences, University of Waikato, Hamilton, Waikato, NEW ZEALAND
E-mail: ek100@students.waikato.ac.nz

Keywords: Paleo submarine channels, seismic geomorphology, Taranaki Basin

Abstract

Understanding the geometry of paleo submarine channels gives key information about their origin and the nature of deposition within them. Quantitative characterisation of paleo submarine channel systems is seldom undertaken, whereas modern-day submarine channel characteristics are reasonably well known. This study addresses these differences by presenting extensive quantitative data (2336 measurements from 126 channel segments) about the geometry of submarine channels within the Miocene Taranaki Basin succession, using seismic geomorphological analysis. Submarine channels have been analysed from four stratigraphic intervals: lower and upper Moki Formation (16 – 13 Ma), and lower and upper Mount Messenger Formation (13 – 7 Ma). The results show differences in channel cross-sectional and planform morphology, indicating significant changes in channel geometry through time. The maximum channel cross-sectional area increases from 0.15 km2 in the lower Moki Formation to 4 km2 in the lower Mount Messenger Formation, decreasing to 1.6 km2 in the upper Mount Messenger Formation.

Lower Moki Formation channels have average sinuosity, meander length, and amplitude of 2.4, 3.2 km, and 2.4 km, respectively. By comparison, the upper Mount Messenger Formation channels have values for the same parameters of 1.0, 0.9 km, and 0.07 km. There is no relationship between Moki and Mount Messenger formation channel occurrences or characteristics with either the timing or magnitude of Miocene changes in sea level, or with short term variations in sediment flux, as suggested in previous work. Instead, longer term changes in subsidence and, in particular, marked progradation of the shelf-slope system and increasing slope gradient, due to increasing rates of sediment supply to the basin through the Miocene, have controlled the frequency and characteristics of the channels. There are close parallels between Miocene Taranaki channel geometry and modern fluvial channel geometry despite orders of magnitude difference in their dimensions.

Hydrothermal plume and particle transport in stratified environment

He Zhiguo[1*], Haoyang Zhang[1]
1. , , , , CHINA
E-mail: hezhiguo@zju.edu.cn

Keywords: Hydrothermal plume, Particle transport, Dynamic characteristics, Computational fluid dynamics

Buoyant plume refers to the plume flow form of fluid driven by buoyancy completely or partially in environmental media. It widely exists in nature and human activities, such as near SST drainage, deep-sea hydrothermal plume and so on. At present, there are more than 700 hydrothermal vents in the world, of which nearly 200 have temperature information. There are significant differences among different vents, but the attention to low-temperature vents is still very low. On this basis, based on the fluent simulation results, the influence range and material diffusion law of deep-sea hydrothermal vent plume under different temperatures and different background flow conditions, including high-temperature and low-temperature hydrothermal field, are analyzed, which is of great significance for chemical growth and hydrothermal ecological community reproduction. While exploring the impact of hydrothermal vents at different temperatures on biological communities, based on the coupled simulation of fluent and edem, this paper analyzes the transport mode of different material particles under the hydrothermal source under the condition of transverse flow, which is helpful to guide the exploration and development of mineral and sulfide resources and reveal the origin of early life on the earth. The research shows that the hydrothermal plume at different temperatures has different plume rising height, mass flux, heat flux and influence range. The sedimentation laws between different material particles are summarized, and on this basis, the transport and deposition laws of different particles under the background flow of layered environment are given quantitatively. The research results have supporting value for the tracing of submarine hydrothermal vents, the study of marine material and energy cycle process, the exploration of seabed mineral resources and environmental assessment.

Characterization and Exploration Potential of Deep-water Depositional System in the Rakhine Basin, Myanmar

Guozhang Fan[1*]
1. Offshore research center, Petrochina Hangzhou Research Institute of Geology, Hangzhou, Zhejiang, CHINA
E-mail: fangz_hz@petrochina.com.cn

Keywords: deep-water,depositional system,exploration potential,Myanmar

The current study documents the seismic facies of deep-water elements of Bengal Fan in Rakhine Basin, Myanmar and addresses their exploration potential. Several gas reservoirs have been discovered in different elements of deep-water systems in Myanmar, such as frontal splays, overbanks, channel complexes and mass transport deposits.

Our observations and results suggest that the depositional elements primarily evolve from confined channel complexes during Eocene to Early-Middle Miocene to channel-levee complexes during Late Miocene to Holocene based on integrated subsurface dataset including high-resolution 3D seismic data and various drilling data as long as some Submarine canyon complexes and mass transport complexes are identified, which is controlled by paleogeomorphology and sediments input coupling the regional tectonic movements.

Four dominant kinds of depositional elements were established based on seismic facies and wireline-log interpretation, namely submarine canyon complex, mass transport complex, confined channel complex and aggradational channel-levee complex. The latter two complexes are tended to relative sand rich and be of better exploration potential. Moreover, the two complexes mainly developed as straight and parallel to each other along North-South in the west part of Rakhine Basin, and more sinuous, frequently migrating stack in the east part of Rakhine Basin, which indicate the difference of paleogeomorphology, sediment supply and potential sand reservoir. For confined channel complexes, the erosional fairway elements, are large and prominent incision flanked by wedge-shaped outer levees. Channel-axis deposits are characterized by discontinuous high amplitude reflectors that are formed by lateral and vertical migration of coarse-grained channel thalweg deposits. Inner levees are characterized by chaotic, or transparent low amplitude reflectors with a stepped shape. Seismic reflections within outer levees are almost always continuous, but can range from low to high amplitude. For aggradational channel-levee complexes, levee sediments are characterized by low amplitude, continuous, and/or relatively transparent reflectors with a double-wedge shape that thins away from channel-fill sediments that characterized by high amplitude, discontinuous reflections on seismic. Within the complexes, secondary classifications were defined to feature the migration of the depositional system.

We infer that the complex and its subdivisions are related to the presence of good reservoirs not only the thickness and distribution but also the physical properties. The elements are statistically analyzed by seismic characterization and gas reservoir parameters and the exploration potential are predicted. The trapping potential includes the structural trap related to the compressional anticline strike to NW-SE and the stratigraphic trap draping on the wings of the structures or sand pinch-out. Comprehensive consideration of the match between structure and depositional system, it is possible that more traps are favorable to develop in the east part of Rakhine Basin because of the larger structure relief and richer sands, and more important is the possible better source kitchen near to the continental sediments supply.

Evolution, 3D-architecture and Reservoir of the Deepwater Channelized System-Insights from rifted lacustrine and deep marine basins

Shu Jiang[1*]
1. School of Earth Resources, China University of Geosciences at Wuhan, Wuhan, Hubei, CHINA
E-mail: jiangsu@cug.edu.cn

Keywords: deepwater channelized system, sequence stratigraphy, reservoir architecture

The deep lacustrine and marine fan are usually composed of channelized system instead of homogeneous sandstone lobe. This study characterizes the depositional evolution and 3D-architecture of the deepwater channelized system using 3D seismic, well logs, outcrops, and core data in the representative Paleogene rifted lacustrine Bohai Bay Basin, Pleistocene deepwater Gulf of Mexico. The results reveal the deepwater channelized system evolves from an unorganized amalgamated pattern by high energy flow to an organized distributary pattern by low energy flow from the bottom to the top in a 3rd order depositional sequence, with an upward increase in sinuosity and decrease in aspect ratio, and aggradation updip and lateral migration downdip.
. The high-density sandstone is deposited in the proximal setting and the low-density sandstone is deposited in the distal setting. The best reservoir is determined by the sediment source, slope gradient, bathymetry, and facies. The amalgamated turbidite sandstone and trunk channel sandstone sourced from the underlying delta front have the best reservoir quality.

Sedimentary configuration, evolution and controlling factors of upper Indian fan channel-embankment composite system since Miocene

Sen Li[1], Jie Liang[1*], Jing Liao[1], Jianming Gong[1]
1. Department of Marine Petroleum and Geology, Qingdao Institute of Marine Geology, Qingdao, Shandong, CHINA
E-mail: lj_100@163.com

Keywords: upper Indus Fan, channel-embankment system, controlling factors

Based on the parameters such as submarine canyon, seismic reflection characteristics, superposition patterns, spatial distribution and time scale, we put forward the identification standards of channel-embankment system of different levels, and established the division methods of channel-embankment composite system. The upper Indus fan channel-embankment composite system is systematically divided. We have selected typical seismic profiles, finely divided the types and characteristics of seismic facies (internal reflection structure and external form) of upper Indus fan channel-embankment composite system, characterized the spatial combination relationship of various seismic facies, and established the sedimentary configuration of different levels of upper Indus fan channel embankment system. Combined with the isochronous stratigraphic framework established by previous studies, we analyzed the differences of the seismic facies characteristics and the sedimentary configuration in the near end, middle end, far end (space) and early-middle-late (time) of channel-embankment system at all levels. Combined with the tectonic background, provenance, paleoclimate, sea-level fluctuations, we analyzed the controlling factors of channel-embankment system evolution at different levels, and finally established a complete spatial-temporal evolution model of upper Indus fan channel-embankment system since Miocene.

Channel inception through bottom current erosion of pockmarks: a numerical simulation study based on the geophysical research in western South China Sea

Kaiqi Yu[1,2*], Alice Lefebvre[3], Wei Li[1,2], Wenhuan Zhan[1,2], Elda Miramontes[4,3]

4. Faculty of Geosciences, University of Bremen, Bremen, GERMANY
E-mail: kaiqiyu@scsio.ac.cn

Keywords: Channel, Pockmark, Bottom currents, Numerical simulation

In deep-marine environments, ocean currents can sculpt the seafloor and control the development of channels by their interaction with rough topography, while the necessary conditions and controlling factors for this process are still unclear. Based on geophysical data analysis, a comprehensive channel system is identified in the western South China Sea, and the alongslope channels in this channel system are proved to be formed by the interaction between bottom currents and pockmark trains (Yu et al., 2022). In order to reveal the process of channel inception through bottom current, a numerical simulation study is conducted based on the morphological, sedimentary and oceanographic settings documented in Yu et al. (2022). The simulation results show that the bottom currents can erode pockmark trains in cohesive sediments, when they are in an appropriate velocity. The action of bottom current will lead to the coalescence of discrete pockmarks and the formation of an “immature channel” with a rough thalweg, as observed in the study of Yu et al. (2022). The interaction of bottom currents with the pockmarks induces a significant seafloor erosion at the streamwise edges of the pockmarks and at the seafloor between pockmarks. Bottom current erosion is strongest at the downstream edges of pockmarks, where the horizontal velocity reaches a maximum and an upwelling forms. The bottom-current erosion also increases as the reduction of pockmark interval distances. There is a maximum distance between pockmarks that can be coalesced by bottom-current erosion into a channel, which is ~6 times the diameter of the pockmark according to the simulation results. This study provides evidence and details of the formation of channels by bottom currents, which helps reconstruct paleoceanographic conditions based on the sediment architecture. It also shows the complex hydrodynamics at these structures that strongly control sedimentary processes and may affect distribution of benthic ecosystems in deep-water environments.

Mixed turbidite–contourite depositional systems are commonly found on continental margins, but their bedforms and associated sedimentary processes have not been studied in depth. In this work, we used multibeam echo-sounder, sub-bottom profiling, and multichannel seismic data from the continental rise of the Cosmonaut Sea, East Antarctica, to (1) identify primary bedforms in a combined-current (i.e., turbidity current + contour current) channel–levee system and (2) inferbedform-associated sedimentary processes. Within turbidite channels and on adjacent levees and distal overbank deposits, scours, furrows, and sediment waves of varying dimensions and trends were identified. These bedforms are interpreted to have formed in two steps, which have been likely repeated over and over again through time. First, scours and sediment waves within the channels were formed by turbidity currents, while sediment waves on adjacent levees were likely formed by synchronous interactions between overspilled unconfined turbidity currents and the Antarctic Bottom Water (AABW) contour current. Second, after waning of the episodic turbidity currents, AABW flow created a field of erosional furrows on a distal overbank, with these furrows truncating the large field of sediment waves earlier generated by the combined flow of interacting currents. Bedform locations, orientations, and truncating relationships are key for identifying the likely origins of mixed-system bedforms.

Characteristics of debrites, turbidites and contourites in the Upper Ordovician Pingliang Formation along southwestern margin of the Ordos Basin, western China

Hua Li[1*]

1. Yangtze University, School of Geosciences, Wuhan, Hubei, CHINA

E-mail: 501026@yangtzeu.edu.cn

Keywords: debris flow, turbidity current, contour current

Deep-sea deposit is one important work in sedimentological field, but work on the ancient sedimentation is relatively rare, especially about relationship between sedimentary record and paleo-environment. Using outcrop, petrography, paleocurrent, trace element, δ13C, δ18O, 87Sr/86Sr, etc., deep-sea deposits had been researched in the Ordovician Pingliang formation along southwestern margin of the Ordos Basin. The Pingliang formation could be divided into five typical lithofacies. Lithofacies 1 is horizontal-bedded micritic limestone, mudstone, chert layer and tuff, which is correspongding to deep-water autochthonous deposits. Lithofacies 2 consisting of calcirudite with massive bedding, result from debris flow deposits. Lithofacies 3 is graded bedded calacrenite with imcomplete Bouma sequence indicating calacentie turbidites. Lithofacies 4 consisting of bioturbated and cross-lamination micrite with fine-coarse-fine sequence, it is due to low energy contour current. And cross-lamination lens-shaped calcarenite (lithofacies 5) being various scale of fine-coarse-fine sequence, is higher energy contour current deposits. The δ13C, δ18O, 87Sr/86Sr and trace elements of these lithofacies show distinctly different features. They are helpful to reconstruct paleo-environment including relative sea-level, paleosalinity, and paleoclimate. The relative sea-level showed rising feature consisting of 3 rising-falling cycles, paleosalinity also display 3 high-low cycles, and the paleoclimate conclude 4 dry-moist cycles. Contour current usually active dramatically when relative sea-level is rising, salinity changes obviously and environment is relatively moist, but turbidity current and debris flow are inverse.

Keywords: Khewra Sandstone, Potwar, Deltaic, Coastal Plain , GR Facies

Khewra Sandstone of Early Cambrian age is proven reservoir rock of Potwar Plateau, Upper Indus Basin, Pakistan. The Khewra Sandstone is largely considered as deposit of deltaic environment. Whereas few geologists are of the view that Khewra Sandstone is part of coastal plain. The distinction between the deposits of above two environments is often very difficult in the absence of regional seismic data.This paper is based on comparative studies of GR facies of Khewra Sandstone and its relative interpretation in Adhi Field. The study shows that over all lithology of Khewra sandstone is same in Potwar and Salt Range & is interpreted as part of coastal plain deposit with mixed Beach-aeolian environment.

Seismic expression, distribution, and paleo-oceanographic implications of contourite deposits in the Browse Basin, offshore NW Australia

David Ricardo Pedreros-Bastidas[1*], Christopher Aiden-Lee Jackson[1,2], Rebecca E Bell[1]
1. Earth Science and Engineering, Imperial College London, London, UNITED KINGDOM
2. Department of Earth and Environmental Sciences, The University of Manchester, Manchester, UNITED KINGDOM
E-mail: drp418@ic.ac.uk

Keywords: Contourites, NW Australia, Deep marine deposits, Sedimentology, Facies

Contourites are marine sediments deposited by thermohaline-induced bottom currents. The distribution, geometry, and size of these deposits are controlled by the presence, direction, and strength of their causal currents, thus they can be sensitive indicators of changes basin geometry, sea-level change, tectonics, and (paleo)oceanography. In this study we use 2D seismic reflection datasets (covering an area of c. 75,000 km) from the Browse Basin, offshore NW Australia to study the interaction between marine currents and tectonics. This is a key location to study, given the abundance of geophysical imaging, and the past and present occurrence of several major thermohaline currents that swept a tectonically active margin. Using 2D seismic data has an advantage since they image large areas of the Earth's subsurface; however, the spacing between individual 2D lines (i.e., 10 km by 10 km) mean it can be difficult to map the distribution and orientation of the contourite deposits smaller than that spacing. We show that the basin contains five main Palaeocene-to-Miocene and Recent seismic-sequences (S1 to S5), which in this area and for the purpose of this work were divided into two main groups. Group 1 comprises seismic sequences (S1-S2) and each of them are 800-1000 ms TWT thick, containing continuous to semi-continuous, low-to-moderate amplitude reflections. It is important to note that S2 can be split into two sub-sequences; the lower sub-sequence has a similar seismic expression to S1, whereas the upper one contains discontinuous, low-amplitude reflections, maybe suggesting slight changes in the energy conditions. The seismic character of Group 1 (and the lower part of S2) is not strongly indicative of deposition under the influence of contour currents, thus we infer they reflect deposition under pelagic to hemipelagic conditions. The second group comprises the middle to upper seismic sequences (S3 to S5) and has a very different seismic expression to Group 1, recording different depositional conditions. The internal reflections found in the sequences of Group 2 define constructional contourite bodies that are locally scoured by channels. S3 contains large (400 ms TWT high by 10 km long wide by 5 km long) clinoforms that are intensely gullied. These clinoforms may document progradation of the carbonate-dominated basin margin or the development of giant bedforms under the influence of bottom currents. Sequence S4 also contains large (up to 300 ms TWT high), steeply dipping clinoforms, whereas the shallowest and youngest sequence, S5 extends up to the seabed and contains abundant evidence for locally deep (up to 200 - 300 ms TWT by a few hundred metres wide) erosion, and the formation of contourite bedforms and related scours found in Group 2, maybe controlled by the Antarctic Intermediate Water and the NW Indian Intermediate Water or their ancient predecessors. Thus, sequences S3 to S5 record a contourite-bearing depositional system strongly affected by the action of bottom currents. The distribution and scale of the described geo-bodies permitted us to interpret potential directions of the bottom currents affecting the deposits, showing how they may have changed as the basin evolved.

Depositional patterns and potential analysis of the 2nd member of the Shahejie Formationin J oilfield of the Liaodong Uplift , Bohai Sea

Hongliang Song[1*], Wei Yang[1]
1. National Offshore Oil Corporation (CNOOC) Limited, Bohai Oilfield Research InstituteChina , Tianjin, CHINA
E-mail: songhl2@cnooc.com.cn

Keywords: J oilfield, The 2nd member of the Shahejie, reservoir, Depositional patterns, potential analysis

The clastic rocks, dolomite and their mixed deposits were drilled in the Es2 of the Paleogene in the J Oilfield. The rapid lateral variation and unclear distribution of the above three types of rock reservoirs have affected the exploration of J Oilfield. Based on logging data, core description, conventional sheet and cast sheet, combined with palaeotopography, paleoclimatic, and paleo-salinity, the study shows that braided channel delta deposits, carbonate platform deposits, deep lake deposits and semi-deep lake deposits are mainly developed in the Es2, and the above three show the characteristics of the wax and wane. The potential for development of dolomite reservoir is small through the study of the main controlling factors of the reservoir physical properties on the basis of sedimentary model, thin section observation and correspondence physical properties analysis, combined with the reservoir distribution characteristics. The sand body on the west side with larger potential is widely distributed on the early age of Es2 Formation according to the seismic phase and attribute characteristics, which is the next major area of adjustment. This method can be used for reference to research similar reservoirs and tap potential in Bohai Bay basin.

Response of marine terrigenous sediment to source-sink processes and weathering intensity in the northern South China Sea since the past 244 kyr

Zhang chi[1], Yang shouye[1*], Huang xiangtong[1], Li fangliang[1]
1. School of Ocean and Earth Science, Tongji university, Shanghai, CHINA
E-mail: syyang@tongji.edu.cn

Keywords: South China Sea, continental margin, Kuroshio intrusion, sea-level change, chemical weathering

The Asian continental margin has been an ideal natural laboratory to catch a glimpse of paleo-climate and source-to-sink processes. However, exploring the past environment information documented in marine siliciclastic records requires a comprehensive knowledge of the influence of sea-level fluctuations, chemical weathering, sediment provenance, and particulate transport on proxies' interpretation. The northern South China Sea (SCS) margin has attracted plenty of investigations due to huge sediment discharges and continuous deposition since the late Cenozoic. Here, based on a 35 m-long sedimentary core (MD12-3429) retrieved from the northern SCS continental slope, we present the results of mass accumulation rates (MAR), grain-size end-member modeling, elemental compositions, and Sr-Nd isotopes in siliciclastic sediments, in order to extract the chemical weathering and Kuroshio intrusion signals stored in marine terrigenous sediment over the past 244 kyrs. On the basis of major and rare earth elements and Sr-Nd isotopic data, Taiwan rivers were identified as the primary source for terrigenous particles in the core, while the sediment from the Pearl River increased during the glacial period. According to grain-size end-member modeling and MARs results, two different hydrodynamic modes, the sea level changes and the Kuroshio intrusion, govern the sediment source-to-sink processes on the continental slope. On the one hand, the dropped sea level promoted the progradation of paleo-Pearl River mouth, which lead to its contribution increased during low-stand intervals. On the other hand, enhanced Kuroshio intrusion into the northern SCS during the prevailing winter monsoon period and El Niño-like conditions might have played an important role in transporting Taiwan sediment during glacial-interglacial cycles. Most major elements and weathering indices (such as CIA, CIW) show great correlation with Al_2O_3/SiO_2, indicating significant hydrodynamic effects. The K/Al ratio and the stacked chemical weathering index (SCWI) were applied to reconstruct the history of chemical weathering. For the past 244 kyr, our chemical weathering indexes generally exhibited high weathering intensity in the interglacial period that in the glacial period and can correlate well with Younger Dryas (YD), Heinrich 1 (H1) events, indicating climate-depend of chemical weathering intensity. Nevertheless, strengthening chemical weathering intensity periods were also observed during two glacial intervals (MIS5 and MIS3). We propose that subaerially exposed and chemically weathering of Taiwan sediment on the continental shelf may account for this phenomenon.

Shelf-margin architecture and deposition variability across the mid-Pleistocene climate transition, northeastern South China Sea

Hanyao Liu[1], Changsong Lin[2*]
1. Department of Military Oceanography and Hydrography & Cartography, Dalian Naval Academy, Dalian, Liaoning, CHINA
2. School of Ocean Sciences, China University of Geosciences, Beijing, Beijing, Beijiing, CHINA
E-mail: lincs58@126.com

Keywords: Sequence stratigraphy, glacio-eustasy, shelf-margin growth, mid-Pleistocene climate transition, Pearl River Mouth Basin

The shelf-margin prism of the Upper Pliocene to Pleistocene in the northeastern South China Sea has recorded significant signatures of glacio-eustatic cycles and paleo-climatic conditions. Integrated analysis of 3D seismic, well-logging, and borehole dating data in the study area provided a detailed depiction of the high-resolution sequence architecture and depositional evolution as they responded to the glacio-eustatic cycles and climate changes. The shelf-margin section of the Upper Pliocene to Pleistocene is comprised of a composite sequence bounded by a regional unconformity, which can be further divided into five sequences confined by subordinate unconformities. The two lower sequences (S1-S2) with similar and simple internal structures, are displayed as having roughly equal thicknesses (ca. 50 m) and gently seaward-dipping foresets. In contrast, the upper three sequences (S3-S5) are characterized by the development of high (200–600 m) and steep (2–5◦) shelf-margin clinoforms, which can be further divided into fifteen clinothems. The sequences generally embody four systems tracts, showing different stratal stacking patterns, and the linking contemporaneous depositional systems including fluvial channels, deltaic and slope fan systems are documented. Based on the chronostratigraphic framework, comparisons have been made between the sequence cycles and the global oxygen isotopic records. The results suggest that the formation of different order sequences may have been in response to the glacioeustatic cycles paced by the Milankovitch orbital cyclicity. The abrupt changes in the sequence and depositional architectures between S1-S2 and S3-S5 are assumed to be related to the significant increases in the amplitudes and durations of the glacio-eustatic fluctuations across the mid-Pleistocene climate transition (MPT). Intensively variable climatic conditions with strengthened monsoons during and after the MPT could have potentially led to an abundant sediment supply, which may have enhanced the development of shelf to shelf-edge delta systems with the large-scale prograding clinoforms.

OSL and radiocarbon dating of a core from the Bohai Sea in China and implication for Late Quaternary transgression pattern

Zhongbo Wang[1*], Zhongping Lai[1]

1. Guangdong Provincial Key Laboratory of Marine Disaster Prediction and Prevention, Institute of Marine Sciences,, Shantou University, Shantou, Guangdong, CHINA

E-mail: zhbwang@stu.edu.cn

Keywords: Bohai Sea, Transgressions, Late Quaternary, Quartz OSL dating, Radiocarbon dating, Sea-level changes

The Bohai Sea is a semi-enclosed continental shelf sea in northern China. Three transgression layers have been identified from the Late Quaternary strata in the western Bohai Sea and the coastal regions, which provide critical information on Late Quaternary sea-level fluctuations and landscape development. The three transgression layers were previously assigned to Marine Isotope Stage (MIS) 1 (transgression 1, T1), MIS 3 (T2) and MIS 5 (T3), respectively, mainly based on 14C dating. However, this chronological framework aroused an enigma that the regional sea level in MIS 3 was even higher than that of MIS 5, conflicting with the context of global sea-level pattern. In order to clarify this issue, here quartz optically stimulated luminescence (OSL) dating (four samples) was used to constrain the T2 chronology of borehole TJC-1 from the western Bohai Sea. Radiocarbon samples (eight) of peaty sediments were also measured for reference and comparison. All the four OSL samples showed saturation ages of >80 ka, suggesting that the T2 layer should have formed at least in MIS 5, instead of in MIS 3. Radiocarbon ages in T2 should have been severely underestimated, with a saturation age range of 22-30 cal. ka BP, similar to all the previous published radiocarbon ages. The renewed OSL chronological framework for Late Quaternary transgressions in the western Bohai Sea is in better compliance with the history of global sea-level change.

Suspended sediment transport in Minjiang River Estuary and northern Taiwan Strait-TS system

Ai-jun Wang[1*]

1. Lab for Coast and Ocean Geology, Third Institute of Oceanography, Ministry of Natural Resources, Xiamen, Fujian Province, CHINA

E-mail: wangaijun@tio.org.cn

Keywords: sediment transport, river plume,. muddy sediment area, Taiwan Strait, Minjiang River Estuary, bottom tripod observation

The muddy sediment area in the north of the Taiwan Strait is the end of the mud belt along the coast of Zhejiang and Fujian. Its material source is affected by the substances entering the sea not only from the Yangtze River, but also a from nearby Minjiang rivers and rivers on the west coast of Taiwan. Therefore, the study of material transport in the mud sediment area in the north of the Taiwan Strait is of great significance to understand the material source and sedimentary environment evolution at the end of the Zhejiang Fujian mud belt. The observation results show that the salinity of the surface water in the Minjiang Estuary and northern Taiwan Strait gradually increases from the Minjiang Estuary to the south, the lowest salinity occurs in the southern Minjiang Estuary, the highest chlorophyll value appears, and the water turbidity is relatively high, indicating that the water body in this area is obviously affected by the Minjiang River. The salinity of the bottom water is the lowest in Xinghua Bay, and gradually increases towards the mid-Taiwan Strait. The areas east of Pingtan Island is covered by high salinity water, while the chlorophyll value is very low, indicating that this horizon is no longer affected by the substances delivered by Minjiang River. The high value area of water turbidity mainly occurs from the coastal waters around Pingtan Island to the Xinghua Bay estuary.

The bottom tripod observation results show that the salinity of the water on the north side of Pingtan Island changes greatly during the tidal cycle. During the low tide, it is obviously affected by the river plume from the Minjiang estuary, and the sediment transport is carried to the southeast, indicating that the sediment from the Minjiang River into the sea makes a great contribution to the muddy sediment area in the north of the Taiwan Strait.

Linking source and sink: geochemistry and zircon U-Pb ages provenance record of drainage systems in potential provenance area and Yinggehai-Qiongdongnan Basin, South China Sea

Fulin Meng[1], Hua Wang[1*], Huajun Gan[1]
1. Ministry of Education, China University of Geosciences, Wuhan, Hubei, CHINA
E-mail: wanghua@cug.edu.cn

Keywords: Yinggehai Basin, Qiongdongnan Basin, Provenance, Geochemistry, Zircon U-Pb age

The Yinggehai Basin (YGHB) and Qiongdongnan Basin (QDNB) has received a large amount of terrigenous sediment from different continental blocks since the Paleogene, preserving Cenozoic sedimentary records of the Tibetan Plateau uplift, the tectonic activity of the adjacent plate, and climate change in Southeast Asia. Large scale of oil and gas reservoirs have been discovered in the YGHB and QDNB recently, but the provenance of the marine sediments in this area are poorly understood. In this study, sandstone samples were taken from drilling cores in the joint area of YGHB and QDNB, and cover all Oligocene, Miocene and Pliocene formations. The trace element, rare earth element (REE) and detrital zircon U-Pb geochronology of sedimentary rocks from the Oligocene to Pliocene is examined in this study to investigate the temporal and spatial variations in provenance since the early Oligocene. The Red River has been supplying sediments with positive Eu anomalies from basic-ultrabasic metamorphic and volcanic parent rocks to most parts of two basins, while Hainan Island has delivered sediments with negative Eu anomalies from granitic and sedimentary parent rocks to the eastern slope area of YGHB. The U-Pb ages of detrital zircon range from 3000 to 30 Ma, suggesting that sediment input is derived from multiple sources. Importantly, the Upper Oligocene Formation contained exclusively Cenozoic, Mesozoic, Palaeozoic, and Proterozoic zircon ages, and the age spectrum showed two major peaks at ca. 245 and 423 Ma, indicates that Upper Oligocene sediments in the northwestern area of the QDNB may have originated from the Red River, which had four major peaks at 254, 418, 751, and 1848 Ma, suggesting that sediments from the Red River entered the QDNB as early as the Late Oligocene. Detailed analyses of these components indicate that both the Red River and Hainan are likely the major sources of the sediments in the two basins, with additional minor contributions from Central Vietnam. The reconstructed provenance evolution model reveals that the Red River Provenance (RRP) provided the sedimentary materials for the Central Depression in the YGHB and western QDNB from the Oligocene to the Pliocene, and it was also one of the sources of the sediments deposited on the Yingdong Slope during the Miocene. Most of the sediments preserved in the Yingdong Slope and QDNB areas were derived from the Hainan Island Provenance (HIP) from the Oligocene to the Pliocene, and sediments deposited in the Central Depression in the YGHB were also derived from the HIP during the Miocene. The joint area of two basins had a mixed sediment source area, including the RRP and HIP, during the Cenozoic.

Sediment provenance and drainage evolution of small mountainous rivers in Taiwan since the last glaciation

Keywords: provenance analysis, climate change, source-to-sink, Late Quaternary, East Asia, clay minerals

As an important component in East Asia sediment source-to-sink systems, small mountainous rivers in Taiwan deliver disproportionately large amounts of sediments to oceans. Although the modern fluvial sediment transport processes, discharge fluxes and sediment compositions have been well investigated, the drainage evolution of these mountainous rivers remains understudied and sediment fluxes are expected to vary greatly in glacial-interglacial cycles due to the tremendous climatic fluctuations. To define how the drainage of Taiwan mountainous rivers has evolved since the last glaciation, we target a sediment core (98 m in length) from the Zhuoshui River delta, western Taiwan and use sediment petrography, heavy mineral analysis, detrital zircon U-Pb geochronology and clay mineralogy to investigate provenance variations and river basin evolution since 60 ka. Sediments of the last glaciation show comparatively high illite crystallinity index values, low metasedimentary lithic fragment and stable heavy mineral contents and similar detrital zircon U-Pb ages with downstream signatures, indicating prominent sediment contributions from the Coastal Plain and Western Foothills regions (elevation < 1 km) during the glaciation. However, characteristics of the deglacial and Holocene sediments indicate high contributions from the higher Hsueshan Range and Central Range regions (elevation > 1 km). We suggest that headward extension and drainage capture since the deglaciation, which was most likely due to the increasing monsoon rainfall, account for the provenance variations in the discharged sediments. This implies a climate-driven drainage reorganization of the small mountainous rivers in Taiwan since the last glaciation. Our findings highlight the previously-overlooked, variable provenance information from Taiwan in glacial-interglacial cycles, and the dynamic source signatures are important to East Asia sediment source-to-sink studies.

Origin and Paleodepositional Environment of the Early Cretaceous Chert in Taolin area, Riqingwei Basin, Eastern China: Evidence from Geochemical Study

Tongtong Chen[1*], Yaoqi Zhou[1], Hanqing Liu[1]
1. School of Geosciences, China University of Petroleum(East China), Qingdao, Shandong, CHINA
E-mail: 244491656@qq.com

Keywords: The continental margin of East Asia, Riqingwei Basin, siliceous rock, orgin, paleodepositional environment

In this study, we performed an inorganic geochemical study of cherts from the Lower Cretaceous Laiyang Formation in Taolin area, Riqingwei Basin, located along the continental margin of East Asia. The study about cherts in Taolin area is relatively weak, so far, the origins of it include exhalative sedimentation, sedimentary-hydrothermal alteration, etc. The goal of this study is to determine the origin and paleodepositional environment of the chert and to establish a depositional model for the Laiyang Formation. An integrated study, involving outcrop investigation, optical observation, X-ray diffraction (XRD) and major, trace and rare element analysis, has been performed on eight chert samples from the Laiyang Formation. These samples contain highly abundant exhalative textures and structures, such as laminae and banded textures, mesh-vein structures and contemporaneous deformations. Thin sections and XRD analyses show that in addition to terrigenous clastics, chert samples are mainly composed of cryptocrystalline to microcrystalline quartz. Based on the petrographic analysis, SiO_2 (58.48%~70.11%; average 63.55%) , Ba/Sr (1.86~6.45; average 3.63) , ΣREE (201.25~247.99; average 221.10) results, $SiO_2/(K_2O+Na_2O)$-MnO/TiO_2 diagram and Fe-Mn-(Cu+Ni+Co)×10 ternary diagram, the chert samples are primarily hydrothermal in orgin, however, portions of samples exhibit effect of terrigenous detrital material. Additionally, $100MgO/Al_2O_3$ (14.11~25.61; average 19.39) , Cu/Zn (0.05~0.44; average 0.24) , MnO/TiO_2 (0.05~0.42; average 0.16) , Al/(Al+Fe+Mn) (0.69~0.85; average 0.75) , δCe (0.86~0.96; average 0.91) and $(La/Ce)_N$ (1.36~1.59; average 1.47) results indicate that the chert samples were deposited on a continental margin in an anoxic environment with strong hydrodynamic conditions. In combination with previous research results, we could conclude that the siliceous rock formed in a continental margin extensional environment.This environment was characterized by well developed hydrothermal activity and anaerobic condition, which was conducive to enrichment of Si and such increased influx of silica to seawater may have been related to the early rifting induced by volcanism. Si-rich hydrothermal fluids were ejected through submarine vents and mixed with seawater to crystallize and precipitate fine siliceous particles, which then underwent diagenetic transformation to form siliceous rocks.

Keywords: Provenance analysis, Source-to-sink, Large river, Drainage reconstruction, China Seas, Tibetan Plateau

Large rivers are bloodlines of continents. Those originating from the Tibetan Plateau and traversing continental East Asia play a critical role in shaping surficial landscape and discharging sediment and nutrient. Although the history of these rivers is relatively short due to continuous Cenozoic perturbations, it has been a long journey to reconstruct their birth and dynamic evolution in which many puzzles and challenges remain. In addition to drainage basin morphometry and thermochronometry and paleoaltimetry of source terranes, the river history is documented in provenance information of ultimate sediment sinks in the China Seas but a regional-scale correlation of provenance data is still developing. In this study, we explore the promise of this holistic perspective in restoring the evolution of three arteries of China (the Yangtze, Pearl, and Red rivers), by compiling and reevaluating a large volume of published provenance data (zircon U-Pb geochronology, K-feldspar Pb isotopes, and whole-rock Nd isotopes) from Cenozoic strata of the East and South China Seas and records of the large river basins. We go beyond the classical averaged paradigm of provenance signatures by carefully investigating intersample variability to provide a basis for grouping comparable samples and detecting outliers. The general inheritance of zircon age spectral patterns and small fluctuation of Nd isotopes in the Neogene strata suggest provenance stabilization in the China Seas and establishment of near-modern drainage configurations. The paleo-drainage basins before the Miocene are interpreted to be smaller than their modern sizes and drainage expansion likely occurred over the Oligocene. Our analysis suggests that the widely accepted model of drainage capture between the Yangtze and Red rivers and its variants may be unlikely. Provenance signatures and paleocurrent measurements of the Paleogene strata distributed in the southeastern Tibetan Plateau margin show inclination to source supply from local terranes instead of through-flowing river systems.

Keywords: sea ice, ice-rafted debris, endmembers analyses, the Okhotsk Sea

Sea ice plays a crucial role in Earth's climate system and its past reconstruction is important to investigate the connections and feedbacks with other climatic components. The sea-ice conditions in the Okhotsk Sea are critical variables for assessing the evolution and response of the surface hydrography and the Okhotsk Sea Intermediate Water to the global climate change. Previous researchers have focused on the south-central part of the sea, however, the history and mechanism of the sea-ice conditions, especially in the source area of the sea-ice formation, are still controversial. Here we examine the history of sea ice activity recorded in core LV87-54-1 recovered from the northern Okhotsk Sea shelf using high-resolution grain-size analyses. We extracted 4 endmembers and use EM4 as the sea-ice proxy, useing AnalySize, a program developed by Matlab platform, to conduct endmembers analyses on the data. According to the ice-rafted debris (IRD) results, seasonal sea ice was persistently predominant in the northern shelf of the Okhotsk Sea since the last glacial. The EM4 content was high and the sea ice activity was intense during the Last Glacial Maximum and Heinrich Stadial 1, while the extreme cold climate condition and weakened moisture transport would allow more sea ice formation. Meanwhile due to relative amplification of the Siberian High with its influence on the northern and eastern Asia, and weakening of the Aleutian Low and location of its center in the northeastern Pacific, strong northern geostrophic winds predominate over the Okhotsk Sea, leading to the active sea ice formation. Sea ice formation decreased at the onset of the Bølling-Allerød warm period. EM4 and IRD levels remained low stably since 11.4ka due to: the Amur River injected more warm fresh water into the Okhotsk Sea, which suppresses subsequent sea ice formation during periods of enhanced East Asian; owing to weakening of Siberian High situated distantly from northeastern coast of Asia, and amplification of Aleutian Low situated in northwestern Pacific near the eastern coast of Kamchatka, eastern geostrophic winds with both northeastern and southeastern components are dominated in the Okhotsk Sea during winters, which occurs a decrease in the sea ice coverage.

Source-sink processes at different scales in the Bay of Bengal since the Last Glaciation and their climate control mechanisms

Jingrui Li[1], Xuefa Shi[1,2*], Shengfa Liu[1,2], Shuqing Qiao[1,2], Hui Zhang[2], Peng Cao[2], Xiaoyan Li[2], Xisheng Fang[2], Xingquan Sun[3], Wenxing Ye[2,4], somkiat khokiattiwong[5], Narumol Kornkanitnan[5]

E-mail: xfshi@fio.org.cn

Keywords: Source-sink, sedimentary pattern, Indian summer monsoon, sea level, Bay of Bengal

Based on the surface and core sediment samples collected from the Bay of Bengal (BoB), source-sink processes at different scales since the Last Glaciation were investigated. We set up a modern sedimentary model with currently highest spatial resolution in the BoB; established age model with high temporal resolution since the Last Glaciation; clarified provenance mixing models and quantified their contributions; made it clear the periodic variation characteristics of terrestrial input and their relationship with the Indian summer monsoon (ISM) and sea-level changes. A “2-3-2” provenance mixing pattern was suggested in the central BoB: Himalaya + Indian Peninsula in the west, Himalaya + Myanmar in the east, Himalaya + Indian Peninsula + Myanmar in the central. Sea level and ISM play controlling roles in the terrestrial supplement from different provenances. The sea level mainly controls the sedimentary pattern through the transfer of the depositional center in the glacial-interglacial scale, while the ISM controls the sediment generation, transport, and deposition process through the control of erosion production, precipitation, runoff, and monsoon circulation. Materials from Indian Peninsula and Myanmar were mainly carried through the surface monsoon circulation. Compared with period before the Holocene, the intensity of the ISM and thus, the southwest monsoon circulation strengthened, which enhanced the transport of Indian Peninsula material to the study area, while the materials from the Indo-Burman Range and Irrawaddy River were limited since they were mainly transported through the northeast monsoon circulation. The estimation results of the quantitative inversion model support the general understanding that the Himalayan source has been dominant since the Last Glaciation, with an average contribution of 70%. However, sediments from the Indian Peninsula and Myanmar have also contributed significant mass to the central Bay of Bengal since 25 ka, especially since 7.5 ka, which has been neglected in previous studies. The percentage of provenance end-member contribution in the Last Glacial Maximum, Heinrich 1, early Holocene climatic optimum, and middle-late Holocene was significantly different, which was closely related to the evolution of the ISM at the millennium scale. The periodicity analysis shows that the percentages of end-member contributions of the three provenances have obvious quarter precession and millennium scale cycles, which provides indirect evidence for the climate control mechanism of regional source-sink processes. These studies provide a basic source-sink connection foundation for regional sedimentology and provide a paradigm for global deep-sea deposition, especially the deep-sea fan deposition pattern.

E-mail: yanshijuan@fio.org.cn

Keywords: Ocean color remote sensing, Turbidity of suspended solids, Multivariate elements, Multivariate statistics

The distribution of turbidity of suspended solidas at the same time cannot be obtained due to the limitation of the survey conditions and the weather environment in the estuary area. To solve this problem on the basis of turbidity of suspended solidas surveying data and remote sensing data in Bohai Sea, the remote sensing water color data closest to the surveying time of each station was extracted, and then the correlation between the measured data of suspended solids data and the ocean color data of the same time in an area near the Yellow River estuary and the central region of the Bohai Sea are calculated in this paper. The results show that the ocean color data obtained from the MODIS 551, 481, 443, and 667 nm bands are highly correlated with the measured turbidity of suspended solids. In the same band, the correlation between the ocean color data and the turbidity data of suspended solids varies in different regions. With the increase in distance from the shore and water depth, the correlation coefficient between the ocean color remote sensing data and the measured turbidity of suspended solids initially ascends. The correlation coefficient between the ocean color remote sensing data and the measured turbidity of suspended solids at the surface is relatively high in the area around the Yellow River estuary with a water depth of approximately 14–16 m compared with that in other areas near the Yellow River estuary. In the central region of the Bohai Sea with a water depth of approximately 16 m, the ocean color remote sensing data show a significantly positive correlation with the measured turbidity data of suspended solids. Based on the above analysis, the model data is selected from the area with good correlation. And then,we established a model to express the relationships between turbidity of suspended solids data at the surface and the ocean color, sediment, water depth, estuary distance, coastal distance, and other factors,which is verified to be effective, and then the model is applied to estimate of turbidity of suspended solids which in the Yellow River estuary.

Detrital zircon records of the deep-time source-to-sink system in northern South China Sea: From orogenic event to provenance transition

Yichao Li[1], Chenglin Gong[1*], Yixin Yu[1], Xiangtao Zhang[2]
1. College of Geosciences, China University of Petroleum (Beijing), Beijing, CHINA
2. Institute of eastern South China Sea, Shenzhen Branch of China National Offshore Oil Corporation Ltd, Shenzhen, Guangdong, CHINA
E-mail: chenglingong@cup.edu.cn

Keywords: Source-to-sink system, detrital zircon, Pearl River Mouth Basin, provenance transition, rain shadow effect

The deep-time source-to-sink (S2S) system focusing on the sedimentary records of pre-Quaternary geological events and paleoclimates is of great significance to reconstruct regional paleogeographic patterns. As a Cenozoic sedimentary basin in northern South China Sea, the Pearl River Mouth Basin (PRMB) experienced complex tectonic evolutionary history, and was characterized by the provenance transition as well as depositional environment change. The intrabasinal low uplifts, coupled to the extrabasinal Pearl River drainage systems, supplied sediments to the basin, forming the deep-time S2S system in PRMB. However, the timing of extrabasinal sediments starting transporting into PRMB remains controversial. Furthermore, the driving mechanism of the transition from intrabasinal provenance to extrabasinal provenance is poorly understood.

Paleogene sandstones from Zhu 1 depression in the northern PRMB provided valuable detrital zircon records for U-Pb geochronology and Eu/Eu* anomaly analysis. The detrital zircon U-Pb ages were used to reconstruct the sediment routing system, and the Eu/Eu* anomalies in detrital zircons were employed to reconstruct the crustal thickness of South China margin. The result shows that there is a single detrital zircon U-Pb age peak in the early Eocene strata, and that the late Eocene strata exhibits multiple detrital zircon U-Pb age peaks. The zircon U-Pb ages comparison between potential source regions and sedimentary basin shows different sediment routing systems during Eocene, indicating the transition from intrabasinal provenance to extrabasinal provenance in PRMB. Meanwhile, Eu/Eu* anomalies in detrital zircons suggest that the crustal thickness increased from ca 30 km to 70 km in South China margin during Cretaceous. This supports the Cretaceous orogenic event in which the Okhotomorsk Block moved with the Izanagi Plate in the direction transition and collided with the South China Block along the east Asian margin. As the response to the Cretaceous orogenic event, the extensive Cathaysian Coastal Mountains developed along the South China margin.

A model is established to explain the relationship between the Cretaceous orogenic event and the late Eocene provenance transition, although there is an obvious span. The Cathaysian Coastal Mountains prevented the humid Pacific air from reaching into the inland of South China, which is known as the rain shadow effect. Therefore, the northwestern side of the Cathaysian Coastal Mountains was arid, whereas its southeastern side was humid. The drainage system developed in humid climate and transported sediments to PRMB along the Cenozoic extensional rift, forming the buffered deep-time S2S system from Cathaysian Coastal Mountains to PRMB.

Keywords: paleoredox evolution, deepwater ventilation, the last deglaciation, the Okinawa Trough

Variability of deepwater circulation during the LGM in the Okinawa Trough (OT) has long been the focus of numerous paleoceanographic studies. However, variations of paleo-redox evolution and initiating mechanism related to deepwater circulation remain unclear. We present molybdenum isotope compositions, redox sensitive elements, and productivity proxies from Core OKT-3 to reconstruct pro-redox conditions and its response to deepwater circulation in the OT since the last deglaciation. Relatively positive value of $\delta^{98/95}$Mo, relatively enrichment of Mo and Cr and low Mn/Al ratio suggested suboxic condition in the OT prior to 11.5 ka. It might be caused by a combination of weak deepwater ventilation in the OT and large amounts of terrestrial freshwater discharge during low sea level period. Negative excursion of $\delta^{98/95}$Mo and slightly enrichment of Mn suggest that deepwater conditions gradually switched from suboxic to oxic during 11.5-7 ka caused by strengthening of the North Pacific Intermediate Water (NPIW) and the South China Sea Intermediate Water (SCSIW) in the OT. The obvious peak of TOC/Al, U/Al and Ni/Al, synchronous with widespread enhanced primary productivity in North Pacific and its marginal sea during 11.5-9.5 ka (PB period) suggested the influence of NPIW within the OT was gradually increasing. Abrupt changes occurred at 7 ka for $\delta^{98/95}$Mo, Mn/Al and Mo_{EF}, Cr_{EF} in OKT-3 suggested oxic bottom water condition. The strengthening Kuroshio Current (KC) induced enhanced advection of NPIW and/SCSIW into the OT facilitated appearance of oxic depositional environment. It's worth noting that strong upwelling triggered high productivity had little influence on deepwater redox condition since 7 ka. Our study suggested better deepwater ventilation and poor organic matter preservation condition likely switched OT from a regional source of venting CO_2 to atmosphere during sea level highstand.

Provenance, Sedimentation and Formation of the Holocene Yangtze Delta: A Multi-approach Investigation

Yuan Shang[1*], Weiguo Zhang[1], Yinglu Chen[1]
1. State Key Laboratory of Estuarine and Coastal Research, East China Normal University, Shanghai, CHINA
E-mail: shangy2010@gmail.com

Keywords: Yangtze Delta, Provenance, Sedimentation of delta process, Zircon U-Pb chronology

Detrital records preserved in the stratigraphy of the delta system provide abundant information related to the Holocene climate change and land-sea evolution. The Yangtze River drainage basin spans longitudinal gradients, links the high Tibetan Plateau and the marginal seas in the western Pacific Ocean, has been mainly affected by Asia Monsoon climate, and under significant anthropogenic modifications recently. The Yangtze Delta (YD), as the main sink of the Yangtze River, its formation process during the Holocene has long been a research subject. In this study, we investigated three sedimentary cores across the YD. By an integrated combination of multiple approaches, including the end-member unmix modelling on grain size data, bulk sediment magnetic properties analysis and detrital zircon U-Pb chronology for sediment source constraints, we aim to decipher a panoramic view of the transport and sedimentation processes and formation history of the Holocene YD. Our unmix modelling shows that although the three cores display distinctive sedimentary compositions, the same sedimentary facies on each core have been under uniform depositional process. The detrital zircon U-Pb provenance records indicate that in the early Holocene, sediment source signature of the upper reaches of the Yangtze basins dominates the Yangtze Estuary sediments. Since the middle Holocene, the YD sediment source shifted to the middle catchments which may be owing to both strong monsoon climate and intensified erosion caused by active human interventions. Marine sourced sediment has likely provided an additional supply for the building of the YD during the last 2 ka.

Keywords: water and sediment transport, Changjiang Diluted Water, cross-shore, Typhoon Chan-Hom

Typhoon Chan-Hom swung by the coast near the Changjiang Estuary on July 11-12, 2015. Post-typhoon surveys, one conducted 3-4 days after Chan-Hom and another exactly one month later, were carried out to investigate her impact on the hydrodynamics, sediment transport and biogeochemical processes of the shelf off Oujiang, nearly 430 km southwest of the Changjiang Estuary. Measured salinity and $\delta^{18}O$ during the first survey showed the presence of a large volume of freshwater, up to 20 m thick, in the upper water column where the Chlorophyll-a concentration was also elevated, indicating additional supply of external nutrients. However, low concentration of suspended particulate matter and particulate organic carbon (POC), and the positive-biased isotopic composition ($\delta^{13}C$) clearly suggest that Chan-Hom caused significant southward transport of freshwater from the Changjiang Diluted Water, but insignificant amounts of terrestrial particulate matter. Measurements of the ^{210}Pb activity of seabed sediments showed post-typhoon freshness of offshore sediment and exposure of “old” sediment inshore, indicating a cross-shore transport of bed sediment during Typhoon Chan-Hom. It has been reported that extremely high resuspension of bed sediment by the typhoon could trigger gravity flows that result in downslope (cross-shore) sediment transport.

Nitrogen fixation changes regulated by EAM system in the northern South China Sea since the last deglaciation

Liwei Wang[1], Feng Ye[1*]
1. Guangzhou Institute of Geochemistry, Chinese Academy of Sciences, Guangzhou, Guangdong, CHINA
E-mail: yefeng@gig.ac.cn

Keywords: last deglaciation, East Asian monsoon system, organic nitrogen isotope, South China Sea

Reconstruction of the nitrogen cycle history is crucial to understand climate changes in the past, present and future, as the marine carbon and nitrogen cycles are tightly coupled. However, the reconstruction of nitrogen cycles and its regulation mechanism in the SCS remain highly uncertain due to the terrestrial inorganic nitrogen (IN) contamination (obscure δ15Nbulk) and the scarcity of high-quality sedimentary records. Here, we present a high resolution δ15N records of organic nitrogen (δ15Norg) since the last deglaciation (16.5 ka) obtained from a well-dated marine sediment core (NH07) in the northern SCS. Unlike most δ15Nbulk records in the SCS, the δ15Norg records show clear response to the typical climatic periods like early Holocene (EH), Younger Dryas (YD), Bølling-Allerød (BA) and Heinrich event 1 (H1). Two possible causes of the observed variations in δ15Norg records are as follows: (1) North Pacific-wide spreading of Eastern Tropical North Pacific denitrification signals through Kuroshio branch and North Pacific Intermediate Water, as δ15Norg show two peaks during the deglaciation, BA and the EH periods, which were identical to the global mean pattern due to the acceleration of global denitrification. (2) Local nitrogen fixation (NF) changes regulated by East Asian monsoon (EAM) system. After careful comparisons of δ15N and climate records from adjacent and global, the latter mechanism shows the most potential to cause the variations in δ15Norg records, and has been further validated by synchronously varying productivity indexs (Opal and ON contents) records in the NH07. Both NF rates and productivity in the SCS were constrained by nutrient supply, which was regulated by the EAM system. Stronger mixing during YD and H1, strong winter moon and weak summer moon, enhances the supply of excess phosphorous (low N:P) from the subsurface waters, thus increased the NF and productivity. This mechanism is consistent with modern observations and glacial/interglacial records in the SCS and the North Atlantic.

Sediment weathering records and "Source-to-Sink" process in the Sunda shelf since the Last Glacial Maximum

Hui Wang[1], Chao Li[1,2*], Junfei Chen[1], Shouye Yang[1,2], Guodong Jia[1,2]
1. School of Ocean and Earth Science, Tongji University, Shanghai, CHINA
2. State Key Lab. of Marine Geology, State Key Lab. of Marine Geology, Shanghai, CHINA
E-mail: cli@tongji.edu.cn

Keywords: Sunda shelf, sediment transfer, provenance, weathering regime

The continental margin is a key area for the study of the combination of sea and land, mainly because the information of climate and sea level change is well preserved in this sedimentary area. The study of terrigenous sediment fluxes in marginal seas is of great importance to the study of global climate change and biogeochemical cycles. The process of terrigenous sediments being weathered and eroded from the source area and sedimentary basin and transported to the marginal sea for deposition plays an important role in the study of "Source-to- Sink" process. The Sunda shelf is the largest shelf in tropical region and the emergence of the broad shelf during glacial period may induce significant change of sedimentary environment. One of the major debate and critical issue for palaeoenvironmental study on the Sunda shelf is how to distinguish the sediment sources and the mechanism of signal transmission, while the key is the impact of shelf emergence on sediment “Source-to-Sink” processes. This study on base of sediment cores drilled by SONNE RV in the continental slop in southwest South China Sea and based on K/Al Rb/Sr CIA WIP and other weathering indexes, the chemical weathering history recorded by 17964-3 cores since 23 ka BP was reconstructed by analyzing the elemental composition of the sediments at the 17964-3 station. It was revealed that the chemical weathering intensity in the glacial period was significantly higher than that in the Holocene. During the last ice age, sea level fell by at most about 120 m compared with the present, and the shelf was widely exposed, we propose that the shelf has played different roles in the glacial-interglacial cycle. In interglacial, the shelf is the Sink of sediments from adjacent rivers in the islands, while it turns to be a Source for sediment deposited in the continental slope during the glacial period. Combined with end-member characteristics of seaborne river sediments around the modern Sunda shelf, we aim to trace the sediment provenance using 234U/238U isotopes and reveal the impact of shelf emergence on sediment transport. Furthermore, we compare chemical weathering intensity and sediment residence time in terms of “comminution age”, in order to find more robust evidences to interpret the enhance of weathering intensity during glacial period.

Fluid inclusion characteristics and material sources analysis of MIS6 stage sediments in the South Yellow Sea

Xiao Huang[1*]
1. Marine Geoscience, Nanjing University, Nanjing, Jiangsu Province, CHINA
E-mail: 1440323211@qq.com

Keywords: South Yellow Sea, Yangtze River, fluid inclusion, material sources

Based on the study of quartz in the Late Pleistocene sediments of core YZ05 from the Yangtze Shoal, the South Yellow Sea, we analyzed the petrographic characteristics of quartz-hosted fluid inclusions, including the number, size and gas percentage, and compared them with the surface fluvial sediments in the upstream, midstream, and estuary of the Yangtze River. It was found that there is a great deal of inclusions in the sediments, in terms of the number and size, most quartz-hosted fluid inclusions are concentrated in the range of 2–5 μm in diameters and 17–47 in number per 10-3 mm3. In addition, quartz-hosted fluid inclusions have different forms, most of which are regular circular, oval or quadrilateral, and the distribution mode of inclusions is mainly banded distribution. The inclusions are mainly secondary, accounting for about 90% of the total. At room temperature, most of the inclusions are liquid-rich and the gas percentage is between 10% and 30%. The characteristics of quartz-hosted fluid inclusions in the sediments of the study area are similar to those of the modern Yangtze River estuary. And there are necking inclusions in the sediments, which indicates that the source rocks of the sediments were formed under high temperature conditions, and the sediments in Shigu in the upstream of the Yangtze River also show the same characteristics. Therefore, our research shows that the sediments in the study area came from the ancient Yangtze River during the Late Pleistocene, and the sediments in the upstream of the Yangtze River reached the South Yellow Sea area at that time.

Study on borehole magnetic strata in northern Liaodong Bay

Zhonglei Wang[1*]
1. Marine Regional Geology Division, Qingdao Institute of Marine Geology, Qingdao, Shandong, CHINA
E-mail: wzhl2010@sina.cn

Keywords: Liaodong Bay, magnetic strata, sedimentation rate and thickness

Liaodong Bay, located in the north of Bohai Sea, is the largest bay in the Bohai Sea. Its sedimentary history is an important window to reveal the tectonic evolution and geographical pattern formation of Bohai sea since late Quaternary. JXC-1 and YKC-2 boreholes are long sequence research boreholes with precise chronological control in the Liaodong Bay.

The continuous low-field magnetic susceptibility measurement and paleomagnetic alternating field demagnetization measurement were carried out, the measurement interval was 2 cm, and the chronostratigraphic framework of the two boreholes was established. The results show that the bottom boundary age of JXC-1 borehole is 1.2 Ma. MBB is located at a depth of 45.18 m, which is quite different from other boreholes in Bohai Sea and its surrounding areas. The bottom boundary age of YKC-2 borehole is about 0.7 Ma, and the deposition of positive polarity of Burong was recorded. No MBB was found. Polarity events such as Gothenburg and Blake are mainly recorded.

The Cenozoic geological structure of Liaodong Bay Depression is mainly characterized by "three depressions intercalated with two convexes", that is, from west to east, Liaoxi depression, Liaoxi uplift, Liaozhong sag, Liaodong uplift and Liaodong depression successively. Based on regional stratigraphic correlation, it is found that the sedimentary thickness of the northern Liaodong Bay has been "thick in the east and thin in the west" since late Pleistocene. Both JXC-1 and YKC-2 boreholes are located in Liaodong Bay Depression. The sedimentation rate and thickness of the two are different, mainly due to the influence of neotectonic movement, namely the Quaternary activity of TanLu Faults. During the past 1 Ma, the Liaozhong sag has been in a state of rapid subsidence compared with the Liaoxi sag, but the subsidence depth cannot be predicted because no marker layer has been detected in YKC-2 borehole.

According to the sedimentary thickness since the Middle Pleistocene, the Bohai Sea and its surrounding areas can be divided into four regions: Bozhong Area, Liaodong Bay Area, Bohai Bay Area and Laizhou Bay Area. Among them, Bozhong area is the subsidence center, and MBB has the deepest burial depth in the whole area. The main tectonic units in Bohai Bay area and Laizhou Bay Area are Huanghua depression and Jiyang Depression respectively, and the burial depth of MBB gradually deepens from south to north. MBB buried depth in Liaodong Bay Area is the shallowest among the four regions. The deposition of the whole Bohai Sea and its surrounding area is relatively continuous, and the deposition thickness decreases from the center to the periphery of the Bozhong depression. These results indicate that, based on the control of neogene tectonic basement, the influence of Tanlu faults activity since the late Pleistocene has been superimposed to control the variation of sedimentary thickness in the region. This study deepens the understanding of tectonic and sedimentary evolution models in this area.

Evolution of sedimentary environment during syn-rifting stage in the deep water area of Pearl River Mouth Basin

Hao Fan[1], Yuantao Liao[1,2*], Yican Mao[1], Shuai Zhang[1]
1. College of Marine Science and Technology, China University of Geosciences (wuhan), Wuhan, Hubei, CHINA
2. Hubei Key Laboratory of Marine Geological Resources, China University of Geosciences (Wuhan), Wuhan, Hubei, CHINA
E-mail: ytliao@cug.edu.cn

Keywords: South China Sea,paleogeographic evolution,sedimentary environment

For a long time, it has been widely believed that the sedimentary environment of the Pearl River Mouth Basin is mainly continental environment during the syn-rifting period. With the deployment of IODP scientific drilling as well as high resolution seismic survey in the deep water area of Pearl River Mouth Basin, the previous argument has met challenge and some studies show that marine transgression may have occurred in the deep water area during the syn-rifting period, especially the marine strata initially developed in mid Eocene. However, there is poorly understanding on how the sea-land environments progressively changed. Therefore, it is very important to detailed analyze the evolution of the sedimentary environment and characteristics of the sedimentary systems during the syn-rifting period in the deep water area. This research is of great significance to understand the formation, evolution of the South China Sea and petroleum exploration in the deep water area.

This study focuses on the deep and ultra-deep water area (ZhuIV Depression) in the Pearl River Mouth Basin. Through the comprehensive correlation of the sedimentary environment between neighbor sedimentary basins and paleogeomorphology reconstruction, it is believed that the transgression of sea water from east to west controlled the change of the paleogeographic transitional patterns during the syn-rifting period. According to the evolution of provenance area, combined with seismic facies-sedimentary facies analysis, the distribution and evolution of sedimentary systems during the syn-rifting period in the study area were clarified. During the lower member of Wenchang Formation development (early mid-Eocene), the eastern margin of the study area was generally open proto-SCS, small sags are characterized by diffuse extension and isolated lacustrine basins in response to high angle faults activities. During the upper member of Wenchang Formation deposition (late mid-Eocene), the Heshan and Xingning sags were mainly dominated by lacustrine deposits due to the local uplift barriers, though the basin was expanded. Some straits were formed and connected with proto-SCS in the southern Liwan sag and the eastern margin of Jieyang and Jinghai sags due to strong detachment fault activities. The sedimentary environment was transferred to marine-continental transitional facies or restricted bay. During the Enping Formation deposition (late Eocene), the range of transgression gradually expanded, coastal-neritic environment appeared throughout the study area.

Early diagenesis of trace metals (Ni, Cu, Zn, Cd, Mo, and U) in sediments from the Changjiang River estuary and implications for the marine element cycles

Zhiwei He[1], Shouye Yang[1*]
1. State Key Laboratory of Marine Geology, Tongji University, Shanghai, CHINA
E-mail: syyang@tongji.edu.cn

Keywords: estuary, porewater, element cycle, early diagenesis

Estuaries play an important role in the transfer of terrestrial trace metals from continent to ocean. Most terrestrial dissolved trace metals are known to be particle-reactive and largely scavenged in the estuarine mixing zone. The immobilization of trace metals at these depositional settings can have significant impact on the global cycles of these metals. In this study, porewater and solid phase data for redox-sensitive, bio-active trace metals (Ni, Cu, Zn, Cd, Mo, and U) were collected on a transect across the Changjiang River estuary at different water depths with varying bottom water oxygen concentrations. We evaluate the respective mechanisms of trace metal accumulation, retention and remobilization during early diagenesis across the physical and chemical gradients. We demonstrate that porewater exchange processes are the predominant mechanism for solute transport between sediments and overlying waters. Sediments are characterized by authigenic fixation of these trace metals through either diffusive uptake or transfer via a particulate phase from water columns. The studied trace metals show differential behavior during early diagenesis: (1) Cu, Zn, and Cd are intimately associated with organic matter; (2) Ni, Mo, and U are closely linked to diagenetic reactions of Mn-Fe oxides. Transient redox conditions, due to the dynamics of the mobile layers, strongly influence the trace metal distributions in both sediment and porewaters. Zinc and other trace metals such as Cd and Mo mainly form authigenic accumulate as solid sulfide precipitates or co-precipitation with Fe-sulfides under conditions of anoxia where sulfide is present, while authigenic U accumulation is mediated by microbially-produced Fe(III) and sulfate reduction at depth. Instead temporarily more oxygenated conditions could have resulted in transient re-oxidation and recycling of trace metals through diffusion across the benthic boundary. These findings thus suggest that elements and nutrients have undergone significant biogeochemical transformations under dynamic environments in the estuary before reaching the open ocean, which have important implications for the global marine element cycles.

Sources and transport processes of sediments on shelf and deep-sea basin: Constraints from quartz particles characteristics

Chunhui Xiao[1*], Yonghong Wang[1], Kaiwei Wang[1]
1. Key Lab of Submarine Geosciences and Prospecting Techniques, MOE and College of Marine Geosciences, Ocean University of China, Qingdao, Shandong, CHINA
E-mail: xiaochunhui@ouc.edu.cn

Keywords: Quartz surface microtextures, Source to sink, South Yellow Sea, Parece Vela Basin

Abstract: Quartz has high hardness, excellent chemical stability, and outstanding weathering-resistance capability, so that the surface microtextures of quartz particles can provide abundant information and details about the sedimentary environment. Due to different geological processes, its surface will form different morphological features, the surface microstructure of quartz particles is closely related to the transport history of sediments and sedimentary environment, and can be used as an indicator of sedimentary environment (Vos et al., 2014), and is of great significance to reveal the provenance, hydrodynamic, and source-to-sink process from inland to deep-sea basin. Scanning electron microscopy observation, geometric parameters analyses, surface microstextures statistics, crystallinity index, and oxygen isotope analyses were performed on the quartz grains extracted from the three core sediments. Two of them from the shelf of the South Yellow Sea (cores H07 and B02) and one from the Parece Vela Basin of the western Pacific Ocean (core C-P19). By comparing the different microstextures and chemical features of quartz from desert, estuary, coastal zone, shelf to deep-sea basin, we can understand the quartz particles sources-to-sink and transport processes. The main findings are as follows, some quartz particles which is able to reach the shelf and deep-sea basin are generally come from Mu us, Badain Juran, and Tengger desert, however, most of quartz on shelf and deep-sea basin come from the nearby sources, only small part comes from aeolian sources. The quartz particles on the shelf mainly come from the fluvial sediment of Yellow River, Yangtze River, and erosive materials along the Shandong Peninsula. Although the cores in shelf are located on the transport path of the East Asian winter monsoon, there are little aeolian dust quartz particles input founded, which may be due to the sufficient supply of near source materials, covering up the small amount of aeolian dust input signals. The features of quartz particles in the muddy area of the continental shelf are different from those outside the muddy area. The properties in the muddy area are similar to those in the deep-sea basin, both with the small particle size, worse IPP roundness (Powers et al., 1953; 1982), and the surface microtextures is mainly mechanical, accompanied by a certain degree of chemical dissolution. The quartz particles on continental shelf but outside the muddy area has larger particle size, better IPP roundness, and the surface microstextures is mainly mechanical with little chemical dissolution. The above results show that the source of quartz particles and local hydrodynamic force jointly determined the properties of quartz particles in the region, but hydrodynamics seem play the more important role in the distribution of quartz in shelf and deep-sea basin.

Deep-time source-to-sink process in eastern China margin

Xiaowei Fu[1*], Weilin Zhu[1], Shouye Yang[1], Rong Yang[2]
1. Tongji University, State Key Laboratory of Marine Geology,, Shanghai, CHINA
2. School of Earth Sciences, Zhejiang University, Hangzhou, Zhejiang Province, CHINA

Keywords: East Asia, Source to sink, landscape evolution, large river system

Source-to-sink philosophy is a geological approach that provides an integrated framework with which to observe geological processes as a continuous and causal system. During the Cenozoic, pronounced landscape changes occurred in the east China margin, companied by reorganizations of large river systems. However, details about these processes remain poorly understood and are hotly debated. In this research, a large number of detrital zircon ages from potential source areas and Cenozoic sediment from the eastern margin of China are systematically compiled. Furthermore, the landscape significance of rift basins in eastern China is also discussed based on the sedimentation patterns. The zircon age spectra in the South Yellow Sea Basin vary significantly in space and time, indicating that the sediment was mainly supplied by local rivers and that the region lacked a dominant large river. In contrast to the South Yellow Sea Basin, three phases of zircon age features were observed in the East China Sea Basin (ECB). Palaeocene-early Eocene sediment exhibiting overwhelmingly late Mesozoic ages was sourced from transversal rivers located around the subsidence centre. This scenario, together with isolated rift basins in eastern China, suggests basin-and-swell physiography. Most of the mid-Eocene to mid-Miocene samples in the ECB show complex zircon age spectra, which are typified by a high proportion of Palaeoproterozoic ages with North China Block and Korea affinities. The dominance of fluvial sediment in the northern part of the ECB means that a large river formed and flowed along the ECB. Since this study represents the first documentation of this river, we name it the East Asia River (EAR). The branch along the South Yellow Sea is named the Sino-Korea River, and the branch that flowed over the Yangtze Block is named the paleo-Yangtze River. The paleo-Yangtze River might have reached the Jianghan Basin starting in the Miocene. ECB samples from the late Miocene to Quaternary are characterized by a high content of Neoproterozoic ages showing present-day Yangtze River features. The evolution of the EAR and deposition in rift basins indicate that the early Cenozoic basin-and-swell physiography terminated in the middle Eocene and was replaced by a southward-tilting landscape across the Korea-South Yellow Sea Basin-ECB region. Resulting from the eastward migration trend of the extension centre in the ECB, the EAR migrated from the western depression zone of the ECB to the eastern depression zone in the late Eocene. The detrital sediment delivered by the EAR became prevalent in the Taiwan region starting in the early Miocene. Our work provides shed new light on the landscape evolution and reorganizations of large river systems in east Asia.

Evolution of sedimentary environment in the eastern shelf of China since ~ 1 Ma and its relation to sea level and climate change

Zhenqquan Yao[1*], Xuefa Shi[1], Jianxing Liu[1], Shuqing Qiao[1], Yanguang Liu[1]
1. Marine Geology, First Institute of Oceanography (FIO), MNR, P.R.China, Qingdao, Shandong, CHINA
E-mail: yaozq@fio.org.cn

Keywords: Sea level, continental shelf, sedimentary environment, glacial-interglacial

The sedimentary environment on the shallow continental shelf provides information on sea level, climate change, and local tectonic changes at the orbital scale. We have performed high-resolution chronological and sedimentological analyses of cores in the Bohai Sea and the Yellow Sea. Through astronomical orbital tuning methods, we established high-resolution age models on orbital time scales for the past ~1 My. Sedimentological analyses and environmental indicators suggest that the sedimentary environment is characterized by alternating shallow marine and coastal/alluvial sedimentary cycles controlled by glacial-interglacial sea-level changes. This result confirms the previous hypothesis that sea-level fluctuations play a dominant role in the sedimentary sequence in this region. In addition, only low-frequency sea-level fluctuations (~100 kyr) are preserved in the South Yellow Sea sedimentary sequence; however, high frequency (~40 kyr) sea-level variations are also preserved in the shallower Bohai Sea sediments, in addition to the 100 kyr cycle. Despite the large spatial variation, this finding suggests that the sedimentary environment of the eastern China margin has been influenced by sea-level changes uniformly over the last million years.

Tectonic Subsidence of the southeast China coast: new evidences from Late Pleistocene transgression in Ningde bay

Ping Liu[1], Jing Chen[1*], Jie Zhang[1]
1. State Key Laboratory of Estuarine and Coastal Research, East China Normal University, Shanghai, CHINA
E-mail: jchen@geo.ecnu.edu.cn

Keywords: Sedimentary geochemistry, Late Quaternary transgression, regional subsidence, land-sea interaction, ancient Zhejiang-Fujian Uplift (ZFU)

Subsidence of the ancient Zhejiang-Fujian Uplift (ZFU) is important to understand opening of the Chinese marginal seas and geomorphology of the east China coast. However, little was known about its subsidence history during the Quaternary. In this study we clarify three marine sedimenty layers constrained by luminescence (OSL) chronology in Ningde area of the southeast China coast, to reveal the regional subsidence process related to the ancient ZFU. The results show that three marine sedimentary layers above bedrock in Ningde area are formed during global sea-level highstands of MIS1, MIS3 and MIS5e, constrained by OSL datings of the three representative cores. Limited marine influence of MIS5e highstand indicated both by microfacies of the representative core and by the paleo-shorline outlined from 120 cores, implies that tectonic subsidence occurs here during the Late Quaternary. The offsets between the peak global sea level and the corrected paleo-shoreline elevations of MIS5e and MIS3 reveal that the average subsidence rate is ~0.5 m/kyr since MIS5e and ~0.8 m/kyr between MIS5e and MIS3 in Ningde area. These evidences suggest that the ancient ZFU possibly subsided rapidly since MIS5e and stabilized since MIS3. This study provides new insights to subsidence history of the ancient ZFU and land-sea interaction in the tectonic subsidence region.

Detrital zircon size and U-Pb geochronology in the Mud Belt of the East China Sea: Implications for provenance analysis

Xiangtong Huang[1*], Ergang Lian[1], Simon V. Hohl[1], Shouye Yang[1]
1. State Key Laboratory of Marine Geology, Tongji University, Shanghai, CHINA
E-mail: xiangtong@tongji.edu.cn

Keywords: detrital U-Pb geochronology, provenance analysis, the Mud Belt of the East China Sea, zircon grain size, residual deposits

With the rapid developments of in-situ analytical instruments and techniques, especially, the laser ablation inductively coupled plasma (LA-ICP-MS), detrital zircon U-Pb geochronology has become the most popular toolkit for provenance analysis over the past two decades. Although numerous studies exist and a myriad of dates have been generated in this community, little attention has been paid to recent sediment deposited on continental margins. Some critical questions have been raised from the literature on the feasibility of zircon U-Pb geochronology in provenance analysis due to the issues of fertility, size effects and the nature of recycling, which urgently appeal us to examine sediments deposited in recent history of Earth thoroughly due to relative abundant information on sources, transport and deposition is available. In this contribution, we examine spatial distributions of zircon grain sizes and U-Pb ages in the Mud Belt of the East China Sea (ECS), aiming to 1) address whether changes in grain size of zircon grains have discernible effects on U-Pb ages and 2) to discuss how provenance signals of zircons can be preserved, modified, and propagated from river point sources to the sinks of the sediments.

The most pronounced feature of zircon grains in the ECS is a fining trend along the Mud Belt from the Yangtze Estuary, sub-aqueous delta in north to the distal end in south, with average equivalent spherical diameters (ESD) decreasing from a range of 100-150 μm to that less than 50 μm. We propose two competing interpretations for this fining trend. The first is due to the loss of mineral abrasion during the transport and the second is as the results of hydrological sorting. The latter is favored because the mean grain sizes between zircon grains and the host sediments are in good agreements with the prediction of the impact law that describes size shifts among different minerals of different densities from a theoretical perspective. Moreover, although there are significant contrasts in zircon grain sizes, most samples in the Mud Belt, except for those located in the distal south end and those close to the coastline, have very similar or identical kennel density estimates (KDE) of U-Pb ages. In addition, as evidenced by high values (>0.9) of Bayesian Population Correlation (BPC) of U-Pb ages and short distances to the modern Yangtze U-Pb ages in a 3D multi-dimensional scaling (MDS) diagram, provenance signals inherited from various fluvial sources could be considered as the most important factor that has determined the U-Pb geochronology in the sediment. At last, we quantitatively estimate the relative contributions from different rivers and residual deposits on the continental shelf using a forward mixing model. Interestingly, our preliminary results suggest that, on average, ca. 20 to 45 % of zircon grains in the Mud Belt have been derived from the the residual deposits formed on the continental shelf during low sea-level stages in the late Quaternary.

Climatic and environmental impacts on the sedimentation of the Southwest Taiwan margin since last glaciation: Clay mineralogical and geochemical investigations

Joffrey BERTAZ[1,2*], Zhifei LIU[1], Christophe COLIN[2], Zhimin JIAN[1], Yanli LI[1]

Keywords: Clay Minerals, Major Elements, Sedimentology, Weathering, East Asian Monsoon, South China Sea

Scientific studies have focused on the understanding of present and past source to sink processes and their controlling factors over the last decades. In a context of global climatic and anthropic environmental change and sea level rise trends, it is necessary to recognize the impacts of past climatic and environmental changes on sediment production, transport, and deposition. This study focuses on the influence of East Asian summer monsoon (EASM) and El Niño Southern Oscillation (ENSO) driven typhoon precipitation variations and sea level changes on source to sink processes in Southwest Taiwan and the South China Sea. Clay mineralogy and major element geochemistry combined with Nd and Sr isotopic compositions from the sediment core MD18-3569 located on the Penghu Canyon bank off Southwest Taiwan were analyzed in order to identify the origin of sediments and the weathering variation of provenance area since the last glaciation. The results indicate Taiwan as the predominant source of sediments on the Southwest Taiwan margin, with few inputs from Luzon and South China. Clay mineralogy and Nd-Sr isotopes show controls of the EASM precipitation and the sea level change on source to sink processes, respectively. Nevertheless, the comparison between variations of smectite/illite+chlorite, kaolinite/illite+chlorite versus clay fraction Nd isotope, illite chemistry, and crystallinity suggests that the sediment provenance variation might be more related to the draining basin change than the Luzon-Taiwan-South China input change. Bulk chemical index of alteration (CIA) variations displays an EASM driven increase of weathering in Taiwan from the Last Glacial Maximum to the early Holocene and an EASM and ENSO driven weakening of weathering during the middle Holocene. Our multi-proxy study indicates the strong link between paleoclimatic and paleoenvironmental changes and Southwest Taiwan and South China Sea source-to-sink processes.

Miocene sedimentary process simulation and sedimentary evolution in EP-B Oilfield, Yangjiang Sag, Pearl River Mouth Basin

Fengchun Sun[1], Taixun Liu[1*], Xiaolin Ma[2], Xin Wen[2]
1. School of Geosciences, China University of Petroleum(East China), Qingdao City, Shandong Province, CHINA

Keywords: Yangjiang sag, delta, forward modeling, sedimentary evolution

The Miocene Zhujiang Formation to Hanjiang Formation in the EP-B Oilfield of Yangjiang Sag, Pearl River Mouth Basin has problems such as unclear sedimentary geometry, development process, sedimentary model and sand body distribution. Based on the delta sedimentary model, combined with logging and seismic data, the sedimentary forward modeling method of Fick's second law (unsteady diffusion) was used to restore the sedimentary evolution process of each interval of the target layer in the study area, and analyze the key interface characteristics. The simulation results show that: (1) The sedimentary evolution of the Zhujiang Formation and the Hanjiang Formation delta can be divided into four sedimentary cycles. During the period of sea level rise, the delta sand bodies of each stage are characterized by vertical accumulation and gradually thicken toward both ends. During the period of sea level decline, the delta sand bodies of each stage are characterized by horizontal accumulation, and the sand body distribution is relatively thin. (2) In the multi-proven delta sedimentary simulation, as the grain size of the sandstone from the Zhujiang Formation to the Hanjiang Formation gradually becomes coarser, the delta gradually transitions from a silt-rich delta to a argillaceous delta, and the adjacent delta lobes are formed by sand bodies. The connected transition is inter-bay development, and the connectivity becomes poor. Based on the 3D geological model obtained by the fusion of multi-information, it can quantitatively reproduce the structural-sedimentary evolution process of the target layer, and explore the depositional process and the controlling factors and formation mechanism of favorable sand body development, providing a reliable prediction model for oil and gas exploration and development in the study area.

Fine Description of Sedimentary Microfacies Based on Waveform Cluster Analysis——Taking EP-A and EP-B Oilfields in Yangjiang Sag as an Example

Zhaojia Su[1], Taixun Liu[1*], Xin Wen[2], Xiaolin Ma[2]
1. School of Geosciences, China University of Petroleum (East China), Qingdao, Shandong, CHINA
2. Research Institute of Petroleum Exploration and Development, Shenzhen Branch of CNOOC Ltd., Shenzhen, Guangdong, CHINA
E-mail: liutx@upc.edu.cn

Keywords: self-organizing neural networ, waveform clustering, seismic facies, sedimentary microfacies, seismic sedimentology

The sedimentary facies of the EP-A and EP-B oilfields in the Yangjiang sag change rapidly in the lateral and vertical directions, and the heterogeneity is strong. The traditional sedimentary microfacies research based on seismic sedimentology analysis mainly extracts the mean square by the stratigraphic slice technology. Root amplitude properties, accuracy and reliability are easily compromised for thinner intervals. Using the self-organizing neural network method, the waveform clustering analysis is carried out, the seismic facies is divided, and the sedimentary microfacies distribution of each interval in the study area is finally determined by combining the existing well data, sedimentary microfacies data and seismic sedimentology analysis. The results show that the waveform clustering analysis based on the self-organizing neural network method can better divide the seismic facies, so as to determine the boundary of each sedimentary microfacies on the plane, combined with the existing sedimentary microfacies research, can more accurately reflect the sedimentary microfacies. The vertical evolution law of facies can provide a basis for further oil and gas development.

E-mail: xfshi@fio.org.cn

Keywords: Asian continental margin, source to sink, sediment, controlling mechanism

The Asian continental margin is located at the convergence and collision boundary of the Eurasian, Pacific and Indo-Australian plates, and is subjected to the strongest land-sea interactions and the most frequent exchanges of material and energy. The rivers in the Asian continental margin contributes about two-thirds of the global sediments from rivers to the ocean, which has a great impact on the sedimentation, biogeochemical processes and marine ecology of the marginal seas and the global oceans. Through international cooperation, we have systematically obtained sediment samples and data in the Asian continental margin from the East Siberian shelf in the north to the Bay of Bengal in the south. Based on these data, we compiled the first 1:3000000 sediment type map of the Asian continental margin, and elaborated the distribution pattern of the sediments; We established a set of effective provenance tracing indexes to elucidate the properties of fluvial sediments, identified the sediments provenance in the Gulf of Thailand, Andaman Sea, Bay of Bengal, South China Sea, Sea of Japan, Sea of Okhotsk and East Siberian Sea, described the transport and deposition processes of the fluvial sediment in the sea, and established the sedimentation model for the key areas; The source, input mode and burial of organic carbon on the shelf at different latitudes and their response to natural processes and human activities have been quantitatively evaluated; The controlling mechanism of sediment source-sink process impacted by the Asian monsoon, sea level change, uplift of Tibetan Plateau, sea current and sea ice variations has been revealed.

Silicate weathering and river sediment routing processes in East Asian continental margins

Shouye Yang[1*]
1. State Key Laboratory of Marine Geology, Tongji University, Shanghai, CHINA
E-mail: syyang@tongji.edu.cn

Keywords: Silicate weathering, sediment source-to-sink process, Asian rivers, continental margin

East Asia is featured by two major types of fluvial sediment routing systems: the mega-rivers in Eurasian continent, e.g. the Changjiang (Yangtze) River, and the small mountainous rivers in Taiwan Island and SE China, e.g. the Zhuoshui River and Mulanxi River. Among which, the small mountainous rivers are relatively less investigated although they play a disproportionate role in sediment discharge and greatly influence the terrestrial material cycle in the West Pacific. Here, we use multiple isotopic proxies (radiogenic and stable Be, Sr, Nd, Li and Si) to trace the silicate weathering and sediment source-to-sink processes in the large river systems and small mountainous catchments (Zhuoshui and Mulanxi Rivers) in the East Asian continental margin, and particularly the weathering mechanisms and environmental signal propagation in the catchments will be discussed.

The systematic observations from a granodiorite weathering profile and Mulanxi River sediments suggest strong fractionations in Li, Si and radiogenic and stable Sr isotopes during weathering and sediment recycling processes. The small dynamic mountains rivers in Taiwan exhibit large sedimentary geochemical and provenance heterogeneity despite their fast sediment transfer from land to sea. The Si and Sr isotopes clearly indicate the quick response of sediment weathering to typhoon impact. Our study will provide more constraints on the earth surface processes in East Asia continental margin.

Provenance and paleoclimate significance of eastern Hainan Island shelf since Holocene

Yongwei Zhang[1*]
1. , , , , CHINA
E-mail: soaman@163.com

Keywords: marine geology,paleoclimate,Hainan Island,provenance analysis,paleoenvironment,Holocene

This research based on the sediment of QZ4,locateing in the eastern shelf of Hainan Island.Through the methods of particle size, clay minerals and geochemistry, the sedimentary environment and material source of eastern Hainan Island are analyzed, and the conclusions are followed:1) Eastern Hainan island shelf sedimentary environment is influenced by various factors, including sea level, climate, ocean current system and human activities, etc., and it can be divided into two phases:Before 8KA, the stage of sea level control was followed by the stage of climate control. And the influence of human activities intensified since 2KA. 2) The materials in the study area were mainly derived from small rivers in Hainan Island, and partly influenced by foreign materials. 3) Two cold events, 8.2KA and 9.7KA, were observed.

E-mail: thanhtramtich@yahoo.com

Keywords: Acoustic facies type, sedimentary processes, Last Glacial Maximum (LGM), systems tract, sequence stratigraphy

Twelve acoustic facies types and three sedimentary systems tracts (LST, TST, and HST) were determined by interpretation of high-resolution acoustic data in Nha Phu Bay and the adjacent shelf since the Last Glacial Maximum (LGM). The acoustic facies types combining with collected sediment samples revealed a range of sedimentary and geomorphological expressions. These expressions can be tied to hydrodynamic processes of deposition and erosion. The lowstand systems tract (LST) comprises sandy sediments exposed on the outer shelf as sand-ridges and underlies the transgressive systems tract (TST) on the middle shelf. LST was developed under shallow-marine settings during the sea-level lowstand 21.0-14.6 cal kyr BP. TST comprises mainly fine sediments deposited during the transgression 14.6-8.0 cal kyr BP in an incised trough of the outer shelf, on the middle shelf, and in the incised valley of the bay. An erosion of the seaward TST portion on the middle shelf occurred during the late transgression. The highstand systems tract (HST) comprises sediments deposited during the sea-level highstand 8.0-0.0 cal kyr BP and is distributed widely in the bay, on the inner-middle shelf, and partially on the outer shelf. A paleo-coast zone around 100-120 m in water depth is recognized through the appearance of sand-ridges and sandy sediments. The coarse-grained sediment distribution and a thin sediment thickness on the inner shelf indicate an erosion-dominated seabed under strong hydrodynamic impactions. The seabed morphology, muddy distribution, and deglacial sediment thickness reveal a dominant sediment-transport pathway out of the bay occurring along the northern bay coast

E-mail: qiaoshuqing@fio.org.cn

Keywords: east China seas, sedimentary organic carbon, source, burial flux, age

Sources and burial of sedimentary carbon in marginal seas are an important part of the global carbon cycle and budget. The east China seas includes the Bohai Sea, Yellow Sea and East China Sea and are characterized by broad shelves. They receives enormous amount of fluvial sediment from the Huanghe and Changjiang rivers and bury abundant sedimentary carbon. Transport and burial of the sedimentary carbon affect marine biogeochemical processes and marine carbon cycle on different time scales, and even have an important impact on the global climate change.

Based on the investigated data of China over the past 30 years and collected information, including 17596 stations of sediment grain size, 567 stations of 210Pb-derived sediment accumulation rates, 6000 stations of organic carbon, 1024 stations of organic carbon isotope, and 447 stations of organic carbon age, we preliminarily compiled a 1:3000000 distribution map of sedimentary organic carbon of the east China seas, elaborated the distribution characteristics, sources and buried flux of sedimentary organic carbon, and discussed the influence of hydrodynamic forces, sediment composition and human activities on it. The results show: (1) TOC contents in the sediments ranges from 0.01 to 2.12% in the east China seas. And there are high values in the mud areas such as the central Bohai, Sea, eastern coast of the Shandong Peninsula, central Yellow Sea, southwest of Jeju Island, old Huanghe River estuary, southeastern of the Yellow Sea, and Zhejiang-Fujian coast. (2) δ13C values are from -25.80~-20.00‰ and ~70% of sedimentary organic carbon is marine source. (3) range of Δ14C in sedimentary organic carbon is -871 ~ -137‰. The age of sedimentary organic carbon is older in the areas near the old Huanghe River estuary, Jiangsu radiating sand ridges, middle and outer shelf of the East China Sea and northeast Taiwan. (4) The burial rates of organic carbon in the mud areas are higher in the east China seas, which reaches maximum value of 68.8 g/m2/yr in the Bohai Sea mud area and is generally low near the old Huanghe River estuary (15.2 g/m2/yr). The burial amount of sedimentary organic carbon is about 8.2 Mt/yr.

Formation of authigenic siderite and pyrite in mud sediments of the Yellow Sea

Xiting Liu[1*], Yu Gu[1], Guangchao Zhuang[2], Houjie Wang[1]
1. College of Marine Geosciences, Ocean University of China, Qingdao, Shandong, CHINA
2. College of Chemistry and Chemical Engineering , Ocean University of China, Qingdao, Shandong, CHINA
E-mail: liuxiting@ouc.edu.cn

Keywords: Early diagenesis, Pyrite, Siderite, Yellow Sea, Sedimentary environment

The formation of authigenic minerals is accompanied by the early diagenetic process of sediments, so authigenic minerals can carry the information of their formation environment (Liu et al., 2019; 2020; 2021). Our preliminary analysis results show that in the lower part of the core, siderite iron content is high, indicating a more oxic sedimentary environment and possibly a continental freshwater environment. In the upper part of the core, the iron content of pyrite increases, which can indicate the beginning of marine transgression. The content of pyrite is also related to the depth of sulfate reduction in this area according to porewater data. The location of the sulfate reduction zone in the study is about 6 m. According to the grain-size results, the core penetrated the mud layer and recorded the evolution of the sedimentary environment since the last glacial period.

The impact of dam constructions on sedimentary records along the mud belt in the inner East China Sea shelf

Rick J Yang[1*], James T Liu[1], Chih-Chieh Su[2], Steven C.-C. Chien[1]
1. Department of Oceanography, National Sun Yat-sen University, Taiwan, CHINA TAIWAN

Keywords: Source-to-sink, Three Gorges Dam, Mud belt

The Anthropocene is a new concept but not yet well constraint geological epoch, and this thinking indicates that humans are gradually having a significant impact on Earth's geology and ecosystems. From the perspective of Anthropocene, human activities in the watershed, such as urbanization, deforestation, damming, etc., have significantly altered the sediment supply. We wanted to know whether such anthropogenic processes could affect the sedimentary record on the continental shelf in a watershed-shelf continuum. In this study, box cores and surface sediments taken at six stations along the Zhejiang-Fujian Zhe-Min) mud belt system were used to investigate the changes in sediment characteristics before and after the construction of dams on rivers along the southeastern coast of China. For example, the Three Gorges Dam (TGD) on the Changjiang River (CJR) around A.D. 2000, the Shuikou Dam (SKD) on the Minjiang River (MJR) around A.D. 1993.
Sample analyses included Multi-sensor Core Logger (MSCL), clay mineralogy, grain-size compositions, and radioisotope measurements. Results in $^{7}Be/^{210}Pb_{ex}$ activity ratio of surface sediment showed that the freshness of terrestrial sediment along the mud belt decreased away from the CJR mouth along the mud belt. The magnetic susceptibility (MSI) has a similar decreasing trend from the Oujang River to the northern Taiwan Strait (TS). The above results indicate that terrestrial signals gradually decreased along the transport pathway. Sedimentation rates calculated from the $^{210}Pb_{ex}$ activity profiles of the box cores also consistently decreased from the CJR to northern TS. Later, the sedimentation rate was used to establish the time span of each box core to show the temporal variability of core sedimentation characteristics. Results showed that the MSI of each box core decreased simultaneously after A.D. 2000. This time point coincided with the operation of the TGD. Kaolinite, which can represent the source of the MJR in the results of clay minerals, has also decreased in stations south of the MJR mouth with the completion of the construction of the SKD. This finding points to the impact of anthropogenic activity in the watershed on the distal marine sediment record.

A novel machine learning fingerprinting method using Sparse Representation for delta sediment provenance analysis

Feng Wang[1*]
1. Institute of Marine Sciences, Shantou University, Shantou, Guangdong, CHINA
E-mail: fengwang@stu.edu.cn

Keywords: Machine learning, Sediment fingerprinting, Sparse representation, Sediment provenance detecting,

Fingerprinting technique is a critical tool for sediment source detection. How to assess more authentic source contributions, based on very limited measured data, is a key scientific question. Sparse representation, a machine learning method, was found to be a good regularizer for natural signals and has the potential to provide answers. Here, we presented a Sparse Representation based Sediment Fingerprinting (SRSF) method and have applied it to analysing the data of sediment cores from the Yangtze River Delta (YRD), where the Yellow River sediment had also contributed to its formation in the last 400–600 years. We quantified the provenance of three cores sediments from the northern YRD using size-specific magnetic and geochemical characterizations. Our results showed that the Paleo-channels of the Yellow River contributed 19.3±5.8% in <16 μm fraction sediment and 23.5±9.2% in 16–32 μm fraction sediment, which was consistent with the previously published results. This study optimized the fingerprinting technique in feature extraction and selection. SRSF method had great potential applications in provenance detection with very limited measured data, the prevention of delta erosion, and land resource management.

E-mail: gorbarenko@poi.dvo.ru

Keywords: Northwestern Pacific, Sea ice, iceberg, Pleistocene

Marine isotopic stages 6.5–1 were established in the Tenji Seamount sediment core LV 76-18 based on accelerator mass spectrometry (AMS) 14C data, benthic foraminifera δ18O stratigraphy, and relative paleointensity excursions. Records of planktic foraminifera δ18O and ice rafted debris (IRD) in sediment cores from the Detroit and Tenji Seamounts were used to outline several periods of surface water freshening and increased IRD accumulation induced by icebergs supply and its melting in the northwest Pacific during the last 190 ka. Iceberg discharge events (IDEs) were as well reconstructed over the last and penultimate glacial periods in the central and eastern parts of the Okhotsk Sea and southwestern part of the Bering Sea. Synthesis of planktic foraminifera δ18O and IRD records along with other related proxies from the studied areas concordantly revealed five IDEs in the northwest Pacific and its marginal seas during the last 190 ka: IDE 1 (42–29 ka), IDE 2 (76–57 ka), IDE 3 (118–110 ka), IDE 4 (152–141 ka), and IDE 5 (179–160 ka). Data showed that IDEs 4–1 occurred at low values of Earth obliquity and under a weak Aleutian Low, facilitating snowfall precipitation and enhancing glacier formation at Kamchatka, which is a priority area for capturing atmospheric moisture transferred into northeast Asia. It is likely that IDEs 2 and 1 occurred during phases I (more extensive) and II (less extensive) of the published Kamchatka glaciations during the Late Pleistocene. According to records of several sediment cores from the Tenji Seamount, the IDE 2 was also characterised by a huge and short IRD peaks that was probably forced by the catastrophic influx of lake water from the Central Kamchatka Depression. An analysis of the mineral composition of sediments in fractions more than 63 microns showed that the sediments of the Detroit Seamount has the feeding provinces of the Koryakia and the Kamchatka Peninsula, and the sediments of the Tenji Seamount, mainly of KamchatkaHigh resolution records from the Detroit Seamount core LV 76-21 show, that IDE 1 was characterized by several short periods of icebergs discharging synchronously with Greenland/Chinese interstadials and decrease of sea ice extension in the Bering Sea and the far northwestern Pacific. During the cold MIS 2 there was increase in the sea ice formation in the Bering and Okhotsk seas and its spreading in the northwestern Pacific.

Changes in sedimentary environment in the subtropical NW Pacific during the Late Quaternary

Jianjun ZOU[1*], Xuefa Shi[1]

1. Key Laboratory of Marine Geology and Metallogeny, First Institute of Oceanography, MNR, Qingdao, Shandong, CHINA
E-mail: zoujianjun@fio.org.cn

Keywords: sedimentary environment, Late Quaternary, Subtropical NW Pacific, Kuroshio Current, North Pacific Intermediate Water;

The sedimentary environment in the subtropical NW Pacific is shaped by a range of crucial factors, including the Kuroshio Current (KC), the East Asian Summer Monsoon (EASM) and the North Pacific Intermediate Water (NPIW). The KC is an important western boundary current in the subtropical NW Pacific Ocean, which brings amounts of warm and high-salinity water from the tropical ocean to the middle-high-latitude areas. The NPIW is characterized by low salinity and mainly occupies the water depth of 300-800 m in the subtropical North Pacific, which is mainly derived from the Okhotsk Sea with little contributions from the Gulf of Alaska. The EASM brings freshwater to the continental margin of the NW Pacific and exerts significant influences on its surface hydrography. These changes themselves and their interactions greatly affect the sedimentary environment of the subtropical NW Pacific during the Late Quaternary. However, the changes of sedimentary environment during the Late Quaternary and processes responsible for these changes still need further exploration. In this study, we present the results from sediment cores retrieved from the Okinawa Trough of the subtropical NW Pacific. This study highlights the important roles of these three factors (KC, EASM and NPIW) in shaping the sedimentary environment during the Late Quaternary in the context of eustatic sea level changes during the late Quaternary.

E-mail: riz@umt.edu.my

Keywords: Sand, Silt, Clay, Marine Sediment, Peninsular Malaysia

Sediment texture is an important characteristic that can be used as an indicator of changes that occur in an environment, especially in the continental shelf environment. This is due to the significant changes in this environment throughout the Holocene period. The purpose of this study is to determine the classification of modern and Holocene sediment texture and to identify the changes in sediment texture that may occur during the Holocene period. In this study, we analyzed 30 surface sediment samples and three cores (TRC3, TER16GC13C, and KELC17) from the east coast of Peninsular Malaysia, Southern South China Sea. Radiocarbon analysis of the shell fragments indicated that the studied cores covered the Holocene period. Most modern sediments on the east coast of Peninsular Malaysia fall into the categories of silty clay, silty clay loam, and silty loam. The same applies to the Holecene's sediment texture which was also dominated by a similar type of sediment texture. In comparison, there was a significant difference in terms of the vertical distribution of sediment texture for core TER16GC13C than core KELC17 and TRC3. The highest percentage of sand was recorded for core TER16GC13C which is up to more than 60%. This condition suggests that the environmental changes at the location of core TER16GC13C are more dynamic than TRC3 and KELC17. The increasing current intensity at core TER16GC13C is one of the potential factors that may affect the high percentage of sand. Therefore, this may suggest that the modern and Holocene sediment of the southern part of the South China Sea falls into the moderately fine sediment textural group.

E-mail: xfshi@fio.org.cn

Keywords: Incised valley fill, Organic carbon preservation, East China Sea Shelf

Incised valleys are generated during river incisions due to a relative sea-level fall. Afterward, as the sea level rose, accommodation was created in the incised valley, allowing sediment and organic carbon to fill. The core MZ03 and seismic profile collected on the southern East China Sea Shelf suggest that the deposits filled the incised valley occurred during Marine Isotope Stage 3 (MIS3). MIS 3 (60-25 ka) is a warm period in the last glacial period, characterized by the frequent occurrence of millennium-scale climatic events and high-frequency sea-level oscillation. Our study aims to investigate the impact of the incised valley filling process on preserving organic carbon in the setting of rapidly changing sea levels.

The deposits that filled the incised valley were not eroded during the LGM and subsequent transgression, allowing the particulate organic carbon (POC) to be preserved for almost 30 ka. During infilling of the valley, the incised valleys are controlled by fluvial, estuarine, and marine processes. The basal fill of the valley is composed of the Minjing bayhead delta-plain and delta-front. The mud exported from the Changjiang constitutes to middle-top of the valley fill. With the total organic carbon, nitrogen, and carbon isotope analysis, the flood event beds of the delta-plain deposits contained the highest organic carbon content (3.4 %). In comparison, the mud from Changjiang coastal mud wedge (middle-top valley fill) yielded TOC that ranges from 0.2 % to 0.7 %. The C/N and the carbon isotope showed that the organic carbon source in the flood event beds was predominantly from C3 plants. The contribution of marine organic carbon dominated the middle-top of the valley fill. The Sr/Ba and Mo/Al were used to indicate the paleosalinity and redox condition. The flood deposits have the lowest Sr/Ba (0.12) and greatest Mo/Al ratios in the core, ranging from 0.3 to 0.63 ($\times 10^{-4}$). The low Sr/Ba indicates that the sediments were less influenced by seawater. The Mo-rich layers could result from a combination of rapid sediment settling and O_2 consumption through the decomposition of organic-rich layers. Due to rapid sedimentation, the fluvial flood beds of the delta plain deposits contain the most enriched organic matter. In contrast, the Changjiang coastal mud has much less organic matter content because post-depositional bioturbation in mud increases short-term redox oscillations, promoting organic carbon degradation. Furthermore, the identification of fluid mud beds (remobilized mud) tends to expose organic matter to oxygen and allows for efficient metabolite exchange with little organic carbon storage. The lower valley fill is characterized by the highest organic carbon fed by the small mountainous river probably due to intense terrestrial flooding caused by monsoon intensification. The middle to top valley fill (coastal mud) has less organic matter content, implying fluvial-dominated delta is perhaps the most favorable place to receive and store the largest amounts of organic matter. These findings have crucial implications for understanding how incised valley filling process affects organic carbon preservation on the shelf.

E-mail: artemova@poi.dvo.ru

Keywords: Diatoms, Late Pleistocene, Holocene, Ice Conditions, Environmental Changes

The results of a detailed study of diatom complexes of Pleistocene and Holocene sediments from Pacific Ocean and ecostratigraphic subdivision of sediments showed that changes in assemblages reflect, first of all, a change in hydrological conditions determined by changes in the circulation of water masses and related processes - paleoproductivity of surface waters, development certain species and their migration.

Several periods of changing hydrological conditions were identified, which were reflected in the composition of diatoms associated with significant paleoclimatic events - periods of cooling, with an increase in the duration of ice standing, periods of warming with a strong freshening of the surface water layer, a change in oceanological circulation, leading to an increase and decrease in supply nutrients. Periods were also identified when large volumes of ice were brought into the study area, probably associated with the supply of large masses of ice by currents, most likely coming down from the glaciers of Korjakija and the surrounding areas.

4. Department of Geology and Geophysics, Louisiana State University, Baton Rouge, Louisiana, UNITED STATES
E-mail: fenghan@fio.org.cn

Keywords: Himalaya-Karakoram, South Asian monsoon, detrital zircon U-Pb dating, Nd-Sr isotope, heavy minerals, detrital apatite fission track dating

South Asia, especially the Indus River Basin, is one of the regions with the most intense surface erosion, the most active tectonic movement and the most significant influence of monsoon climate in the world. The coupling of erosion, tectonics and monsoon in this region plays a very important role in global climate change and environmental evolution. Although the Neogene (< 23 Ma) history of the Indus River Basin erosion, the Himalaya-Karakoram tectonic activities and the South Asian monsoon changes are relatively clear, the Paleogene (> 23 Ma) records are still lacking. Also, it is not clear whether the Cenozoic erosion process in the Indus River Basin was controlled by tectonic activity or monsoon climate. In this study, we conduct detrital zircon U-Pb dating, Nd-Sr isotopic composition, heavy mineral assemblages and the detrital apatite fission track (AFT) dating on the Indus Fan sediments from the Arabian Sea since ~30 Ma, to reconstruct the erosion history of the Indus River Basin since the Oligocene. Detrital zircon U-Pb age spectrum, Nd-Sr isotopic compositions and heavy mineral assemblages of the Indus Fan sediments demonstrate that, the Himalaya and the Eurasian plate are the main sources of the Indus Fan deposits since the Oligocene. During ~26-16 Ma, the Himalayan source contributed the most to the sediments, which may reflect the extrusion and rapid uplift of the high-grade metamorphic Great Himalayan sequence. The Karakoram strike-slip fault (KF), which activated at ~16 Ma, may be the main reason for the increased contribution of Eurasian plate source during ~16-6 Ma, even though the development of the Lesser Himalaya duplex started at ~12 Ma. The Lesser Himalaya was finally brought up to the surface at ~6 Ma and began to supply erosive material to the Indus Fan, increasing the contribution of the Himalayan source region. The detrital apatite fission track age distributions of the Indus fan sediments show relatively stable and rapid erosion (from 0.6 mm/yr to 1.2 mm/yr) during ~30-16 Ma. This suggests that at least ~30 Ma, a rapid erosion in the Himalaya and Karakoram had begun, and that a geomorphological pattern similar to the present one had been established in the Indus River Basin. The change of provenance or tectonic movements was not consistent with the history of erosion in the Indus River Basin. This suggests that the South Asian monsoon may be the dominant factor that controlling the erosion rate in the Indus River Basin. Tectonics, as the main factor affecting sediment provenance, has a minor effect on the erosion rate of the basin. The increase of ~8-7 Ma erosion rate and subsequent unstable fluctuations may be related to the enhancement of glacial erosion caused by global cooling and the disturbance of high-frequency/high-amplitude climate change to the erosion process.

E-mail: zoujianjun@fio.org.cn

Keywords: Paleoclimate , Paleoproductivity, Holocene Climatic Optimum , Bering Sea

The high north latitude climate has undergone significant changes during the Holocene Climatic Optimum (HCO), but the response of high-latitude marine environment to the HCO remains unclear, particularly in the Bering Sea. In this study, a suite of multiply proxies including sediment grain size, biogenic components (TOC, $CaCO_3$ and Opal) and organic matter stable isotopes ($\delta^{15}N$ and $\delta^{13}C$) of core LV63-19 retrieved from the Bering Sea Green Belt during the China-Russia joint expedition in 2013. The sediment core LV63-19 has an average sedimentation rate of 102cm/ka, which provides high-quality material to examine the response of the Bering Sea marine environment to the HCO. Our results show a pronounced increase in paleoproductivity in the Green Belt during the HCO period (11.5 ~ 9.0 ka). The enhanced paleoproductivity of the Bering Sea is mainly attributed to the dampened sea ice cover, increased duration of phytoplankton growth, and increased nutrient supply. The increases in nutrient supply are not only sourced from the terrestrial contribution but also an increased upwelling of nutrient and carbon-rich deepwater .It is an important reason for the formation of dark laminated sedimentary layers that the productivity blooms in the Bering Sea Green Belt during the HCO , but it is still constrained by multiple factors.

E-mail: vasilenko@poi.dvo.ru

Keywords: Lithostratigraphy, sedimentation, Upper Quaternary sediments, Lomonosov Ridge, Arctic.

We studied 18 sediment cores taken from the southern the submarine Lomonosov Ridge (Siberian area) during the marine expedition of the R/V Akademik M.A. Lavrentiev" in 2020. We analyzed lithological description, magnetic susceptibility, density, moisture and colorimetric characteristics. The elemental composition was analyzed by the X-ray fluorescence method for 16 cores.

We compared our magnetic susceptibility, density, Mn content and lithology data with ones for sediment cores PS2757-8 and SWERUS-C3-29-GC1 (Jakobsson et al., 2016; West et al., 2021). In result, we set boundaries for MIS1 – MIS5 and established the position of five stratigraphically significant levels (Jakobsson et al., 2016; West et al., 2021). We also identified 6 additional stratigraphic levels. Based on this, we estimate the sedimentation rates. There is a clear trend towards an increase in sedimentation rates from east to west in the study area. In addition, we found that the accumulation of distinct gray layers occurred very quickly at the end of glacial stages at the beginning of interglacial stages. Possibly, the rate of accumulation of these layers was determined by the disintegration of continental and shelf glaciers during periods of deglaciation.

Expedition research was funded within the framework of the program of the POI FEB RAS (No. 121021700342-9), grant of the National Program for Global Change and Interaction between Air and Sea (No. GASI-GEOGE-04) and grant of the National Natural Science Foundation of China (No. U1606401). The processing of the material and the analysis of the obtained data were carried out at the expense of the RSF grant No. 19-77-10030.

Keywords: color stratigraphy, Dansgaard-Oeschger cycles, climate changes

Here, we present a high-resolution record of the East Asian monsoon (EAM) obtained from a new mid-latitude archive of climate variability in the Northern Hemisphere during 30-125 ka. For this purpose, the sediments of the semi-enclosed Sea of Japan, which is a unique region of interaction between oceanic, land, and atmospheric circulation, were used. Using an original photocolorimeter, records of the color brightness (CL) of the Sea of Japan sediment core were obtained with a resolution comparable to the EAM curves of Chinese caves. The age mogel was established by identifying Heinrich events and then by detailed correlation of Dansgaard-Oeschger (DO) interstadials on the CL curve with those recorded in Greenland ice cores and Chinese caves. Comparison of DO cycles recorded in Greenland, Chinese caves, and the Sea of Japan makes it possible to better understand the mechanisms of formation and teleconnection of DO cycles in the Northern Hemisphere. During MIS 3, DO cycles 17-5, recorded in three archives, show the general millennial climate changes characteristic of the cores of Greenland. During MIS 5.2 and 5.3, Greenland ice core indicates gradual cooling after the start of the DO 23 interstadial period, while both EAM records show progressive warming followed by a sharp cooling, indicating differences in environmental evolution between the North Atlantic and the tropical Pacific. .

Keywords: major and trace elements, Pb isotopes, provenance, IRD; Liman Cold Current, Sea of Japan

The Sea of Japan (JS), a unique marginal sea without any large river influxes in the western Pacific, provides ample information about the evolution of sea-level, East Asian Monsoons (EAM), sea ice activity, and ocean currents in geological time. However, insufficient investigation in the western JS limits our knowledge of East Asian climate change. This study utilizes major and trace elements and Pb isotopes of fine siliciclastic components (<63 μm) of core LV53-18-2 and determines the provenances using statistical methods and discrimination diagrams. The results show that the terrigenous debris of LV53-18-2 was mainly composed of aeolian dust from northeast China, ice-rafted debris (IRD), and volcanic materials from the Far East coast over the last 30 kyr. During the late last glacial period, sea ice activity carried weakly weathered IRD to the study area. Meanwhile, the strengthened East Asian Winter Monsoon (EAWM) brought dust from northeast China to the study site owing to the cold climate and enlarged sandy land. During the late last deglacial period to early Holocene (15-8 kyr), ascending boreal summer insolation drove the intense melting of sea ice. This led to the deposition of large amounts of weakly weathered IRD and remarkably influenced the chemical composition of the core. After 8 kyr, the global sea level rose to -15 m below the modern sea level and opened the Tatar Strait. Consequently, freshwater supplied by the Amur River entered the JS and gave birth to the Liman Cold Current (LCC), which transported more mafic materials from the Kema Terrane upstream.

Grain size variation of Asian dust in the silt and clay fractions of Japan Sea sediment revealing the variability of westerly and East Asian winter monsoon (EAWM) changes in the past 10 million years

Keywords: Asian dust, PARAFAC endmember modelling, Taklimakan dust, Gobi dust, Ordos dust

Japan sea sediments consist of various detrital materials of eolian and riverine origin. Understanding the provenance of eolian dust is vital for reconstructing the variability of wind patterns and monsoons in the past. A complete aeolian accumulation rates in silt and clay fractions from the Late Miocene to Pleistocene were reconstructed at the Integrated Ocean Drilling Program (IODP) Site U1425 in the Japan Sea.

A total of 180 samples were collected from the Hole 1425D, which had 370 m in length and covered the last 9.69 m.y. Grain size separation was conducted to evaluate the mineral composition in silt (>4 μm) and clay (<4 μm) fractions by X-ray diffractometer (XRD). Mineral composition suggests the source variabilities in silt and clay fractions, which could be interpreted as provenance shifts occurring in 8 and 2.7 Ma.

Parallel factor analysis (PARAFAC) was applied to decompose X-ray diffractograms into individual subcomponents to identify the sources and quantify their contributions. Six-components PARAFAC model was established and 3 Asian dust sources (Taklimakan Desert, Gobi Desert and Ordos Plateau), a riverine source of Japan Island Arc, and 2 biogenic sources of diatomaceous and Opal-CT were identified.

The results show that Taklimakan dust is dominated by the silt fraction, while Gobi dust is dominated by the clay fraction, and they are controlled by the relative contributions of different pathways of dust transport, such as the westerly winds and East Asian winter monsoon (EAWM).

Clay-size dust from Gobi increased during three periods, late Miocene global cooling (LMGC), intensification of Northern Hemisphere Glaciation (iNHG), and mid-Pleistocene Transition (MPT), which reflected increased EAWM winds associated with global cooling and glaciation. Taklimakan became the major dust contributor to the Japan Sea sediments during the warmer climate periods in the latest Miocene to early Pliocene and the Late Pleistocene, where westerly wind activity dominated eolian transport. Dust from Ordos increased greatly 0.95-0.85 Ma due to enhanced Asian aridification since 2 Ma in Northwest China.

Keywords: Asian dust, 405-kyr cycles, ENSO-like state, Western Pacific, Early Pleistocene

Asian dust deposition in the northwestern Pacific is generally linked to high-latitude paleoclimate evolution during the Quaternary. However, whether low-latitude tropical Pacific processes, such as El Niño-Southern Oscillation (ENSO), influence Asian dust input into the northwestern Pacific remains uncertain. Here, we present clear periodic variations in potassium content (K (wt.%)) and gamma-ray attenuation (GRA) bulk density, which are closely linked to the variations in Asian dust, in a sediment core recovered at Site U1438 in the Amami Sankaku Basin (ASB), northwestern Philippine Sea. Based on the shipboard age-depth model, we tuned the GRA to the mass accumulation rate curves on the Chinese Loess Plateau and the 8-kyr-lagged obliquity curve and established the astronomical timescale.

The K (wt.%) content and GRA were higher during glacials and lower during interglacials, as driven by the variability in the Northern Hemisphere ice sheet (NHIS) during the Quaternary. In addition, strong long eccentricity 405-kyr cycles were observed in the dust records (K (wt.%) content and GRA) during the early Pleistocene. The 405-kyr filter results showed that increased (decreased) Asian dust corresponded to the La Niña-like (El Niño-like) state, suggesting that Asian dust input into the northwestern Pacific was modulated by ENSO on 405-kyr cycles in the early Pleistocene. Our study illustrated the possible link between long eccentricity 405-kyr cycles in the Asian interior and low-latitude forcing, including potential modulation by ENSO.

How Did Sediments Disperse and Accumulate in the Oceanic Basin, South China Sea

Weiwei Ding[1,2*], Fei Wang[2]
1. Ministry of Natural Resources, Key Laboratory of Submarine Geosciences & Second Institute of Oceanography, Hangzhou, Zhejiang, CHINA
2. School of Oceanography, Shanghai Jiao Tong University, Shanghai, CHINA
E-mail: wwding@sio.org.cn

Keywords: Sedimentary budget; Sedimentary provenance; Controlling factors; IODP; Oceanic basin of South China Sea

Quantification of the sedimentary accumulation and dispersion process of the South China Sea (SCS) not only establishes an important part on the “source-to-sink” process in East Asia, but also shed lights on the submarine slope failure and associated submarine canyon/channels formation. Based on geological interpretations of more than 30 multichannel seismic profiles covering the whole oceanic basin with constraints from IODP Expedition drilling results, we calculated the sedimentary budget of the oceanic basin since the Oligocene on a million-year geological scale. Sediment isopach maps in different geological time were reconstructed to understand the controlling factors dominating the Cenozoic sedimentary accumulation and dispersion process, as well as the possible sedimentary provenances. Results show that the sedimentary budget of the whole oceanic basin increased gradually with time, although the rate has not been consistent over time. It was complicated by regional tectonics, including the spreading of the SCS, the uplift of the Tibet Plateau and the Taiwan, the Asian monsoon, the onland river systems, as well as the sea level changes. Submarine channel/canyon systems developed in the continental margin acted as the major conduits for terrestrial sediments discharging into the oceanic basin. Opposite trend occurred in the Southwest Sub-basin (SWSB) during the Late Miocene, and in the Northwest Sub-basin (NWSB) during the Pliocene. The former might be related with the local rifting event in the Mekong Shelf, which trapped most of the terrestrial input. While the later was due to the retreat of the Central Canyon and Pearl River Canyon in the Late Pliocene. Sediment isopach maps indicate that the sediments accumulation mainly focused on the NWSB and the northern flank of the East Sub-basin (ESB) before the Late Miocene, with the depocenters generally distributed at the mouth of the channel/canyon systems and slope foot area near basement highs; but gradually migrated to the SWSB and the southern flank of the ESB since Pliocene due to the high sea level and increase of the Mekong River runoff. An exception is the depocenter in the northeast part related with the Taiwan orogeny. Either the thickness or the range increased and spread to the central basin caused by the huge amounts of terrestrial sediment accumulation due to the continuous uplifting and denudation since the Late Miocene. The primary sediment provenances include the South China, Tibet Plateau, Indo-China Peninsula, and Taiwan Island, with minor contributions from the Hainan Island, Palawan, Luzon Islands, as well as local basement highs developed on the continental margin.

Keywords: Orinoco Delta, Mayaro Formation, shelf conduit, collapse scar, tidal distributary channels

Prominent outcrops of the Pliocene Orinoco Delta along the southeast coast of Trinidad Island display a well-known, very thick Icehouse succession of storm-wave dominated delta lobes, as part of a 10-12 km thick Neogene continental-margin prism. There is a previously discovered, steep incision or conduit (400 m wide) with south and north-bounding erosion surfaces, cutting deeply into the Mayaro Formation shelf-edge delta deposits. The ca. 100 m-thick infill of the conduit shows an initial muddy succession passing upwards to very coarse-grained debrites, rotated and slumped blocks, and structureless sandstones that pass upward to a stacked series of sandy to muddy channel fills. The channels show spectacular tidal rhythmites, probably developed on the point bars of subaqueous tidal channels. As one piece of the topset of the shelf-edge delta clinoform, this conduit displays features of the linkage hub between the landward on-shelf delta systems and the basinward slope deposits.

New fieldwork and a re-examination of the incision-infill reveal new details and suggest three possible origins of the conduit: the first is a no river feeder, shelf-edge collapse scar, extending onto the upper slope and infilled by deeper to shallower deposits. This shelf-edge cutting canyon interpretation is supported by the presence of hardground ichnology on the steep walls of the incision and the abundance of chaotic blocks and debrites in the lower two-thirds of the incision infill. The second is a shelf channel or valley linking fluvial channels to on-shelf and outer shelf deltas. This river-connected, subaqueous shelf valley origin, is supported by the upward-coarsening nature of the infill succession and especially the occurrence of shallow-water tidal channels in the upper third of the infill. The third is a canyon developed mainly during transgression or highstand with a collapsed canyon-head infill and an overlying muddy tidal-channel system that had only limited sediment bypass to the deepwater slope and basin floor. This case represents both the shallow-water and the deeper water features of the infill succession, and is supported by similar large shelf-edge collapse features seen elsewhere in the Cruse and Moruga Formations of the paleo-Orinoco margin. This case, unrelated to river supply, also benefits from slight rotational shelf-edge uplift to trigger collapse.

The known Cedar Grove growth fault was active and located some 4 km to the west from the present coast on the southeast corner of Trinidad Island. The growth-fault trapped thickened outer shelf to shelf-edge delta-front and delta-plain sediments within the hanging-wall compartment as the fault stretched about 20 km along strike. All the shelf-edge aggradation and its partial collapse were likely triggered by growth-faulting. After some muddy backfilling and coarse-grained block collapse into the invaginated shelf-edge, this scalloped area attracted a belt of subaqueous tidal channels, thus healing the eroded topography.

Ordovician-Silurian and Devonian sedimentary complexes of Mendeleev Rise, Wrangel Island and Chukotka and their correlation

Marianna Ivanovna Tuchkova[1*], Sergey Gennadievich Skolotnev[1], Sergey Dmitrievich Sokolov[1], Valeria Eduardovna Beloshey[1]

1. Russian Academy of Science, Geological Institute Russian Academy of Science, Moscow, RUSSIA
E-mail: tuchkova@ginras.ru

Keywords: arctic region, paleozoic deposits, carbonate-terrigeneous

There are great similarities in the structure of Paleozoic (O3-S and D2-3) units of Chukotka, Wrangel Island and Mendeleev Rise: synchronous intervals without sedimentation, similar composition of sandstones and general facies patterns. During the studied stratigraphic intervals, shallow water environments are established – carbonate sedimentation for Ordovician-Silurian and terrigenous for Devonian. In Silurian stage, shallower facies were located in the East both for the Mendeleev rise and for Wrangel Island, which is also confirmed by the transport direction. In the Devonian, there is a terrigenous type of sedimentation with a similar composition of sandstone both on the Mendeleev uplift and on Wrangel Island and Chukotka. Transport direction has been established from North to South for the Chukchi region.

The stage of the Ellesmere deformations in the Early Devonian is recorded by absence of deposition on the Mendeleev rise and the accumulation of quartzite sandstones in shallow water environments on Wrangel Island and more deeper ones in Chukotka, which indicates a peneplenization and the weathering crust forming on the adjacent land.

For the Upper Devonian, a parent source probably represented by a series of islands composed of granitoids and meta-sedimentary rocks, because the synchronous sandstone’s composition varies in different sections of Wrangel Island and Chukotka.

Temporal and Spatial Differences in Sediment Dynamics and Processes on the muddy deposit off the Shandong Peninsula: An Observational Study

Fukang Qi[1], Jingping Xu[1,2*]

1. Department of Ocean Science and Engineering, Southern University of Science and Technology, Shenzhen, Guangdong, CHINA

2. Southern Marine Science and Engineering Guangdong Laboratory (Guangzhou), Southern Marine Science and Engineering Guangdong Laboratory (Guangzhou), Guangzhou, Guangdong, CHINA

E-mail: xujp@sustech.edu.cn

Keywords: coastal sediment dynamics, suspended sediment transport, strong wind events, muddy deposit

Sediment from the Yellow River, one of the largest rivers in the world in terms of sediment discharge, is known to be responsible for the elongated distal mud deposit off the Shandong Peninsula. The hydrodynamic and sedimentary mechanisms that maintaining the unique 'Ω'-shape topography and sedimentary structure have always been intriguing to the research community. Instruments including bottom-mounted tripods and moorings were deployed at three stations across the deposit (at water depth of 40, 26 and 55 m respectively) to record the synoptic and seasonal (summer vs winter) variations of oceanographic forcing and sediment dynamic responses. Empirical Orthogonal Function (EOF) analysis was performed to examine the covariability of suspended sediment concentration (SSC) on various forcing factors including waves, winds, currents etc. It shows that tidal flows were the most important physical forcing for SSC variation in summer. Large waves in winter could significantly enhance sediment resuspension at the top of the deposit (the shallowest site) but not as much at either side of the deposit where water is deeper. It is the residual currents (first mode which explained about 40% of the standardized covariability) driven by along-shelf winds that overpowered the winter waves at the 40 m site. In general, advections dominate the southward sediment transport pattern in summer. In winter, however, resuspension due to frequent strong winds dominates the southward sediment transport on the top of the deposit, whereas advection due to residual currents is mainly responsible for the sediment transport in the further nearshore.

Submerged beach rocks from the continental shelf of southern Brazil

Iran Carlos Stalliviere Corrêa[1*], Jair Weschenfelder[1], Cristiani Bahi Santos[1]
1. Centro de Estudos de Geologia Costeira e Oceânica, Universidade Federal do Rio Grande do Sul, Porto Alegre, Rio Grande do Sul, BRAZIL
E-mail: iran.correa@ufrgs.br

Keywords: Beach rocks, continental shelf, southern Brazil

The continental shelf of southern Brazil presents three alignments of beach rocks, submerged, between Chuí and Torres. For this study, we used on-board maps, seismic profiles and dive data information. A GPS was used for the location of the beach rocks. The depth was obtained by echo sounding and precision aneroid. The first beach rock, located to the south, is made up of two blocks, Hermenegildo South and Hermenegildo North, 0.70 and 14 km from the coast and with their peaks at ±9 m and ±13 m from the depths. Then there is the beach rock Fronteira Aberta, 19 km from the coast and its summit at ±13 m depth. The next is formed by two blocks, Albardão South and Albardão North, with their peaks at ±7 m and ±8 m and ±23 km and ±12 km from the coast. It is followed by the Capela beach rock which is at a depth of ±7 m and 0.50 km from the coast. The fifth beach rock, Minuano, is also divided into south and north, with their peaks at ±19 m and ±17 m depth and 26 km and 35 km from the coast. The next beach rock, called Carpinteiro is located 30 km from the coast and divided into South and North, with their peaks at ±14 m and ±15 m depth. The next is the Barra Falsa beach rock, divided into south and north. Their summits are between ±13 m and ±15 m deep and with a distance of 15 km and 20 km from the coast. The eighth beach rock is also divided into two sectors, South and North, with its peaks at ±15 m and ±13 m depth and 0.50 km and 1 km from the coast. The next beach rock, Solidão, has its summit at ±21 m depth and is 1.5 km from the coast. The tenth beachrock, Capão da Canoa, is divided into South and North, with their peaks at ±25 m and ±27 m depth, and 2.6 km and 4 km from the coast. The last beach rock, Torres, is divided into South and North and their peaks are at ±24 m and ±20 m in depth and 1.3 km and 1.8 km from the coastline. In general, we can say that the internal continental platform of southern Brazil, presents three alignments of beach rocks: the first located between 7-10 m, the second between 13-19 m and the last between 20-30 m, corroborating with the terraces described by several authors. According to the sea level variation curve, the beach rocks located between 7 and 10 m deep have an age of ±7,100 years AP, those located between 13 and 19 have an age of ±7,500 years AP while the sandstones of beach that is in the depth between 20-30 have an age of ±8.000 years AP.

E-mail: sichen720@hotmail.com

Keywords: paleo-Orinoco Delta, tidal cycles, tidal bundles, rhythmites, tidal constituents

The Orinoco Delta is one of the few river deltas where both modern and ancient tidal processes records can be studied. The ca. 5 My succession on the island of Trinidad contains remnants of paleo-Orinoco deltaic deposition preserving both tide- and wave-influenced delta lobes within the same time intervals, just like its modern Orinoco Delta that has both wave-dominated and tidal-dominated lobes. The tide-influenced delta lobes and estuaries preserve some spectacular tidal bedding signals including tidal rhythmites. The tidal record encoded within the tidal rhythmites is preserved well enough that the primary tidal constituents responsible for the tidal currents that deposited the rhythmic facies can be inferred.

Lower to upper Pliocene tidal rhythmites have been examined in two main paleo-Orinoco sub-environments: (1) estuary and delta lobe deposits of Morne L'Enfer Fm. at Erin Bay and (2) abandoned tidal channels associated with tide-influenced delta-front deposits from Telemaque sandstone Member of Manzanilla Formation at Matura Bay. Both wave- and river-current signals are also present in most of the study areas.

Tidal constituent analysis of unusually well-preserved paleo-Orinoco tidal rhythmites reveals a hierarchy of tidal signals that include semi-diurnal, diurnal, fortnightly (neap-spring), monthly (perigee-apogee), semi-yearly, and possibly seasonal and yearly cycles that span thickness intervals ranging from mm to meters.

The tidal constituents were dominated by, in decreasing importance, M_2, S_2, and likely K_1 rather than O_1. The modern data clearly show that K_1 is more important in terms of tide-generating potential than O_1, as was likely so in the Pliocene. In both the rock and modern records N_2 is more significant than O_1, P_1, and K_2 are in terms of tide-generating potential. The comparison between the constituent analysis of the ancient tidal record and the modern tide measurements reveals their similarities in tidal patterns and constituent types and from this we deduce that the tidal constituents responsible for the Pliocene Orinoco Delta tides were mixed semidiurnal tidal cycles similar to those found today in Trinidad (Atlantic type-synodically dominated) rather than Caribbean (tropically-dominated) type.

Furthermore, the thickness of the tidal rhythmites, accumulated either by ponding in near-abandoned channels or by lateral accretion in dunes within channel bars, allows sediment accumulation rates to be estimated. In the alternating sand- and mud-dominated rhythmites the preserved laminae thickness is positively related to tidal current strength, sediment discharge, and seasonal changes, and also reflects environmental processes.

EVIDENCE OF FLUVIAL DOMINANCE IN THE MOST FAMOUS ANCIENT TIDE-DOMINATED DELTA: A REINTERPRETATION OF THE UPPER CRETACEOUS SEGO SANDSTONE AND BUCK TONGUE, BOOK CLIFFS, UTAH

Keywords: varying river discharge, river flood, interflood, fluvial-dominated delta, deltaic deposits, Western Interior Seaway

Interpreting nearshore systems and rocks is particularly challenging given the presence of multiple processes varying in space and time. In this study, we provide a reassessment of the relative roles of fluvial, tidal, and wave processes in the deposits of the Sego Sandstone and Buck Tongue, which probably represent the best studied and most widely interpreted ancient tide- (or mixed tide-wave-) dominated delta. Detailed sedimentological analysis at selected localities confirmed that potentially tide- and wave-generated sedimentary structures (e.g., bidirectionality, heterolithic bedding, hummocky cross stratification) or evidence for brackish water (e.g., trace fossils) are common; however, in most of the cases, a dominant fluvial signature that has been so far unrecognized can be interpreted. This signature consists of a cm- to dm-scale alternation of sandstone and heterolithic beds representing flood-interflood periods of a varying river discharge. Evidence for marine incursions is often present only in the interflood beds and subordinately to the dominant river-derived interbedding. Recognition of widespread fluvial processes across the studied units would highlight a historical and persistent overinterpretation of tidal (and wave) processes. We suggest that the widely used approach for interpreting nearshore deposits applied to the Book Cliffs but also elsewhere is inappropriate to decipher the complexity of these systems.

Study on division of sequence stratigraphy and its petroleum geological meaning of the Silurian marine siliciclastic depositional systems in the Tarim Basin, China

Yuanzhuang Chen[1*], Zhongpei Zhang[1], Jiang Wu[1], Weibiao Zhang[1], Guojun Xie[1]
1. Oil-Gas Exploration Research Institute, Exploration and Production Research Institute, SINOPEC, Beijing, CHINA
E-mail: chenyz.syky@sinopec.com

Keywords: Division of sequence stratigraphy, sedimentary facies, source-reservoir-caprock assemblage, favorable exploratory targets, Silurian, Tarim Basin

The Silurian has a residual area of about 24.9 × 104 km2 (96,139 mi2), and many hydrocarbon shows have been encountered in the Kepingtage sandstones in the Tarim Basin. Based on the cores, logging, seismic, and analysis data, division of sequence stratigraphy, characteristics of sedimentary facies, and its petroleum geological meaning of the Silurian in the basin were studied. The Wenlock Yimugantawu Formation and the Llandovery Tataaiertage and Kepingtage formations are Silurian in age. The Silurian can be divided into three second-order sequences, and ten third-order sequences. The Kepingtage Formation consists of Lower, Middle, and Upper Members, and the Lower Member is divided into three third-order sequences (Sq1, Sq2, Sq3), and the Middle Member is Sq4, and the Upper Member is divided into two third-order sequences (Sq5, Sq6). The Tataaiertage Formation consists of Lower and Upper Members, and is divided into two third-order sequences (Sq7, Sq8). The Yimugantawu Formation is divided into two third-order sequences (Sq9, Sq10). The third-order sequences of Sq1, Sq5, and Sq7 belong to the type - I sequence, while the others are the type - II sequence. Four types of depositional systems were identified in the Silurian, including shore-neritic-deep water shelf, tidal flat, tidal flat-shore composite, and braded delta systems. The sandstones of Sq1, Sq2, Sq3, and Sq5 at the depths of 4200 – 6230 m have porosity of 0.73% - 20.62%, averaging 8.25%, and permeability of 0.01-1855 mD, averaging 12.22 mD, indicating that the Kepingtage sandstones have good reservoir quality and are the potential exploration layers.

Deep water shelf of Sq 4 is developed in the depositional center of the Manjiaer and Awati Depressions. Organic carbon content of the deep-water shelf black shales ranges from 0.47% to 0.92%, their chloroform bitumen ‘A’ ranges from 177.5 to 417 PPm, and their vitrinite reflectance ranges from 0.74% to 1.34%. The thermal simulation results from Shun 1 well show that the source rocks of Sq4 were in early maturation in 290 Ma (Ro>0.5%), in middle maturation in 230 Ma (Ro>0.7%), and in late maturation in 40 Ma (Ro>1.0%). Sandstones of fluvial, braided delta, upper foreshore in Sq 1, Sq 2, Sq 3 are widely distributed across the basin. The neritic-deep water shelf mudstones of Sq4 form regional caprock, and the tidal red mudstones of Sq 7 form local caprock. Combinations between Sq1-Sq3 and Sq4, having syngenetic source-reservoir-caprock assemblage and favorable accumulation conditions of hydrocarbons generating from the Cambrian - Ordovician source rocks, are the potential oil-bearing layers. The sandstones from Sq1 to Sq3 and Sq5 around the margins of the Manjiaer and Awati Depressions, and in the Shuntuoguole Low uplift are the favorable exploratory targets.

Facies Associations, Stacking Patterns and Conceptual Depositional Model of Early Devonian Strata in Eastern Saudi Arabia

Hasan Algheryafi[1*], Carlos Roselli[1]
1. Gas Reservoir Characterization Department, Saudi Aramco, Dhahran, Eastern, SAUDI ARABIA
E-mail: hasan.algheryafi@aramco.com

Keywords: Shoreface, estuarine, fluvial, sequence stratigraphy

The Arabian Plate witnessed several transgressive and regressive episodes during the Early Devonian. During the Pragian-Emsian, two regressive events separated by a transgression are characterized by specific facies associations, stacking patterns, and gamma ray signature.

This study is based on subsurface core data. Lithofacies at sub-foot scale, interpretive sedimentary processes and depositional environments, combined with wireline and image logs. Palynological analysis was found crucial for localized stratigraphy.

Overall, the Formation of study is representing paralic depositional environments subdivided into a lower, middle, and an upper unit. The lower unit is dominated by shoreface successions that are cut by prograding tidal channels. The middle unit displays a variety of facies associations indicating estuarine channels, barriers, washover sediments, tidal sand and mud flats, central basin, flood-/ebb-tidal deltas. Different elements of these facies coexist to form stacked bayhead deltas. The upper unit is dominated by prograding tidal channels, marshes, and floodplain deposits.

Cross sections across depositional strike and down depositional dip show the lateral variation of facies associations and a sequence stratigraphic framework. Image logs are used to establish an overall depositional dip direction and better predict lateral facies change. Stacking patterns in the cross sections are classed as: 1) lower unit representing a forced regressive system, 2) transgressive middle unit, and 3) an upper normal regressive system.

The overall lithofacies characteristics and associations aided in identifying sedimentary processes and depositional environments. Further analysis on the stacking patterns resulted in interpreting two regressive events separated by a transgression. This dataset along with cross sections were used to classify the regressive successions as a forced regressive system and a normal regressive system.

Delineation of 3rd order depositional sequences and sea level changes during Bathonian-Oxfordian, Kachchh basin, Gujarat, India

Diwakar Mishra[1*]
1. Department of Geology, University of Dodoma, Dodoma, TANZANIA
E-mail: mishradiwakar988@gmail.com

Keywords: Microfacies, 3rd order depositional sequences, Bathonian-Oxfordian succession, Kachchh basin

Kachchh sedimentary basin is a peri-continental basin in the extreme west of Indian Peninsula.
The Mesozoic rocks ranging in age from Middle Jurassic to Upper Cretaceous occur conspicuously in the various major uplifts, and are exposed extensively in the Kachchh Mainland, Wagad, the 'Islands' of Pachcham, Bela and Khadir, and the Chorar hills. The Mainland outcrops expose a continuous succession from Bathonian to Santonian and consists of most prominent ridge extending for about 193 km from Habo in the east to Lakhpat in the west. On the basis of detailed field studies in Jhura dome, Kachchh Mainland and laboratory investigation of 60 rock samples, the 370m succession of rocks is stacked in to three 3rd order depositional sequences. The stacking pattern of microfacies assemblage refers to the architecture of vertical succession of depositional sequences. Transgressive sequence-I, Regressive sequence and Transgressive sequence-II have been recognised. The 84m Transgressive sequence-I consisting of four microfacies assemblages: (i) Oolitic fossiliferous grainstone - Sandy fossiliferous grainsone, (ii) Oolitic fossiliferous grainstone - Calcareous mudstone, (iii) Pebbly fossiliferous grainstone - Calcareous mudstone, (iv) Fossiliferous intraclastic grainstone - Calcareous mudstone representing upward deepening facies succession. The 130 m Regressive sequence composed of five microfacies assemblages: (i) Fine grained sandstone - Siltstone, (ii) Pebbly fossiliferous packstone - Siltstone, (iii) Pebbly cherty calclithite microfacies, (iv) Gypsiferous mudstone - fine grained sandstone, (v) Medium to coarse grained sandstone microfacies showing upward shoaling facies succession and the 155m Transgressive II consists of five microfacies assemblages: (i) Gypsiferous mudstone-Medium to course grained sandstone, (ii) Sandy fossiliferous packstone - Gypsiferous mudstone, (iii) Sandy oolitic packstone - Siltstone, (iv) Conglomeratic fossiliferous oolitic packstone microfacies, (v) Conglomeratic fossiliferous ironstone microfacies showing upward deepening facies succession.
From the present study It is inferred that there is marked deepening of sea during Bathonian as indicated by microfacies assemblages of transgressive sequence -I. Shallowing of basin during Callovian is suggested by microfacies assemblages of Regressive sequence that deposited during gradual increase in sediment supply and maximum deepening of basin in Early Oxfordian is marked by microfacies assemblages of Transgressive sequence- II that deposited during rapid sea level rise. The relative sea level curves indicate several sea level fluctuations during whole sequence prior to major sea level drop at the end of the transgressive sequence-II. The microfacies study reveals that the relative sea level cycles might have been controlled due to active tectonic mechanism (Cloetingh,1986; Kauffman,1984).

Analysis of the sedimentary reservoir architecture in a tide-dominated estuary: The study of the Athabasca block in Canada McMurray Formation Oil Sands Reservoir

Weixue Zhang[1], Yanshu Yin[1*], Wenjie Feng[1]
1. School of Geosciences, Yangtze University, Wuhan, Hubei, CHINA
E-mail: yys6587@126.com

Keywords: tide-dominated estuary, McMurray Formation, architecture elements, tidal bar, lateral accretion

Tidal-dominated estuary is a system with complex hydrodynamic characteristics and sedimentary processes, influenced by bidirectional currents and sea-level fluctuations. Based on high-resolution seismic data, 168 well coring datas and logging data, a detailed description of the sedimentary characteristics, architecture model and evolution of the tidal-dominated estuary reservoir in the Lower Cretaceous McMurray formation is presented. The results are as follows: 1) The lithofacies associations are divided into 9 types of architecture elements. The nine architecture elements are channel, salt marsh, fluvial point bar, tidal point bar, mud flat, mixed flat, sand flat, tidal bar and offshore. The boundary surfaces of each architecture elements are depicted and the logging characteristics is concluded. 2) The plane and vertical distribution of architectural elements are revealed, and the sedimentary model is constructed. In the longitudinal section of estuary, the architecture elements is fluvial deposits (channel, fluvial point bar, salt marsh), tidal flat (mud flat, mixed flat and sand flat), tidal sand bar, tidal flat, and offshore from land to sea. In the cross section, tidal sand bar, sand flat, mixed flat, mud flat, tidal point bar and salt marsh are distributed successively from the center to the sides. 3) The main reservoirs such as sand flat and tidal sand bar are distributed in the incised valley formed during mid-short-term regression, and the frequently incised sedimentary landform controls the distribution range and plane morphology of the main reservoirs (sand flat and tidal bar). Tidal bars are mainly distributed in the incised valley with larger water depth. The sand flat is primarily distributed in the flat area of the lateral edge of tidal sand bars or in the incised valley. The sand flat and the mixed flat occured the erosion and filling phenomenon inside. Tidal bar has a wide band shape with a typical high-angle continuous lateral deposits.

Diagenesis of shale oil reservoir in Lucaogou Formation, Junggar Basin

Wendao Qian[1*]
1. College of Marine and Technology, China University of Geosciences, Wuhan, Hubei, CHINA
E-mail: qianwendao@cug.edu.cn

Keywords: mixed rocks, diagenesis, Jimusar Sag

Hydrocarbon exploration has been increasingly concentrated in mixed rocks its large quantities. Mixed rocks are always heavily cemented, while high quality reservoirs have large numbers of pores created by dissolution and/or dolomitization. Thus, one of the major challenges for characterization of mixed rocks are to understand the distribution of diagenesis, associated products and controlling factors responsible for determining the quality and overall heterogeneity of the reservoirs. This study takes the Lucaogou Formation in Jimusar Sag as an example to study the diagenetic evolution of the reservoirs. Through comprehensive core analysis, the control factors of reservoirs development under different burial depths were identified, and the differential genesis was revealed.

Source-to-sink analysis for the late-Quaternary Qiantang River incised-valley fill and its implications for delta-shelf-estuary dispersal systems globally

Xia Zhang[1*], Ming Chun Li[1], Dalrymple W Robert[2], Shou Ye Yang[3]

1. School of Earth Sciences and Engineering, Nanjng University, Nanjing, Jiangsu, CHINA
2. Department of Geological Sciences and Geological Engineering, Queen's University, Kingston, Ontario , CANADA
3. State Key Laboratory of Marine Geology, Tongji University, Shanghai, CHINA

E-mail: zhangxiananjing@163.com

Keywords: Changjiang, delta-shelf-estuary system, elementary geochemistry, mixing model, sediment budget, zircon U-Pb geochronology

The Changjiang (i.e. the Yangtze River) debouches a huge amount of sediment to the East China Sea and exerts a significant effect on the evolution of the down-drift Qiantang River system. This study quantitatively documents the temporal change in the import of Changjiang sand and mud to the late Quaternary Qiantang River incised valley by establishing separate mixing models based on zircon U-Pb ages for the sand and trace-element compositions of the mud fraction. Results indicate that the Qiantang River provided all of the sediment to its valley before ca 8.0 cal. kyr BP. However, its sediment proportion decreases upward due to the onset of export of sediment from the Changjiang after its delta had prograded sufficiently. Changjiang mud, a major component (ca 87%) of the Changjiang-derived sediment, is considered to be primarily supplied through the resuspension and landward transportation of sediment from the inner-shelf mud wedge in the East China Sea by flood-tidal currents and waves. Changjiang sand, which arrived in the Qiantang River valley later than the mud, is interpreted to be derived from the reworking of older deposits on the East China Sea shelf and along the northern margin of the Qiantang River estuary. In the later part of the valley fill, Qiantang River sediment is only ca 9% of the Changjiang contribution, although Qiantang River mud has begun to be exported recently. The Changjiang contribution to the Qiantang River system constitutes ca 50% of the total sediment load discharged by the Changjiang during the 8–6 cal. kyr BP period, but <4% since 6 cal. kyr BP. This study illustrates the need to exercise caution when interpreting compositional data from linked coastal-shelf sediment-dispersal systems with significant along-coast transport, and is expected to be applicable in a general way to other linked river-coastal-shelf systems.

Rapid accumulation of early Holocene tidal rhythmites in the paleo-Han River estuary, Korea: Evidence of intensified summer monsoon

Seung Yeon Sohn[1], Joohee Jo[1], Kyungsik Choi[1*]
1. School of Earth and Environmental Sciences, Seoul National University, Seoul, KOREA, SOUTH
E-mail: tidalchoI@snu.ac.kr

Keywords: tidal rhythmite, early Holocene, summer monsoon, Han River delta, sediment discharge

Rapid transgression occurred globally during the early Holocene, leading to estuarine deposits in the incised valleys with typically insignificant fluvial sediment loads except for major rivers. High monsoon-related sediment discharge in the early Holocene has been documented from the major rivers, but little is known about the fluviosedimentary response of the small to moderate rivers. Facies and stratigraphic analysis of long (~ 50 m) borehole cores, obtained in the northern Gyeonggi Bay, west coast of Korea, revealed that up to 35-m-thick Holocene deposits consist of two units, i.e., Lower and Upper units. Lower unit is 15–20 m thick and is characterized by interlaminated sands and muds and a slightly fining-upward textural trend. Upper unit is less than 10 m thick and displays a slightly coarsening-upward textural trend. Parallel to ripple cross-laminated and cross-bedded sands constitute the major facies of Upper unit. Lower unit hosts 15-m-thick tidal rhythmites, displaying hierarchical tidal rhythmicities in the laminae thicknesses, including diurnal inequality, neap-spring tidal cycles, fortnightly inequalities, and semiannual tidal cycles. AMS radiocarbon dating indicates the rhythmites succession formed between 9–8 ka B.P. (14C dates) when the summer monsoon intensified to result in high sediment discharge like many tropical to temperate regions. Despite the moderate discharge of the Han River (1/45 of the Yangtze River and 1/30 of the Brahmaputra River), such rapid accumulation (~15 mm/yr) indicates that the sediment loads of the paleo-Han River are comparable to those of the large rivers in the early Holocene. The enhanced sediment discharge of the paleo-Han River is further aided by the geology and morphology of the catchment area, which is composed mostly of impermeable granitic bedrocks with a steep slope gradient, promoting surface runoff. The tide-dominated paleo-Han River estuary was fed by fluvial muddy sediments in the early Holocene transgression and became a deltaic setting with a relatively sediment-starved condition in the late Holocene sea-level highstand when the summer-monsoon intensity has decreased notably. The absence of well-developed tidal rhythmites in Upper unit is ascribed to the mixed-energy condition in the late Holocene when the northern Gyeonggi Bay was subject to offshore waves. The present study showcases that relative sea-level changes under shifting climate regimes played a crucial role in the stratigraphic evolution of the Han River delta.

Multi-stage Miocene forced regressive deposits on the northern South China Sea shelf: Responses to a southwesterly flowing paleocurrent

Shuqin Huang[1], Haiteng Zhuo[1*], Ming Su[1], Jin Feng[2], Zhigao Li[2], Lin Ding[2], Jiayuan Du[2]
1. SCHOOL OF MARINE SCIENCES, SUN YAT-SEN UNIVERSITY, zhuhai, Guangdong, CHINA
2. CNOOC, ShenZhen Ltd, shenzhen, Guangdong, CHINA
E-mail: zhuoht3@mail.sysu.edu.cn

Keywords: Pearl River Mouth Basin, Sequence stratigraphy,Forced regressive deposits, SW-oriented paleocurrent

In this study, high-resolution 3D seismic, log and core data were used to identify multiple stripe sand deposits in Miocene strata in the Huizhou Sag, Pearl River Mouth Basin, northern South China Sea.

Analysis of stripe sand deposits includes seismic facies analysis and seismic geomorphology analysis: (1) Seismic facies analysis: Three main types of seismic facies can be recognized within stripe sand deposits : Seismic facies1 located in front of the stripe sand deposits has a wedge shape and pinching out seaward with very high amplitude reflections; Seismic facies 2 located in central part of stripe sands has moderate-high amplitude and high angle reflections with clinoforms characteristic; Seismic facies 3 located in tail of stripe sand deposits has parallel to sub-parallel and low-amplitude reflections with wedge shape, numerous scour gutters can be found here. (2) Seismic geomorphology analysis: By means of RMS amplitude and color-blended (RGB) spectral decomposition extractions from top to base of stripe sand deposits, we found that entire stripe sand deposits have a NE-SW orientation with characteristic of NE-narrow and SE-wide, its interior develop striate structure in the middle part especially.

After analysis above, we consider stripe sand deposits to be beach ridge sedimentary facies. Identified beach ridges in study area may form in stage of sea level fall, the presence of forced regressive beach ridge deposits can be evidenced by: (1) In the seismic section, the interior of forced regressive deposits is typical of upward and toplap characteristics, with the presence of a basinward-dipping upper bounding surface as a whole.; (2) In logging, it shows the Coarsening-upward sandstone with abrupt change of top and bottom, and the thickness of forced regressive sand body in the same period changes from thin to thick in sedimentary tendency, but in general, the thickness of the youngest forced regression wedge is the largest; (3) The bottom interface of the sharp-based sandstone can be observed on the core, and below the RSME are fine-grained silty sand or mudstone, in which a large number of bioturbation can be found;

In identified beach ridges deposits, one of the oldest period (developed after 23.8 Ma) appeared with the NE to SW divergence characteristics, so we speculated that the dominant SW-oriented paleocurrent was already exists since 23.8 Ma. Carbonate platform and uplift in the southeast region gradually developed landward, the strike of beach ridge deposits gradually changed from the whole nearly parallel to paleoshoreline to the northern half nearly parallel to the platform edge and the southern half nearly parallel to the paleoshoreline. Subsequently, the carbonate platform gradually retreated seaward, and the strike of beach ridge deposits formed gradually parallel to the paleo-shoreline, which may indicate that the flow direction of the NE-SW paleocurrent had some changes in the narrow area between the carbonate platform and paleoshoreline.

How to orientate a shallow-marine silicilastic platform in 3D? A stratigraphic study from the Ktawa Group in Morocco (Late Ordovician, Gondwana)

Déborah Harlet[1*], Guilhem Amin Douillet[1], Jean-François Ghienne[2], Pierre Dietrich[3], Chloé Bouscary[4], Fritz Schlunegger[1]

4. Institut des Dynamiques de la Surface Terrestre (IDYST), Université de Lausanne, Lausanne, Vaud, SWITZERLAND

E-mail: deborah.harlet@geo.unibe.ch

Keywords: Stratigraphy, HCS, siliciclastic, Gondwana, Ordovician, Morocco

The Southern Anti-Atlas of Morocco contains shallow-marine siliciclastic sediments from Late Ordovician time. These were deposited on the northern platform of Gondwana and are part of a large-scale flooding, which started in the Latest Precambrian. Here, a set of 42 stratigraphic profiles were logged in the field in order to constrain the Ktawa Group (Sandbian to Katian). Drone-based 3D photogrammetric reconstructions allowed to calibrate the logs thicknesses. The profiles were correlated through satellite and drone-based images along a ca. 175 km long continuous transect. The transect contains sections with orientations pointing from NE to SE, allowing to discuss semi-3D interpretations.

The Lower Ktawa Group is dominated by shales, punctuated by fine to coarse sandstones units forming successive cuestas. Six different sand cuestas outcrop in different zones of the transect. A general model can be hypothesized, whereby each cuesta includes a low-energy upper offshore parasequence at its base, which is subsequently truncated by high-energy storm-dominated (reworked) HCS beds during the ensuing transgression. Two cuestas, however, differ from this model and call for additional refinements. They include bioturbated, coarse-grained and cross-bedded deposits with a sharp base (i.e. tidal?).

Although the general stratigraphic framework is relatively well understood, the orientation of the system remains challenging. Two main hypotheses are drawn, and seem to explain equally well the data. One possibility is a system with a dominant W to E proximal-to-distal trend. Clinoforms would be organized as prograding sequences towards the E. The alternative model is a system oriented S to N, where each cuesta represents a laterally restricted “megalobe”. A switch in feeders and/or differential subsidence could explain the lateral shift in emplacement of the cuestas. In both models, the two cuestas containing coarse-grained units would represent major regressive excursions. Furthermore, both models require syn-sedimentary differential subsidence to account for the measured sediment thicknesses.

On the larger scale, the study region (Foum-Zguid region) is transiting eastward into a time equivalent shale-dominated area (Tagounite region), until reaching another sandy area approx. 300 km further NE (Erfoud region). Hence, in a W to E clinoform interpretation, the basin would have a conjugated coastline to the NE with another depositional system orientated S to N. In a S to N "megalobe” interpretation, two parallel depositional systems would fill a globally S to N oriented basin, thus forming a single and coherent trend for all formations.

E-mail: sanem.acikalin@newcastle.ac.uk

Keywords: clay coating, reservoir quality, tidal systems

Understanding the reservoir properties (texture, architecture and chemistry) is crucial for successful extraction and injection of fluids and gases from/to subsurface reservoirs. Mineral composition, storage capacity and pore connectivity of reservoirs are typically controlled by combination of depositional and diagenetic factors. Depositional properties such as mineralogy, grain size, sorting and fluid chemistry provide a template for burial diagenetic pathway

There is a strong link between (depositional) detrital clay content and their distribution on pore scale attributes. Excess detrital clay typically fills pores and bridges pore throats resulting in reduced permeability. However, the presence of limited amount of grain coating detrital clay has a positive influence on reservoir attributes by inhibiting burial cementation and hence retaining porosity and permeability. Therefore, understanding the detrital clay type and distribution is crucial for prediction of subsurface reservoir attributes.

This study examines the distribution of detrital clay coated grains and clay coat forming processes on and around bar formations in a modern estuary (Ravenglass Estuary, UK). Material covers surface sediments from a range of facies and up to 5m long cores representing deposits since the last glacial maximum. The preliminary results suggest that, almost all facies associations host clay coated sands, however, thickness, continuity and distribution of clay coats vary. Tidally influenced sands display wide range of grain sizes and typically contain less than 2% total detrital clay. The majority of the clay fraction occurs as clay coats. Discontinuous clay coats with heterogeneous distribution is typical in this facies. Bar associated salt marshes are typically finer grained and typically richer in total detrital clay (reaching up to 9.5%). In this facies association, clay coats are more common and coats are typically continuous. However, with increasing detrital clay content, the habit of detrital clay evolves from grain coating to pore filling, decreasing the depositional porosity and permeability. These findings are valid for both surface and shallow subsurface sediments of the Ravenglass estuary.

We suggest that high energy environments with limited detrital clay content (c. 2%) are likely to be characterised by discontinuous clay coats and hence more prone to quartz cementation during mesodiagenesis. Relatively finer sediments (fine sand), deposited by lower energy processes, typically display more continuous clay coats. These deposits are more likely to retain higher porosity and permeability due to inhibited quartz cementation during mesodiagenesis. However, a further increase in detrital clay content would result in pore filling clay which would have a detrimental effect on reservoir quality in buried sandstones.

These preliminary results and numerical cut-offs, of 2 and 9.5% grain coating clay,, will be further refined by additional systematic data collected both from surface and subsurface sediments. Understanding of grain size, clay content and clay coat attributes will be discussed in this presentation.

The mixed sedimentary characteristics and genetic mechanism of Canglangpu Formation of the Lower Cambrian in the eastern Sichuan basinSW China

Zebin Tong[1], Zhonggui Hu[1*]
1. School of Geosciences, Yangtze University, Wuhan, Hubei, CHINA
E-mail: cdut1978127@sohu.com

Keywords: eastern Sichuan basin,Canglangpu Formation,mixed sedimentation,distribution law,genetic mechanism

The mixed sediments of the Canglangpu Formation in the eastern Sichuan basin are widely developed and have good exploration prospects, but the relevant research and understanding are still weak. Deepening the research on the mixed sediments of the Canglangpu Formation is of great significance to the exploration of mixed reservoirs in this area. During the depositional period of the Canglangpu Formation, the study area experienced two complete transgression-regression cycles, with obvious stratigraphic differentiation between the upper and lower members. The lower part is mainly composed of sedimentary carbonate diamictite, and the upper part is mainly composed of sedimentary clastic diamictite, which are mainly distributed in the coastal-neritic shelf sedimentary environment. On the basis of previous research, combined with the observation of typical outcrop profile, the identification of thin rock section, and the study of drilling and logging geological data, a model for identifying the electrical response of the melange in the study area was established. Combining lithofacies features with logging facies features, a diagram for the classification of diamates suitable for this area is proposed. The study area is dominated by facies-change mixed sedimentation, and the sedimentary environment is a complete mixed coastal-detrital mixed shelf-carbonate mixed shelf sequence. Two mixed sedimentary facies and five Subphases and 12 microphases. The mixed sediments of the Canglangpu Formation, under the special background of alternating uplifts and depressions, have obvious characteristics of ring-like development around underwater paleohighs. The main factors controlling the formation of mixed layers are vertical tectonic movements and sea level changes. The dominant reservoir facies belts in the area are concentrated in the oolitic shoals and sand shoals developed in a ring-like shape around the paleohigh.

Geomorphology and sediment dynamics of the Liyashan oyster reefs, Jiangsu coast, China

Hangjie Lin[1], Qian Yu[1*], Zhiyun Du[1], Yiyang Fan[1], Yunwei Wang[1], Shu Gao[1]
1. School of geography and ocean science, Nanjing University, Nanjing, Jiangsu Province, CHINA

Keywords: oyster reefs, suspended sediment concentration, hydrodynamics, drag coefficient, spatial patterns

Oyster reefs and their spatial patterns are deemed to change the local hydrodynamic condition and exert profound impacts on the grain size, concentration and transportation of suspended sediments. Meanwhile, high suspended sediment concentration often results in excess mortality among oysters. Oyster reefs are rare and vital ecosystem in Liyashan national marine park, Jiangsu Coast, China, however, urgent conservation efforts should be made on account of the drastic reduction in reef areas. To investigate the sediment dynamics and the geomorphology, we employed two tripod observation systems and carried out UAV aerial surveys, alongside elevation measurement with RTK. High mud content (60%) was found in the bed sediment at the reef ridge, causing much lower drag coefficient than other recorded values of living oyster reefs, indicating the death of oysters and the degradation of reefs in Liyashan. Ridgelines of the string reefs at 45 degrees to the current direction and high suspended sediment concentration in the water body (50–370 mg/L) that exceeds the threshold (200 mg/L), which will affect nutrient uptake efficiency and further result in gill saturation, decrease of clearance rate and associated deposition, were probably crucial causes of the death of oysters. Our findings are useful for restoring natural oyster reefs and designing artificial reefs for nature-based coastal defense.

Keywords: sand beach, intertidal sand bars, UAV aerial survey, satellite imagery, bedform analysis

Multiple intertidal sand bars are sedimentary landforms commonly found on low-gradient sandy coasts with a significant tidal range exposed to low-moderate wave energy. They play an important role in the context of environmental, ecological, and functional coastal protection strategies. Nevertheless, the understanding of their morphodynamics is hampered due to the lack of high-resolution field data and convenient tools for bedform analysis. Here, the morphodynamics of intertidal sand bars was investigated at two adjacent tidal beaches on the north and south coasts of a small estuary on the Lianyungang coast of China by repetitive RTK-GPS leveling, UAV aerial surveys, surface sediment sampling, satellite remote sensing analysis, and automatic bedform analysis. Two distinct types of intertidal sand bars are found to the north and south of the Longwang River mouth (Lianyungang, Jiangsu, China), namely, low-amplitude ridges (or called ridges and runnels) and sand waves. The northern area is characterized by 2-5 oblique, asymmetrical, and dynamic bars that appear at the seaward end of the intertidal zone from where they migrate landward, to finally attach to the steep beach on the landward end of the intertidal zone, presenting a life cycle of ~14 years. The southern area, by contrast, is characterized by 6-9 parallel, complete, continuous, symmetrical, and stable sand bars that occupy the lower part of the intertidal zone. The different morphodynamic behavior of the two bar systems is attributed to sediment supply in each case. The combination of UAV aerial surveys, satellite imagery, and quantitative bedform analysis has demonstrated their great potential in documenting the response of intertidal sand bars to human activities and global change effects.

The impacts of compaction-influenced accommodation and erosion resistance on the morphology of fluvial-dominated deltas: a modelling study

E-mail: A.A.Valencia@tudelft.nl

Keywords: Process-based forward models, compaction, accommodation, erosion resistance, channel dynamics, delta morphology

The first-order impact of compaction, which reduces bed thickness, has been shown to influence delta morphology by increasing sediment retention upstream of the delta through additional accommodation. However, compaction also impacts the erosion resistance of sediments. This study uses a numerical approach to understand how the combined volume reduction and increase in erosion resistance of compacted sediments affects delta morphology. For this purpose, a new erosion resistance formula for cohesive sediment was derived and integrated with the compaction module of Delft3D, which was previously developed to quantify only compaction-induced volume reduction. The updated code was then used to generate a series of seaward prograding and vertically stacking deltas. For each delta, a compaction rate between 0 to 10 mm year-1 was assigned. The simulated deltas are analyzed by first classifying the delta into depositional environments: delta top, delta front, and pro delta. Then, for the delta top and delta front depositional environments, the accommodation and erosion resistance encountered by new sediments depositing in these regions are calculated. Finally, the impact of compaction on morphological changes in the simulated deltas due is quantified using the planform aspect ratio, which is related back to the channel bifurcation and avulsion behaviour. The simulated deltas experience two stages of development, starting with a progradation stage through rapid basin infilling, followed by an aggradation stage as the deltas encounter a deeper water depth. In lower compaction scenarios (0 – 0.1 mm year-1), the impact of erosion resistance is more dominant, stabilizing the channel, leading to more frequent bifurcation, which mainly occurs during the delta progradation stage. As the compaction scenario increases to 10 mm year-1, more accommodation is created in the delta top, destabilizing the channel. This leads to more frequent avulsion, characterized by regional avulsion closer to the channel mouth during the delta progradation stage and nodal avulsion that splits the channel around the delta apex during the aggradation stage. Avulsions mainly carry the sediment load parallel to the initial shoreline, transitioning from an elongated delta top shape to a semi-circular shape. For the first time, the presented modelling results unravel the interaction between the compaction-driven volume reduction and the associated increase in erosion resistance on delta morphology. This new insight can be applied to comprehend the controlling process in ancient delta deposits and predict the evolution of modern deltas under a changing climate.

E-mail: hehechen89@gmail.com

Keywords: Shoal water delta, mixed carbonate-siliciclastic beach bars, seismic geomorphology, rift basin

Recent studies of ancient rift basins focus on the tectono-sedimentary models, which emphasize the control of tectonics on the distribution and evolution of depositional systems in rift basins, whereas these studies seldom address stratigraphic dominated depositional models. Compared to footwall depositional systems, hanging wall depositional systems are especially underexplored due to their fine-grained, thin-layered, and widely distributed features. We integrated seismic data, cores, and well logs to define the dispersal of hanging wall depositional systems that are related to the fluctuation of lacustrine level in the late syn-rift and post-rift stages. We identified one third-order sequence (SQ1) on the seismic reflection data and subdivided five fourth-order sequences (SSQ1–SSQ5) based on the features of parasequence sets. The strata in SQ1 record a complete regressive and progressive lacustrine process. We interpreted shoal-water deltaic systems and mixed carbonate-siliciclastic beach-bar systems in the SQ1. Within SSQ1 and SSQ2, sediments fed from the northwest, west, and southwest, and developed shoal-water deltaic systems with an average width range of the distributary channel belts within 680–1220 m. In SSQ3, beach-bar systems gradually changed from clastic beach bars to mixed carbonate-siliciclastic beach bars in a basinward direction. Clastic beach-bar systems and mixed carbonate-siliciclastic beach-bar systems were extending north–northeast with an average length of approximately 8–3.5 km and a width of 4–1 km. For those in SSQ4 and SSQ5, shoal-water deltaic systems prograded into the lacustrine, and distributary channel belts occur with an average width range within 520–880 m. We developed a spatial and temporal quantitative evaluation of deltaic and beach-bar reservoirs within a third-order sequence on the hanging wall dip slope, and it has potential worldwide implications for other hanging wall dip slopes in rift basins.

E-mail: 249292975@qq.com

Keywords: shale lithofacies, reservoir characteristic, oil-bearing property,Fengcheng Formation,Junggar Basin

Compared with the conventional lacustrine shale, the Permian Fengcheng Formation in the Junggar Basin is a complex sedimentary construction deposited under the background of an alkaline limited lake basin and controlled by terrigenous supply, volcanic activity and endogenous chemical deposition. Aiming at the problem that it is difficult to determine the dominant lithofacies of the alkaline lacustrine shale in the Fengcheng Formation of the Hashan piedmont in the Junggar Basin, Starting from the drilling test data, through macroscopic core observation, microscopic identification, X-ray diffraction mineral analysis and total organic carbon test, and comprehensively considering sedimentary structure, mineral type and organic matter content, five types of shale lithofacies were classified. By means of field emission scanning electron microscopy, high-pressure mercury intrusion, casting thin sections, micro-CT scanning, two-dimensional nuclear magnetic resonance and other testing methods, the classification evaluation of reservoir characteristics and oil-bearing properties of different shale lithofacies was carried out. It is clarified that the organic-rich laminar endogenous chemical deposits are characterized by high TOC, medium S1 and mesopores, and shale oil is mainly in a bound state, and occurs in nano-scale matrix dissolved pores, micro-scale dolomite and feldspar secondary pores, which is the dominant lithofacies in the source rock layer. Laminar terrigenous clastic sediments containing organic matter and layered pyroclastic sediments containing organic matter are characterized by medium TOC, high S1 and high porosity, and shale oil is mainly free, and occurs in micron-scale fractures and secondary dissolved pores, which is the dominant lithofacies of the reservoir.

Mixed sedimentary characteristics of the first member of Shahejie Formation and its control on reservoir quality, Bohai Sea

xiaojun pang[1*], qingbin wang[1], liming dai[1]

1. Bohai Petroleum Research Institute, Tianjin Branch of China National Offshore Oil Corporation Limited, Tianjin, CHINA
E-mail: pangxiaojunupc@163.com

Keywords: Diacite, salt water lake, high-quality reservoir, the first member of Shahejie Formation, Bohai Sea

The mixed sedimentary facies belt, lithology and physical properties change rapidly in the first member of the Shahejie Formation in the Bohai Sea, and the mixed sedimentary characteristics and the origin of the high-quality reservoirs are not clear.

Aiming at the above problems, the facies belts and rock types and their distribution of mixed sediments were divided by drilling and seismic. The relationship between different facies, different rock types and porosity and permeability is analyzed by rock types, cast thin sections and physical properties. Use carbon-oxygen isotopes, trace elements and other geochemical data. The formation environment of bioclasts, micrite dolomite crust and calcite and dolomite between skeleton particles in mixed sediments was analyzed. The characteristics of mixed sediments and their control on reservoir quality are discussed.

The results show that: (1) There are three types of sedimentary facies, namely, nearshore mixed fan, nearshore mixed shoal, and far-shore mixed shoal in the first member of Shahejie Formation in the Bohai Sea, which are further divided into mixed channel, mixed clastic shoal, and mixed facies. Debris beach, mixed micrite and other microphases. And the formation of bioclast-dominated, terrigenous debris-dominated and chemical precipitation carbonate-dominated diamictite. (2) The analysis of carbon and oxygen isotopes, thin sections and geomorphology of the diamictite in the first member of Shahejie shows that the lake basin was a closed-semi-closed saline and shallow lake basin in this period. The diamictite is relatively developed on the local uplift belt. The local uplift zone is mainly composed of harder rocks. The local uplift zone is close to the water surface and has sufficient sunlight for a long time, which provides a development location for the development of diamictite. Under the condition of intermittent supply of terrigenous debris, the intermittent supply of terrigenous debris provides sufficient time for the mud in the near-source fan/braided river delta to be washed away by waves. And it provides clear water conditions for the growth of snails and other organisms. (3) The volcanic rock base provides a large amount of nutrients such as nitrogen, phosphorus and potassium for the prosperity of snails and other organisms in the diamictite. Intermittent supply of terrigenous clasts provides feldspar, quartz, and lithic particles for the development of diamictite. (4) Volcanic rock bases, local uplifts, and intermittent sources in saline environments are the depositional conditions for the formation of diamictite in large-scale mixed sediments. (5) Enclosed by dolomite cladding and early dolomite cement, the cavity pores and intergranular primary pores of the mixed water channel, mixed clastic shoal, and snails in the mixed bioclastic shoal are largely preserved. . The bioclastic-dominated mixed bioclastic shoal reservoirs have the best physical properties. The water channels and mixed detrital beaches dominated by terrigenous detritus are followed. Mixed micrite shoals and near-source fan/braided river delta reservoirs dominated by chemical precipitation with minimal bioclastic content are the worst. The results provide effective guidance for the exploration of diamictite oil and gas reservoirs in the first member of the Shahejie Formation in the Bohai Sea.

Substrate erosional features beneath mass transport deposits and their implications for sand-hosted gas hydrate in the Qiongdognan Slope, north South China Sea

Jinfeng Ren[1*]
1. Gas Hydrate Engineering Technology Center, Guangzhou Marine Geological Survey, Guangzhou, Guangdong, CHINA
E-mail: jf_ren@163.com

Keywords: Linear substrate erosion, Mass Transport Deposits, Late-Quaternary slope, South China Sea

Substrate erosional features beneath mass transport deposits (MTDs) are becoming increasingly apparent and important in understanding of the erosional mechanisms of the seafloor and long distance transport of deep-water deposits in shelf margin. Based on the high-quality seismic dataset, five thin MTDs associated with concave incision were identified in the late-Quaternary lower slope regions of Qiongdongnan basin, north South China Sea. Compared to 'background' hemipelagic sediments, such thin MTDs at the seismic scale are characterised by higher gamma ray, resistivity, velocity, bulk density and lower neutron porosity on logging-while-drilling (LWD) data, as well as high dip and random azimuth in high-resolution resistivity image. Four linear erosional features with different geometry and scale, such as from large to small megascour and cat-claw scours, grooves, peel-back scours and striations in turn, were characterized by seismic topography, horizon dip slice and horizon amplitude attribute. An undeformed block and a deformed block at the bottom of MTDs were recognized by higher gamma ray, bulk density, velocity and resistivity as well as lower porosity and permeability than these of MTD's matrix. Such blocks were semi-consolidated in the core photograph and may be resulted from strong dewatering and shear compaction at the base of MTD. Megascour is interpreted as a consequence of substrate tooling of large and rigid blocks when they over-run the loose and unconsolidated sandy substrate. Cat-claw scours, radially distributed grooves, peel-back scours and divergent striations are also related to the further fragmentation of large blocks due to the friction with the substrate or variations in flow dynamics. Like the meandering channel incision, such erosional features can also be as an auxiliary indicator for the presence of turbidite sands in seismic profile, assisting to find the sand-hosted gas hydrate in the deepwater area of passive continental margin.

Features and Model of Mixed Sediments in Continental Rift Basins: A Case Study on the Lower Section of the 1st Member of Shahejie Formation in Lixian Slope, Raoyang Sag

Yifan Du[1*], Xiaomin Zhu[1], Linglong Li[1]
1. Department of Geology, China University of Petroleum (Beijing), Beijing, CHINA
E-mail: mr.duyifan@outlook.com

Keywords: continental rift basin, Raoyang Sag, 1st Member of Shahejie Formation, beach-bar, mixed rock, paleoenvironment

Not only do mixed rocks distribute in marine basins, but they also distribute in a large number of hanging wall slope areas in rift sags. In the lower section of the First Member of Shahejie Formation, the Raoyang Sag experienced rapid flooding, resulting in a great increase in the lake basin area and accommodation space. The siliciclastic influx from the river-delta systems was transferred in the lake basin by waves and coastal currents and deposited with carbonate sediments to form a set of coastal shallow-lake and beach-bar facies, which was distributed throughout the area. In order to clarify the characteristics and sedimentary model of the mixed rocks in the hanging wall slope areas of the rift sags, this work is mainly based on the core data and logging data of the Lixian slope. Through the core and slice observation, grain size analysis, log facies analysis, we studied the sedimentary characteristics and distribution of mixed beach-bars in the work area. Seismic data, pollen data, and trace element data were analyzed to restore the depositional environment controlling factors such as paleoclimate, paleo-provenance, paleogeomorphology, and paleo-water characteristics in the First Member of Shahejie Formation. On these bases, the sedimentary model of the mixed beach-bar in the rift sags was systematically summarized. The results showed that the beach-bar facies developed in the hanging wall slope area of Raoyang Sag can be divided into siliciclastic beach-bars, carbonate beach-bars, and mixed beach-bars according to petrologic characteristics. Moreover, mixed beach-bars can be divided into component-mixed beach-bars and stratified-mixed beach-bars. The lithology of component-mixed beach-bar was mainly calcareous sandstone, sandy oolitic limestone, and bioclastic limestone; Stratified-mixed beach-bars were mainly composed of biological limestone or dolomite interbed with thin layers of sandstone and siltstone. The distribution of mixed beach-bar was controlled by factors such as paleoclimate, paleo-provenance, paleogeomorphology, and paleo-water characteristics. Therefore, different sedimentary patterns developed in different positions and different sedimentary stages on the slope. Based on the differences of the paleo-sedimentary environment in different areas of the slope, the hanging wall slope of the rift sag can be further divided into a near-shore ramp, a far-shore ramp, and a far-shore low uplift. In the early stage of flooding, the water depth of the lake basin was large. Stratified-mixed beach-bars and carbonate beach-bars were deposited in the near-shore ramp, and component-mixed beach-bars were deposited in the far-shore ramp. Carbonate beach-bars were mainly distributed on the far-shore low uplift; For the late flooding stage, the water gradually became shallower. Consequently, siliciclastic beach-bars were mainly developed in the near-shore ramp. Component-mixed beach-bars and stratified-mixed beach-bars were formed in the far-shore ramp. This research can provide new ideas for not only the study of mixed rock sedimentary systems but also oilfield exploration.

Relationship between rapid lacustrine transgression and formation of hybrid siliciclastic-carbonate beach bar in a rift basin: A Case study based on the Bohai Bay Basin

Zili Zhang[1*]

1. Petro China Southwest Oil Gasfield Company, Petro China Southwest Oil Gasfield Company Exploration and Development Research Institute, Chendu, Sichuan, CHINA

E-mail: Pipi-D-king@hotmail.com

Keywords: Rapid lacustrine transgression, beach bar, Depositional system modal, Rift lacustrine basin, Palaeogene, Bohai Bay Basin

The early stage of each rifting episode in the lacustrine rift basin is conducive to the formation of large-scale beach bar. However, negligible research has been conducted on the beach bar types of hybrid sedimentation in lacustrine rift basin, especially for the hybrid siliciclastic-carbonate deposit (material) types, temporal and spatial distribution, and hybrid deposit causes, which indicate the distribution state of sediments in the early stage of rifting episode. In this study, the first member of Shahejie formation in Baxian sag, Bohai Bay Basin, was considered as an example for the first time, and abundant geological and geophysical data, including drilling data, well log curves, and high-quality full-coverage 3D seismic volume survey data, were obtained. Lithologic results indicate that the beach bar can be divided into four types: clastic beach bar, carbonate beach bar, hybrid siliciclastic-carbonate beach bar, and storm beach bar. The (hybrid siliciclastic-carbonate) beach bar is the result of the differential accumulation of terrigenous clastic and endogenous carbonate in the basin under the rapid lake transgression. The distribution of beach bars is inherited on the plane, and the syn-palaeogeomorphology controls the distribution of beach bars. The fault tilt plate and local palaeotopographic uplift are important development components of beach bars. The distribution of beach bars has a good correlation with the change of lake level vertically and a mirror symmetrical relationship with the maximum lake flooding surface. This study demonstrates that climate and provenance determine the type of beach bar, while palaeogeomorphology determines its shape and spatial distribution. The initial stage of rifting often corresponds to the process of rapid lake transgression, and the supply signal of terrigenous clasts experiences the characteristics of hysteretic response, which is conducive to the precipitation of carbonate rocks in the basin under the dry climate background. This study not only defines the types and spatial distribution characteristics of sediment in the initial stage of episodic rifting in lacustrine rift basin, but also provides guidance for the search of lithologic oil and gas reservoirs (traps).

Keywords: Lacustrine mixed sediments, Compositional mixing, Nearshore biota, Depositional evolution, Bohai Bay Basin

Mixed siliciclastic-carbonate sediments have been widely studied, especially those of marine origins. However, it is rarely investigated in continental settings. Boreholes from the Qinhuangdao-A (QHD-A) block in central Bohai Bay Basin sampled lacustrine mixed sediments during the Eocene period (32-38 Ma), providing an opportunity to facilitate this aspect of research. Here, an integrated facies analysis combined microscopic and core data reveals a siliciclastic fan-delta system that mixed with nearshore bioclastic shoals, forming the major “compositional mixing” and subordinate “strata mixing”. Moreover, seismic data, well-logs, and lithofacies logs divided mixed sediments into three evolutional units (U1-U3). The U1 and U2 were dominated by compositional mixing, showing that volcaniclastic sands and gravels mixed with bioclastic debris that are composed of shallow-depth biota assemblages. Within the U1, it occurred locally due to high siliciclastic input during the low-level period. Peak, however, took place in the U2 because lake level rise led to increasing accommodation and decreasing siliciclastic influx. With further deepening of water depth in the U3, shallow-depended biota was not well developed and carbonates increased. The change results in a distinct depositional sequence of strata mixing that centimeter-scale carbonates interbedded with siliciclastic beds in the highstand. In this study, the relatively warm climate and low tectonic activity may result in prevailing occurrences of nearshore biota, which offers a vital foundation for the formation of mixed sediments approaching to a fault-controlled steep hanging-wall margin. Furthermore, lake-level change is a key gauge in regulating evolutions of the mixed sediment type. These findings are clear that under certain conditions, mixed sediments can take place with amounts of siliciclastics, which bring new insights into mixed deposits, especially in continental settings.

Keywords: Clay minerals, mixed sediments, Saline lacustrine basin, Diagenesis, Qaidam

Previous scholars have studied clay mineral distribution and its effects on reservoir properties of sandstones, but it is not clear how clay minerals origin, evolve and influence reservoir properties of saline lacustrine mixed sediments. Aiming at clay mineral development mechanism of saline lacustrine mixed sediments, and taking the Neogene in the northwestern Qaidam Basin (NWQ) as the target layer, this research described the drilled cores of five key wells and 30-40 wells, used X-ray diffraction, rock analysis, pyrolysis and other methods, analyzed the characteristics of lithologies, clay mineral types, contents, assemblages and distribution of the Shangyoushashan (N22), Xiayoushashan (N21) and Shangganchaigou (N1) formations, and discussed clay minerals' origin and diagenetic evolution. Mixed fine sediments including fine sandstones, siltstones, mudstones, and carbonate rocks are developed in the Neogene of NWQ, where shale kerogens mainly belong to type III with a small amount of type II2. Diagenesis types include compaction, cementation, disolution and others, the N22 is in the early diagenetic stage B, the N21 at the early diagenetic stage B-middle diagenetic stage A, and the N1 in the middle diagenetic stage A-B. Clay minerals are mainly composed of montmorillonite mixed layer (I/S), illite (I) and chlorite (Ch), with sporadic smectite in the shallow layer. The contents of montmorillonite mixed layer decrease while those of illite and chlorite increase vertically with the increase of depth. The contents of montmorillonite mixed layer, illite and chlorite in the N21 and N1 increase from NW to SE along the source direction. The contents of illite and chlorite increase while those of montmorillonite mixed layer decrease gradually from SW to NE perpendicular to the source direction. On the whole, the total contents of clay minerals in these three formations are relatively stable in the study. The clay mineral types and contents are affected by climate, sedimentary facies and diagenesis. Saline lakes under alkaline conditions are developed in NWQ during the Neogene. Smectite and montmorillonite mixed layer are relatively rich in shore and delta front subfacies while illite and chlorite relatively rich in semi deep lake. The Neogene are rich in potassium ion (K+) under the influence of the parent rock. With the deepening of the water body, the contents of K+ increases, the EH decreases and the PH increases, which is conducive to the existence and enrichment of divalent iron ion (Fe2+) and magnesium ion (Mg2+). In the water body with alkaline conditions rich in K+, aluminum ion (Al3+) and K+ are replaced by Fe2+ and Mg2+ from smectite and transformed into illite. At the same time, Fe2+ and Mg2+ are relatively enriched, which provides a material basis for the formation and of chlorite. Clay minerals have effects on fine grained reservoirs and their oil and gas distribution, so the research results are meaningful to shale oil and gas exploration of saline lacustrine mixed sediments.

Lacustrine Mixed Siliciclastic-Carbonate Sediments in Paleogene Funing Formation of The Subei Basin, Eastern China: Characteristics and Origin

Wei Li[1*]

1. Research Institute of Petroleum Exploration and Development, Sinopec Jiangsu Oilfield Company, Yangzhou, Jiangsu , CHINA

E-mail: 543860715@qq.com

Keywords: Subei Basin, Gaoyou sag, Jinhu sag, Funing Formation, mixed sediments, lacustrine basin

The study of sedimentary characteristics and genetic mechanism of mixed siliciclastic-carbonate sediments (MSCSs) is not only the focus of sedimentary geology, but it is also an important issue in petroleum exploration and development. We have discovered the lacustrine MSCSs, the interstratified siliciclastic-carbonate sediments and the textural mixture of siliciclastic and carbonate materials (s-MSCSs) in the second member of the Paleogene Funing Formation (E_1f_2) in the Gaoyou and Jinhu sags, Subei Basin, eastern China. We use core, mud-log and thin-section data to clarify the E_1f_2 s-MSCSs into five types, and we also use geochemical data of the E_1f_2 mudstone including X-ray diffraction (XRD) whole rock, XRD clay, and trace elements to quantitatively analyze lake paleosalinity. The E_1f_2 s-MSCSs mainly consist of siliciclasts, ooids, intraclasts, and mud, and they could be siliciclast-dominated, allochem-dominated, or without dominant components. We analyze that mixed sediments occur under either traction flow or gravity flow. The s-MSCSs of the traction flow origin develop small-scale, wavy cross-bedding and consist of siliciclasts and ooids of similar size; the s-MSCSs of the gravity flow origin develop massive bedding and graded bedding with complex lithology, and they mainly consist of siliciclasts and allochems of different size. We hypothesize that the increase of lake paleosalinity controlled by the climate and the moderate siliciclast influx under stable tectonic setting provide the material source for s-MSCSs in the lacustrine basin. Multidirectional flow is common during the deposition of s-MSCSs of traction flow origin, and seasonal flooding produces s-MSCSs of the gravity flow origin. Lacustrine s-MSCSs in the Gaoyou and Jinhu sags have significantly smaller scale and quantity, and ooids rather than bioclasts occupy most of the carbonate components.

Keywords: Paleogeomorphic Recovery,Seismic Attributes,Machine Learning,Filling Geological body,Image Filters

Palaeogeomorphology is usually an important factor controlling the development of regional sedimentary facies and reservoir distribution. After the formation of palaeogeomorphology, it will be affected by multiple factors such as tectonic deformation, sedimentary filling, differential compaction, weathering and denudation, so that it is difficult to restore to the original form in the study. Filling type palaeogeomorphology refers to the depression or low part of palaeogeomorphology is filled by different lithology during the sedimentary process. Due to the thin and uneven distribution of the later filling geological body, the response characteristics of the seismic profile are not obvious, so it is difficult to use seismic information to identify the lithology and restore the paleogeomorphology of the stratum containing filling. In view of the above geological problems, this study adopts machine learning method to restore the palaeogeomorphology of filling strata. The core of this study is as follows: Firstly, selecting the sensitive seismic attribute of protruding filled geological body anomaly; Secondly, image filtering is carried out on the optimized sensitive seismic attributes to highlight the edge of filling geological body; Thirdly, clustering analysis of filtered attributes is carried out to magnify the difference between geological bodies and palaeostratigraphy, and classifying the filled geological bodies and sediments of the same period. After clustering, the distribution of geological bodies can be calculated and paleogeomorphology can be restored. This method can be used to identify and characterize filled geological bodies, and on this basis, the influence of filled geological bodies on palaeogeomorphology can be eliminated. Compared with the traditional method of palaeogeomorphology restoration of stratum thickness, it can more closely approximate the original palaeogeomorphology and reflect the palaeoenvironment at that time, which is of great significance to the interpretation of sedimentary facies and reservoir prediction.

Oceanographic controls on mixed sediments on continental slope

Xingxing Wang[1*]
1. College of Marine Science and Technology, China University of Geosciences (Wuhan), Wuhan, Hubei, CHINA
E-mail: wangxingxing@cug.edu.cn

Keywords: Oceanographic processes, Mixed sedimentary processes, Mixed sediments

Oceanographic processes play an important role in submarine morphology, sedimentary processes and the associated deposits. Based on the integration of 3D seismic data and piston cores from the northern South China Sea (SCS) margin, this study identifies mixed deposition that composes of foraminiferal sands, clastic silts and less quartz sands, which were deposited by mixed sedimentary processes dominated by gravity flows and contour currents. The silt-free mixture of foraminiferal and quartz sands are featured with sandy contourites and observed in the piston cores that are located in the thalweg of slope channels. Meanwhile, they are displayed within the interval of turbidites, indicating the sandy sediments were initially sourced from shelf and delivered into the deep-sea slope through gravity flows. The dating results suggest the gravity flows occurred during and after last glacial maximum, when the paleo-shoreline was far from shelf edge. Combined with the morphological features and seismic-reflection features, this study suggests that terrigenous coarse-grained sediments were difficult to reach to shelf edge and be delivered into deep slope finally. Instead, the foraminiferal sands around shelf edge have a great potential to get into the slope channel through the gravity flows triggered by oceanographic processes (i.e., intense slope current and internal waves). Silty sediments are mostly featured with contourites. This study sheds light on how oceanographic processes influence mixed deposition occurred on continental slope, which is meaningful for the understanding the origins of mixed sediments elsewhere.

Sedimentary characteristics and genetic mechanisms of a mixed sediment system in shallow lake area:An example from Wenan Slope,Baxian Sag,Bohai Bay Basin,Eastern China

Shuanghui Xie[1], Xiaomin Zhu[1*], Guangdi Liu[1]
1. College of Geosciences, China University of Petroleum(Beijing), Beijing, CHINA
E-mail: xmzhu@cup.edu.cn

Keywords: Wenan Slope, the first member of Shahejie Formatin, mixed sediments, genetic mechanisms, mixed models

Mixed siliciclastic-carbonate sediments were widely distributed in Bohai Bay Basin. To determine the sedimentary background and characteristics of the first member of Shahejie Formation in Wenan Slope, core, logging, seismic and analytical test data were collected for sedimentology research. Then, genetic mechanisms of mixed sediments were specific and models of mixed siliciclastic-carbonate sediments in shallow lake were built.

Beach-bar systems with mixed sediments were widely developed in shallow lake environments during the large scale lake transgression of first member of Shahejie Formation (Es_1). The sedimentary background was as follows: 1)Wenan Slope during Es_1 interval was gentle, which the palaeoslope angle was between 0.9-1.5°; 2)the spore and pollen spectra were particularly characterized by a high abundance of Quercoidites, which indicated varied warm and arid conditions; 3)the lithology, paleontology and sedimentary structures of the Wenan Slope showed that the lake basin's body of water was relatively shallow(less than 10m).

Beach-bar systems deposits were characterized by complex lithology. The classification of mixed rocks in this study was considered by siliciclastic components and carbonate components. The study showed that lithology included sandstone, siltstone, oolitic limestone, biostromal limestone, oolitic sandstone and oolitic siltstone. An identification of lithology was established, which used core, photomicrographs and logging. Based on their depositional arrangementwe recognized two kinds of mixed sediments, called “compositional mixing” and “strata mixing” respectively. The compositional mixing was characterized by oolitic sandstone and oolitic siltstone, which refers to two different components accumulated in space and time and were observable at bed scale. The later referred to clastic rocks, carbonate rocks and mixed rocked organized in meter-scale interbedded beds (Chiarella et al., 2017). The compositional mixing deposited limitedly in the near-shore ramp. The distribution of strata mixing was widely. In the early stage of transgression, the compositional mixing deposited. When the lake level was suitable, the strata mixing deposited.

The gentle-slope paleogeomorphology and warm paleoclimate were the important preconditions for the development of mixed sediments in continental lacustrine basins. The mixed sediments were mainly controlled by changes of the relative lake level and supply of siliciclastic. In this study, there are three types of genetic mechanisms, called facies mixing, punctuated mixing and in suit mixing (Mount,1984). In suit mixing and punctuated mixing were characterized by compositional mixing. Facies mixing was characterized by strata mixing. During the large scale transgression of Es_1, siliciclastic input was restricted and carbonate increased. In the far-shore ramp, siliciclastic influx by fluvial discharge were limited to develop, and bioclastic cemented siliciclastic, which called in suit mixing. In the near-shore ramp, facies mixing deposited. Both compositional mixing and strata mixing are distributed. When the lake level was suitable, supply of siliciclastic was increased, facies mixing developed widely. In the near-shore ramp, the siliciclastic carried by the delta front mixed with the carbonate deposits and then formed a small range of mixed deposits, which genetic mechanism was punctuated mixing.

Sedimentary characteristics, geomorphology and seismic response of mixed sediments in K6 Oilfield, Bohai bay, China

Longtao Cui[1*], Shaopeng Wang[1], Cheng Guo[1], Li'an Zhang[1], Zhuo Li[1]
1. Bohai oilfield research institude , Tianjin Branch of CNOOC Ltd., Tianjin, CHINA
E-mail: cuilt2@cnooc.com.cn

Keywords: Mixed sediments, Sedimentary characteristics, Seismic response, Bohai bay

The lower Shahejie Formation of K6 oilfield are characterized by thin interbedded mixed sediments, with complex sedimentary facies, lithologic types and distributions, which restrict further exploration and development.

In order to study the sedimentary, seismic response and distribution characteristics of the reservoir in K6 oilfield, an isochronous stratigraphic framework was firstly established, and the paleogeomorphology of each oil group in the lower Shahejie Formation was restored. Secondly, combined with the core, 3D seismic data, geomorphology and DST data of the study area, different sedimentary facies characteristics and their seismic responses are studied.

The result shows that there are mainly three sedimentary types developed in the area, mixed deposition, braided-delta, and valley (fan-delta filling). (1) mixed deposition are developed around the higher platform in the middle of Kenli16 area. The lithology is dominated by terrigenous clastic carbonate diamictite and carbonate terrigenous clastic diamictite, and the reservoirs are characterized by thin interbeds (mostly less than 2 meters). The seismic response is a set of parallel phase axis with high amplitudes and low frequencies. (2) The braided delta from the west provenance is overlapped at the platform. And the delta front develops alternately with the diamictite. The seismic response is a set of progradation reflection with high-frequency and weak-amplitude. (3) The valley is in the shape of an incised channel in the seismic section, and develops on the east side of the study area. The thickness of reservoir is large (mostly more than 5 meters), and the core slices show that coarse-grained sandstone develops. The DST data shows oil production of the valley reservoir can reach to 400 tons per day, which is significantly higher than other types of sedimentary facies. Analysis indicates that the structure, paleomorphology and sedimentary structure are the main factors affecting the seismic response and sedimentary characteristics.

According to the seismic response characteristics of different sedimentary facies, the reservoir distribution was finely described. The actual drilling confirmed that the sedimentary facies was accurately described, with reservoir prediction accuracy reaches to 80 %. Under the guidance of reservoir research, the daily oil production reaches 2,000 tons, which effectively guides development of the mixed-sediment oilfield.

Dolomitization and Lithology Basement Influence on the High Quality Reservoir of Siliciclastic and Carbonate Mixed Deposition in Paleogene System of Bohai Sea Area

Huan Lu[1,2*], Qingbin Wang[1], Xiaofeng Du[1], Hao Liu[2], Yanfang Chen[1]
1. Bohai Oilfield research institute, CNOOC Limited, Tianjin Branch, Tianjin China, Tianjin, CHINA
2. Ocean Science department, China University of Geoscience(Beijing), Beijing, CHINA
E-mail: luhuan@cnooc.com.cn

Keywords: Dolomitization, Lithology Basement, Siliciclastic and Carbonate Mixed Deposition, Forming Mechanism, Shahejie Formation

This study investigates factors controlling high quality mixed reservoir forming in Shahejie formation in Bohai Sea area.

On macro level, the scales of mixed reservoir were influence by basement lithology, sedimentary environment and paleogeomorphy feature. Petrographic combined with petrophysical analysis, four types of reservoirs are summarized.
Type I reservoir (represented by Q29 structure): beach bar bioclastic dolomite and fan delta dolomitic conglomerate mixed deposition, which is of volcanic basement uplift tectonic background in the near-shore steep slope zone, is of large reservoir scale.
Type II reservoir (represented by B36 structure): mixed deposition of oolitic dolomite and dolomitic conglomerate reservoir in the background of the superposition of delta sandstone in the near-shore gentle slope belt and the uplift of volcanic basement, is of large reservoir scale. Type III reservoir (represented by B13 and J9 structure): bioclastic dolomite reservoir of the off-shore volcanic basement uplift background, is of medium scale.
Type IV reservoir (represented by C2 structure): dolomitic conglomerate, oolitic dolomite, calcareous conglomerate and clastic dolomite reservoir with the off-shore marine carbonate basement is of small reservoir scale.

On micro level, microfabric and genesis of microbial dolomitization is analyzed by advanced technologies. Spherical dolomite and cyanobacteria were characterized by Scanning Electron Microscopy, Cathode Luminescence and Electron Probe. Organic matter components were identified by Laser Raman and Infrared Spectroscopy, and 3D characterization of organic matter was performed by Laser Confocal Focus. The formation stage and genetic mechanism of microbial dolomite were determined by Laser Microanalysis of C\O isotopes. Fabric characteristics of microbial dolomite were established through Maps and Focused Ion Beam.
Dolomitization sequence is obtained based of the origin, occurrences and its forming temperature from low to high: micrite dolomite<spherulite dolomite<syntaxial dolomite<gravitational dolomite<microcrystalline envelope domite<isopachous rim or dog-tooth dolomite< blocky cements (syntaxial and mosaic dolomies) < microcrystalline saddle dolomite.
Type I reservoir is mainly developed with gravitational dolomite and dog tooth dolomite, which will significantly increase compaction resistance of rocks and further preserve favorable reservoir physical property. The forming of microcrystalline saddle dolomite is related to mantle-derived CO2 and hydrothermal activity in deep strata.
Type II reservoir is featured with spherulite dolomite, dog tooth and associated with micritic envelopes, both of which are related to biological activities. In both type I and II reservoir, the volcanic basement and microbial dolomitization process are influenced with each other. The basement lithology influence carbonates by providing rich Mg2+ in volcanic material which will result in the bio-organism flourishment, and further favored micritization and dolomitization. Carbonates impact siliciclastics by providing rich Ca2+ minerals for early carbonate cement precipitation. The isopachous cement will enhance rock compression strength, and

early syntaxial calcite cements are followed by ubiquitous dissolution with the effect of acid fluids in deep layers.

Type III and IV reservoir is composed of micritic dolomite, intergranular syntaxial dolomite and mosaic dolomites whose physical properties are poor. Favorable reservoir properties only occurred as a result of selective dissolution by meteoric water leaching, non-selective dissolution of carbonate syntaxial cements and intercrystalline pore generation during dolomitization process.

Sequence architecture and depositional evolution in the north-eastern shelf (33.9-10.5 Ma) of the Pearl River Mouth basin, South China Sea

Jiawang Ge[1*]

1. Geoscience and Technology College, Southwest Petroleum University, Chengdu, Sichuan Province, CHINA
E-mail: gjwddn@163.com

Keywords: Sequence architecture, depositional evolution, paleo-Hanjiang River deltaic system, shelf, South China Sea

Based on integrated analyses of seismic, well-logging, core data and paleontological data, we systematically document the sequence architecture and depositional evolution of north-eastern shelf of the Pearl River Mouth Basin (PRMB) in the northern South China Sea (SCS). The depositional pattern of the Hanjiang River and Dongsha Uplift related deposits is firstly established in the study. The infill of the Late Oligocene to Middle Miocene successions on the north-eastern continental shelf part of the PRMB can be divided into three composite sequences (CS3-CS5) that are bounded by regional unconformities and comparable conformities. These composite sequences could be further divided into nine sequences that are defined by local unconformities or transgressive-regressive boundaries. Depositional-geomorphological systems represented on the shelf mainly include inner-middle shelf deltas, shoreface deposits, reefal platforms, shelf sand-ridges and fine-grained deposits.

Large-scale shelf-deltaic deposits are prominent in CS3 driven by very high sediment input from a strongly uplifted and possibly enlarged catchment area after immediate lithospheric breakup of the SCS. The rapid Early Miocene transgression, apparently enhanced by tectonic subsidence, caused a great retreat of Hanjiang River-related systems in CS4; shoreface (CS4-1) to reefal deposits (TST of CS4-2) and finally shelf muddy deposits (CS4-3) are recorded around the Dongsha Uplift. A muddy-prone deposition of CS5 is related to the enhanced tectonic subsidence but less sediment supply. The NE-striking geomorphic pattern of sand-ridge related systems possibly caused by the intensification of the south-westerly flowing paleocurrent likely related to the Dongsha Movement after ca. 13.8 Ma.

The north-eastern shelf of the Oligocene to Middle Miocene SCS records the interactive responses to tectonism, sea-level change, sediment supply and oceanic hydraulics. It indicates that reefal platform deposits in the TST of CS4-2 and shoreface deposits in CS4-1 are present around the Dongsha Uplift in the north-eastern shelf of the SCS. This study has potential implications for the sedimentology architecture as well as further reservoirs and hydrocarbon evaluations in shelf area of the SCS.

Identification and evolution model establishment of braided - meander sedimentary system in east China Sea

Bo Chen[1], ping dong Duan[1*], hui ying Liu[1], Fang Ding[1], Chen Chen[1]
1. research institute, CNOOC, Shanghai, CHINA
E-mail: duandp@cnooc.com.cn

Keywords: braided-meander transition, Seismic sedimentology, Depositional system, Evolutionary model, Xihu depression

Huagang Formation in Xihu Sag in the East China Sea is a river delta interactive transitional deposit. It is one of the important oil and gas bearing strata and one of the important development strata in Xihu sag. Due to the rapid vertical and horizontal changes of channel sediments and the lack of offshore well data, reservoir prediction has always been the focus of attention. Using seismic sedimentology method, combined with core and logging data, this paper identifies the river type, constructs the plane distribution form of rivers in Huagang Formation, and establishes the vertical evolution law.

Based on the application of seismic sedimentology method, it is considered that during the period of Huagang Formation, delta plain and front sedimentation are mainly developed, and three types of distributary channel deposits such as braided flow type, meandering type and serpentine type are developed.

In the low stand stage, the terrain is gentle, the material source is sufficient, and a / s > 1. The sediments are mainly vertical accretion, which is in the form of braided flow distributary channel. The river channel is relatively large, with a width of about 2.0km. The river channel boundary is mainly low curvature and straight. In this period, the river channel is mainly vertical accretion, so the lateral pinch out points are clear. Three to five box shaped single sand bodies are developed vertically. The thickness of single sand varies from 20 to 40m. Along the river channel Narrow and long strip-shaped core beach sand body, with an average length of 2.28km, a width of 0.82km and an area of 1.88km2; During the transgression period, the sea level dropped to the low point and gradually increased, the material source supply gradually decreased, and the lithologic particle size became finer. It is mainly argillaceous siltstone, with the development of meandering distributary channel deposition, the curvature of the channel increased significantly, and large-scale edge beach deposits were developed locally. The channel width is 0.5 ~ 1.2km, and the sandstone thickness is 8 ~ 30m; During the highstand period, the sea level rises to the maximum flooding surface, and the material source supply is scarce. The stratum mainly develops mudstone, and locally develops small-scale river channels, which is characterized by a set of mud wrapped sand. The stratum as a whole is a set of anti rhythmic deposition. The thickness of sandstone is generally less than 10m, generally 1 ~ 5m. Small meandering river channel deposits are developed, the river channel width is less than 100m, flowing from northwest to Southeast, with large curvature, frequent diversion and mutual cutting and overlapping.

This achievement enriches the understanding of the sedimentary model of Huagang Formation in Xihu Sag, explores the application of seismic sedimentology method, and is of great significance to the identification, characterization, evolution, exploration and development of channel sand bodies in the study area.

Improved seismic sedimentology in the study of fluvial-delta facies reservoir

Lou Min[1*]
1. Research institute, Shanghai Branch of CNOOC Ltd, Shanghai, Shanghai, CHINA
E-mail: 674672901@qq.com

Keywords: East China Sea Shelf Basin, Huagang Formation,Fluvial delta facies, Seismic sedimentology

The delta-fluvial deposit of the Oligocene Huagang Formation in the Xihu Sag of the East China Sea Shelf Basin is characterized by rapid change in sedimentary facies.And the conventional slice attributes have poor morphology, making it difficult to predict the reservior and satisfy the subsequent exploration and development of lithologic reservoirs. The traditional seismic sedimentology technology is optimized by applying the characteristic technologies such as frequency-boosting interpretation, inversion-conventional -90° phase shift joint construction of seismic lithologic bodies, nonlinear slices, paleogeomorphology restoration, and multi-attribute fusion, and obtains slice-attribute geological forms. Typical, conducive to sedimentary interpretation.

The study found that the Huagang Formation developed three types of sedimentary bodies: braided rivers(Fig. 1) , meandering rivers(Fig. 2) and shallow water deltas(Fig. 3), and the vertical sedimentary evolution was controlled by the mid-term base-level cycle and paleogeomorphology(Fig. 4). In the early to mid-term base-level cycle ascent, vertical superimposed sand bodies developed, mainly braided channel deposits; in the late ascending cycle and the early descending semi-cycle, isolated sand bodies developed, mainly meandering river deposits; In the middle-late period of the mid-term base level decline, migratory medium-thick sand bodies developed, mainly composed of shallow-water delta deposits. Restricted paleo-geomorphology controls sand body distribution, while non-restricted paleo-geomorphology has little effect on sand body distribution. Based on reservoir characterization, it is proposed that the fault sealing type and the reservoir updip pinch-out type structural lithological traps are the main directions for the next rolling potential in this area. The relevant seismic sedimentological characteristic methods have certain reference significance for the fine characterization of fluvial-delta facies reservoirs in other regions.

The seismic sedimentology of tidal systems of the Pinghu Formation in Xihu Sag, Eastern China

Yinghui Liu[1*], Dingping Duan[1], Bo Chen[1], Fang Dingle[1], Chengrui rong[1]
1. Research institute, Shanghai branch of CNOOC.ltd, Shanghai, CHINA
E-mail: liuyh70@cnooc.com.cn

Keywords: Tidal flat,Tidal channel,Seismic sedimentology,Transgressive System,Pinghu Formation,Xihu sag.

The exploration of Pinghu Formation in Xihu sag has achieved great success in recent years. The sedimentary system, sedimentary facies and sand body types of Pinghu Formation have attracted wide attention but still stay controversy for its depositional background of transitional marine and continental settings. In this paper, the types and distribution characteristics of sand bodies in Pinghu Formation are described in detail by seismic sedimentology combined with core and logging data.

Based on the core, logging and analysis data, this paper defines the typical transgressive system tract (TST) of Pinghu Formation as a tidal flat system. On the seismic stratal slices, the sandstone of tidal channels is 2-5 m thick.

During the transgression period, the sea level in the study area was relatively high, and the sediment supply is less in a very low-gradient slope terrain setting. Thus, the hydrodynamic tidal current are relatively strong. Widespread core observations include double clay layers, reaction surface, rhythmic bedding, tidal bundles and bioturbation. The lithologic assemblage of core observations is dominated by mudstone and coal deposits, which are summarized as tidal flat deposits in the TST period. The sandstones are linear-like but relatively isolated.

Coal seams are widely developed in TST with a content up to 4%. It is formed in the tidal flat facies where the sea level continues to rise and is widespread. It represents the maximum flooding and shows a high-continuous and strong amplitude on the seismic section.

Strata slicing of the transgressive zone (Fig. 1) show that a series of narrow stripes of inverted dendritic tidal channels, similar to modern tidal channel deposits developed in the low zone in the east of the study area. It is characterized by wider roots, gradually branching off landward, and gradually narrowing in its width. The width of the tidal channel sand body in the work area is between 80 m and 320 m. The wells penetrated the end position of the tidal channel, with a thickness of only 2m~5m and a width-to-thickness ratio of about 30:1.

This study enriches the cognition of sedimentary model of Pinghu Formation in Xihu sag (Fig. 2), and explores seismic sedimentology of thin tidal channel sandstones constrained by isochronous coal seam framework, which has potential significance for sedimentology architecture and further reservoir and oil and gas evaluation in Xihu sag.

Lithological characteristics of lacustrine mixed rock in the Paleogene and its influence on reservoir physical properties in lower Ganchaigou Formation in Yuejin area, Qaidam Basin, China

zezhou li[1], yixiu zhu[1*]
1. College of Geosciences, China University of Petroleum(Beijing), Beijing, CHINA
E-mail: zhuyixiu@cup.edu.cn

Keywords: mixed rocks, lacustrine carbonate rock, physical control factors, Qaidam Basin, Paleogene

The mixed rocks of the paleogene lacustrine are widely distributed in the Yuejin area of the Qaidam Basin, China, and the carbonate mineral content is obviously dominant. In-depth discussion of lacustrine carbonate rocks is beneficial for the further exploration and development of mixed-rock oil and gas reservoirs. With the help of cores, well logging, analytical laboratory data and regional seismic data from multiple wells in the study area, the lithology, physical properties and diagenesis characteristics of the mixed rock reservoirs dominated by lacustrine carbonate rocks in the upper part of lower Ganchaigou Formation were analyzed. Discuss the formation environment of different lithology, reservoir space type characteristics, and the influence of different lithology and evolution on the reservoir physical properties of lacustrine carbonate rocks. The Paleogene in the Yuejin area has developed carbonate-dominated mixed rock lithological assemblages. Several major rock assemblages can be seen, including lacustrine limestone(lacustrine dolomitic), mudstone, siltstone and mixed rock assemblages.Grain limestone(grain dolomite), micrite limestone(micrite dolomicrite), muddy-marl stone (muddy-dolomite stone), algal limestone (Algal dolomite), limy mudstone (dolomite mudstone), mudstone, limy siltstone (dolomite siltstone), lime-bearing argillaceous siltstone, all of them are mixed rocks with no more than 50% carbonate mineral composition, clay mineral composition and silt composition. Different rock types and lithological combinations reflect the multiple effects of changes in the lake depositional environment, the alternation and evolution of clear water deposition and mixed water deposition, and the mixing of terrigenous materials during the upper part of lower Ganchaigou Formation depositional period. Lithology has obvious control effect on the storage space, algal limestone, grain limestone, limy siltstone(dolomitic siltstone) have high porosity and good reservoir properties, while the porosity of the micritic limestone, argillaceous siltstone and mixed rock is relatively low, and the reservoir properties are poor. Regional geological data can be used to evaluate the reservoir properties of different types of mixed rocks and predict favorable oil and gas exploration targets.

3. Bohai Oilfield Research Institute, Tianjin Branch of China National Offshore Oil Corporation Limited, , CHINA
E-mail: htzhu@cug.edu.cn

Keywords: mixed siliciclastic-carbonates,mixed sediments,control factors, Huanghekou Sag

It has been confirmed by exploration practice that mixed siliciclastic-carbonates can serve as favorable reservoirs for oil and gas, which is a hot research topic nowadays. The Bohai bay basin is one of the most developed areas of mixed siliciclastic-carbonates in continental lacustrine basin, with a diverse range of types. Base on the core observation, thin section identification, cathodoluminescence, seismic data, and trace elements analysis, the development characteristics, main control factors and vertical sequence of mixed siliciclastic-carbonate in the First Member of Paleogene Shahejie Formation in Huanghekou sag of Bohai Bay Basin were studied systematically. The results show that the bottom-up mixed siliciclastic-carbonates development is composed of section I-granular dolomitic glutenite, section II-granular dolomitic sandstone, section III-granular dolomitic (gray) rock, section IV-mud dolomitic (gray) rock, and section V-mud shale. Among them, Section III is a high-quality section for reservoir development because it contains a large number of gastropods and ostracods. However, complete sequences are relatively rare due to a variety of conditions, and often have some sections missing. The development of mixed siliciclastic-carbonates is controlled by multiple factors (e.g., paleostructure, paleogeomorphology, sediment supply, climate, and lake level change). Near the source area, the development of carbonate rocks is inhibited by the large supply of land-derived clastic, and the overall expression is a mixed siliciclastic-carbonates clastic (section I and II). Away from the source area, the terrestrial clastic supply is weaken and its influence on carbonate sedimentation is limited. Section III -granular dolomitic (gray) rock and section IV -mud dolomitic (gray) rock are developed. The depositional environment stabilizes and mud shales form as the lake level rises and the water column deepens. This study can promote the deepening of mixed sedimentation research and provide a scientific basis for mixed siliciclastic-carbonates reservoir prediction and hydrocarbon exploration.

Characteristics and formation mechanism of mixed siliciclastic-carbonate fine-grained deposits in the saline lacustrine basin: A case study of the Lower Youshashan Formation in the northwestern Qaidam Basin

Dehao Feng[1], Chenglin Liu[1,2*]
1. College of Geosciences, China University of Petroleum(Beijing), Beijing, CHINA
2. State Key Laboratory of Petroleum Resources and Prospecting, China University of Petroleum (Beijing), Beijing, CHINA
E-mail: liucl@cup.edu.cn

Keywords: mixed deposits, diagenesis, reservoir quality, saline lacustrine basin, Qaidam Basin

With the breakthrough of unconventional resource exploration, mixed fine-grained reservoirs are also a crucial tight reservoir with massive hydrocarbon occurrence. However, despite having made significant contributions to hydrocarbon occurrences, mixed fine-grained rocks in saline lacustrine basins show great mineralogical and petrophysical properties heterogeneity in petroleum exploration activities. The controlling factors and formation mechanism of high-quality reservoirs remain enigmatic, bringing significant challenges to hydrocarbon prediction. The Lower Youshashan formation with the characteristics of fine grain size and complex lithology in the northwestern Qaidam Basin constitutes important oil reservoirs. Here, core and thin section observation, scanning electron microscope, X-ray diffraction, porosity and permeability test, carbon and chlorine analysis, and high-pressure mercury intrusion were carried out on different lithofacies of mixed fine-grained rocks to clarify the characteristics and formation mechanism of high-quality reservoir. The reservoir lithology of Lower Youshashan formation is mainly composed of fine-grained sedimentary rocks such as mudstone, marl, siltstone, argillaceous siltstone and silty mudstone, and fine sandstone, Oolitic Limestone and algal limestone are developed in some areas. In the freshwater environment, it is dominated by mechanical sedimentary differentiation, and the lithology is mainly clastic rocks such as siltstone. In brackish water and saline water sedimentary environment, chemical sedimentary differentiation increases, and mixed siliciclastic-carbonate and carbonate rocks and mixed rocks are relatively developed. With the increase of water salinity, the siltstone decreases, which is mainly mixed rocks containing evaporite minerals.Typically, the mixed siliciclastic-carbonate deposits contains high content of carbonate minerals. The content of carbonate minerals is generally greater than 30%, while the content of quartz, feldspar and clay minerals is similar, mainly between 20% - 50%, reflecting the strong mixing phenomenon of siliciclastic and carbonate minerals. Evaporite minerals (content < 10%) are also common in reservoir samples. The porosity and permeability of the Lower Youshashan formation are generally low with average porosity and permeability of 7.81% and 5.73 md respectively. The pore type of the mixed siliciclastic-carbonate reservoirs is mainly the residual intergranular pores, secondary dissolution pores and fractures. Fractures and carbonate dissolution pores greatly improve the reservoir space and are the key factors for the formation of high-quality reservoirs. The reservoir quality of mixed fine-grained rocks in the study area are mainly controlled by sedimentary environment, water salinity, diagenesis, tectonic stress and thermal evolution of organic matter. The sedimentary environment and water salinity control the rock type and mineral composition of the reservoir. Mixed siliciclastic-carbonate fine-grained rocks with high clastic content or carbonate mineral content have relative high reservoir quality. This research will provide new insights into reservoir quality evaluation and sweet spot prediction in mixed siliciclastic-carbonate fine-grained reservoirs.

Characteristics and a depositional model of mixed siliciclastic-carbonate rocks of the upper Lower Jurassic Da'anzhai Member Ziliujing Formation (Huilong area, Sichuan Basin, SE China)

Ziliang Liu[1*]
1. College of Energy Resources, Chengdu University of Technology, Chengdu, Sichuan, CHINA
E-mail: bugliu2001@163.com

Keywords: Mixed sedimentary rocks, Depositional model, Da'anzhai Member, Ziliujing Formation, Jurassic; Sichuan Basin

The term "mixed sediments" is used to describe a mixture of terrigenous clastic and carbonate rocks. There is a comprehensive understanding of mixed deposition in the marine environment, deposition in continental environments is relatively poorly understood. Here, we report the results of a study of the Da'anzhai Member of the Ziliujing Formation in the Huilong area of the Sichuan Basin, southwest China. The geological context provides the opportunity to characterize the various sedimentary microfacies and to propose a model of the development of sedimentary lithologies in a continental lake succession. Our approach includes a comprehensive microfabric analysis of field outcrops, and studies of drill-cores, and well-logs, and it enables us to reconstruct the evolution of sedimentary processes and sedimentary microfacies in the study area. The study of petrofabric characteristics such as combination of rock types, bedding structures and fossil content, revealed that the Da'anzhai Member in the study area comprises lacustrine mixed carbonate-siliciclastic strata, which formed in shallow littoral and deep lacustrine sedimentary environments. The studied facies were subdivided into five mixed-sediment facies-types, representing the following depositional environments: high-energy shelly beach, low-energy shelly beach, sandy shoal, shallow lacustrine and deep lacustrine. The observed characteristics of the mixed-sediment facies of the upper Lower Jurassic (Lower Toarcian) Da'anzhai Member in the Huilong area, combined with a previous study of the provenance of the siliciclastic (terrigenous supply), and carbonate rocks (mainly from deposition of shell material), we concluded that the deposition of lacustrine mixed sedimentary successions in the study area was predominantly controlled by changes in lake level, siliciclastic and biogenic sediment supply, and hydrodynamic conditions.

Genesis of dolostones under weakly mixed siliciclastic-carbonate sedimentation as the response to the late carboniferous icehouse climate: a case study of the Xiaohaizi Formation in the Tarim Basin

Mei Yan Fu[1*]
1. College of energy, Chengdu University of Technology, Chengdu, Sichuan, CHINA
E-mail: fumeiyan08@cdut.cn

Keywords: Tarim Basin,Xiaohaizi Formation,Weakly mixed dolomite,Terrigenous quartz

Mixed siliciclastic-carbonate sedimentation is commonly developed in the environment of frequent sea level fluctuations caused by the Glacial-interglacial cycles of the Carboniferous-Permian Gondwana continent, which are widely distributed in Tarim, Upper and Lower Yangtze regions of China, North America and Western Europe. In this paper, the origin of weakly mixed dolomite containing terrigenous clasts in carboniferous in Bamai area, Tarim Basin is studied by means of petrography and isotope study. The dolomite is an important oil and gas reservoir in the study area. This set of dolomites has a residual grain structure and contains 1-8 wt. % terrigenous debris, including quartz, feldspar, kaolinite and illite. Based on the paleo-environmental proxies such as Ti/Al, Mg/Sr and Vi/(Vi+Ni), the mixed deposits of Carboniferous in the study area were developed under intermittent humid climate, and most of them were related to sea level decline. Increased chemical weathering caused by humid climate can provide more terrigenous debris for offshore shelf areas [1]. The $\delta^{18}O$ of the weakly mixed dolomite is heavier than that of the unmixed limestone, which may be related to the glacial climate. As the lighter ^{16}O entered the ice sheet preferentially, ^{18}O was relatively enriched in seawater during this stage [2]. The Mg/Sr ratio of weakly mixed dolomite is lower than that of limestone, which reflects the cold paleo-environment in the stage of sea level decline. In addition, $^{87}Sr/^{86}Sr$ of weakly mixed dolomite is slightly heavier than that of limestone without obvious mixed dolomite, which is close to or slightly higher than that of Carboniferous seawater, indicating that seawater is mainly derived from fresh water. The cathodoluminescence of the dolomite is very poor, which is related to the low Mn content in seawater at the same period. In the stage of glacial sea-level decline, downflow was formed due to the increase of seawater volume from the coastal zone carrying terrigenous detritus to the vicinity of carbonate shoal, and the supply of Mg^{2+} in seawater and the enhancement of seawater circulation led to peneogenetic dolomitization of dissimilar grains such as bioclasts and sand. The fall in sea level also led to the exposure of carbonate flats, resulting in weak cementation and retention of intergranular pores, resulting in the formation of weakly mixed dolomites with good reservoir properties.

Model and genetic mechanism of mixed siliciclastic and carbonate sediments in continental rift basin: a review of Bohai Sea area

Wei Xu[1*], Xiaofeng Du[1]

1. Bohai Oil Reserach Institute, China National Offshore Oil Corporation, Tianjin Branch, Tanggu, Tianjin, CHINA

E-mail: xuwei32@cnooc.com.cn

Keywords: mixed sediment, sedimentary model, genetic mechanism, reservoir characteristic

Lacustrine mixed reservoirs, which possess large thickness, favourable reservoir quality and high productivity, are generally distributed in the Palaeogene of the Bohai Sea area. It becomes a research focus in Bohai continental rift basin by considering complex geological conditions and various types of mixed deposition.

Based on numerous exploration practices, this paper summarizes the genetic mechanism and model of Palaeogene mixed sediments in Bohai Sea area. The mixing processes are macroscopically controlled by regionally stable tectonic setting and locally intense fault activity, arid climate and saline water, unstable siliciclastic supply of local uplift inside basin and positive palaeo-geomorphologic unit. In consideration of the relationship with siliciclastic supply, two genetic types of mixed sediments are identified as proximally mixing and distally mixing. Based on further analysis of different slilicic lastic sedimentary system, palaeo-geomorphologic setting and characteristic of basement rock, the above two models could be divided into 6 specific mixed types: 1) proximal mixing with fan delta; 2) proximal mixing on the flank of fan delta; 3) proximal mixing on the flank of braided river delta; 4) proximal mixing on the abandon braided river delta; 5) distal high-energy mixing; and 6) distal low-energy mixing. An independent facies system of continental mixed sedimentation has been first established in the Bohai Sea area which consist of three types of facies, seven types of subfacies and twelve types of microfacies.

Comprehensive analysis shows that types of proximal mixing with fan delta, mixing on the flank of fan delta, mixing on the flank of braided river delta and distal high-energy mixing tend to form excellent reservoirs on account of large thickness, coarse grained, low content of matrix, rich in bioclasts or carbonate particles and general dolomitization.

We propose several issues should be emphatically discussed in current genetic mechanism researches on mixed sediments: 1) growth habit of calcareous shell paleobiology and microbial dolomitization; 2) relationship between fine-grained mixed sediments and shale reservoirs; and 3) seismic prediction technology for mixed sediment reservoirs.

Keywords: Mixed carbonate - siliciclastic sequences, Neoproteorozoic, Death Valley, Carbonate factory, Microfacies

The sedimentary record of the Pahrump Group in Death Valley comprises well-exposed successions of mixed carbonate and siliciclastic deposits. Despite the abundance of studies focussing on the depositional dynamics of mixed carbonate – siliciclastic deposition in the Phanerozoic, the record of similar Proterozoic examples is comparatively sparse. Using high-resolution stratigraphy and microfacies analyses, this study investigates the Tonian Horse Thief Springs Formation within the Pahrump Group of Death Valley, California, in order to propose first-order constraints on the interplay between carbonate and siliciclastic deposition in the early Neoproterozoic. The mixed successions are unlike many previously studied examples interpreted as being caused by glacio-eustatic sea-level changes, thus arguing for a more relevant tectonic influence on siliciclastic deposition. This interpretation is supported by detailed microfacies analyses of siliciclastic-rich dolostones, which show abundant soft-sediment deformation features suggesting sudden pulses of sandstone deposition onto a shallow marine carbonate shelf. The Tonian carbonate factory recovered quickly after being smothered by siliciclastics, particularly due to abundant stromatolite growth. A new relationship between siliciclastic input, carbonate fabric diversity, and carbonate preservation is established based on microfacies analyses, putting forward that siliciclastic deposition had a significant impact on the formation and preservation of later-stage diagenetic dolomite cements, as well as on stromatolite morphology and carbonate fabric diversity within the microbialites. Repeated siliciclastic incursions had a significant impact on the Proterozoic carbonate factory of the Horse Thief Springs Formation, as well as on diagenetic modification and preservation of shallow marine carbonates, and we establish previously unexplored relationships between carbonate and siliciclastic strata in the Proterozoic.

Identification, distribution and evolution of mixed siliciclastic-dolomitic deposits in Jeribe/Upper Kirkuk reservoir, southeast Iraq

Guo sheng Qin[1*], Youjing Wang[1]
1. CNPC, Research Institute of Petroleum Exploration & Development, Beijing, CHINA
E-mail: qin8002008@163.com

Keywords: Identification, distribution ,mixed siliciclastic-dolomitic

There are several important transformations of carbonate to clastic in the evolution history of Middle East. The Ghar/Kirkuk sand transformed to Asmair carbonate is the typical mixed deposit in southeast Iraq, the Jeirbe/Upper Kirkuk reservoir in H oilfield is the represent of this process. Identification, distribution and evolution of this mixed deposits is great useful for the development of this reservoir, and can shed light on the mechanism of mixed deposits.

The seismic data, logging data and core analysis data were used to recognize and describe mixed siliciclastic-dolomitic deposits in different scale: stratigraphic/seismic scale, lithofacies/well log scale and core/plug scale. In the seismic scale, the surfaces between dolomite and sand are well identified due to the different wave impedance, the mixed deposit is mostly developed above and below the wave impedance transformation interface. In well log scale, based on the lifhofacies correlation of diferent wells, the mixed deposit is distributed in layers as a whole, with good stability, and its thickness varies with different locations in sequence. In core/ plug scale, four types of mixed lithology (dolomite bearing sandstone, dolomitic sandstone, sandy dolomite and sand bearing dolomite) were identified. The evolution of mixed siliciclastic-dolomitic deposits in Jeribe/Upper Kirkuk reservoir is controlled by facies: form bottom to top, the faices changed from alluvial to transitional facie and finalized evolved to carbonate platform. The mixed lifthofacied changed from sand dominate deposit to dolomitic dominate deposit.

Carboniferous mixed deposition characteristics of marine-continental transitional facies in Bayanhot Basin

Yanlei DONG[1*], Yuting ZHONG[1], Wei LV[1], Yizhe ZHANG[1], Jianfeng ZENG[1]
1. College of Geoscience, China University of Petroleum, Beijing, Beijing, CHINA
E-mail: yanleidong@163.com

Keywords: Mixed deposition, Marine-continental transitional facies, Carboniferous, Bayanhot Basin

Bayanhot Basin is structurally located in the southeast of Alxa Block, Inner Mongolia Autonomous Region, and its general strike is NE-SW. At present, it is in the early stage of exploration and development, and oil and gas have been shown by drilling, but the exploration work has not made a great breakthrough. Therefore, it is of great significance to clarify the sedimentary facies types, and depict the distribution characteristics of sedimentary systems, so as to provide evidence for optimizing favorable zones for oil and gas exploration.

Considering the characteristics of tectonic evolution, provenance system, logging facies and seismic facies, sequence stratigraphy and depositional system study of the Carboniferous in Bayanhot Basin were carried out by core, drilling, logging and seismic data, as well as grain-size, heavy mineral, thin section and paleontological analysis data. The results show that three third-order sequences, namely SC1c, SC2j and SC2y, were developed in the Bayanhot Basin from bottom to top, roughly corresponding to the lower Carboniferous Chouniugou Formation, the upper Carboniferous Jingyuan Formation and the Upper Carboniferous Yanghugou Formation.

And the lithology of Lower Carboniferous Chouniugou Formation is limestone, dolomite, argillaceous limestone and calcareous mudstone interbedded with pebbled sandstone. The lithology of Upper Carboniferous Jingyuan Formation is dark gray and grayish green mudstone, silty mudstone interbedded with light gray siltstone-fine sandstone in different thickness, interbedded with thin coal. The lithology of Upper Carboniferous Yanghugou Formation is dark gray fine sandstone, pebbly sandstone, sandy conglomerate interbedded with silty mudstone and coal.

The Carboniferous in the study area is mainly composed of tide-dominated delta, gravity flow, shoreland and mixed shelf. Tide-dominated delta is mainly developed in the west and east, shoreland is developed in the central and mixed shelf in the south of the work area. It was found that underwater distributary channel and mouth bar in tidal-dominated delta front, coastal sand bar in shoreface and sandy shoal in mixed shelf are favorable exploration zones.

Sedimentary architeture and seismic response of the Huangniuling Formation in the Maoming Basin

wu qi lin[1*]
1. School of Petroleum Engineering, Guangdong University of Petrochemical Technology, maoming, Guangdong, CHINA
E-mail: 86800051@qq.com

Keywords: Maoming Basin, Fan Delta,Seismic response

Recently, fan delta research is mainly focused on paleomorphology, sedimentary features, reservoir evaluation, etc., with less research on fan delta seismic architeture. This paper integrates Tectonics, Sedimentology, and Seismic Numerical Simulation as a guide to study the fan delta outcrops of the Huangniuling Formation in the Maoming Basin, to delineate the geological configuration of the fan delta braided channels through observation and measurement of the field outcrops, and to carry out seismic orthogonal simulations of the fan delta braided channels of different overlapping types using the high-order interlaced grid finite difference method based on acoustic equations. At the same time, the seismic response characteristics of the Huangniuling Formation were analyzed to summarize the stacking pattern of the fan delta braided channels, which provides a basis for the seismic interpretation of the fan delta.

Study on Sedimentary facies of the middle sub-member of Shahejie Foemation in Qingshui area, Liaohe Depression, Bohai Bay Basin,China

Yujie Chen[1], Yixiu Zhu[1*]
1. , , , CHINA
E-mail: zhuyixiu@cup.edu.cn

Keywords: sublacustrine fans, deep lake-semi-deep lake facies, sandstone, natural gas

Sedimentary facies is a combination of depositional environment and sediments formed in this environment, and a depositional system which be constituted by the combination of different types of sedimentary facies of organically connected under certain natural conditions constitutes. The oil and gas source rocks in the middle sub-member of Es_3 in Qingshui area are widely developed, with large thickness, and the organic matter of good type, high abundance and high degree of thermal evolution. The conducting research on the types of sedimentary facies in the study area by using the research methods of sedimentary geology, combined with information about drilling, logging, seismic, core, etc, and previous research results. The results show that the sublacustrine fans facies are mainly developed in the middle sub-member of Es3 of the study area, and followed by deep lake-semi-deep lake facies. The sublacustrine fans facies are distributed in the north and south of the study area, and can be divide into two subfacies such as in middle fans and outer fans. Among them, the middle fans subfacies can be further divided into several microfacies including discriminating channel, inter-discriminatory channel, front edge and side edge of discriminative channel. In addition, the deep lake-semi-deep lake facies are mainly developed in the east of the study area. The sedimentary facies as the mirror about different depositional environments during sedimentary period, obviously controlling the distribution of reservoirs. Sandstones are extremely developed and distributed of continuous flake surrounding the middle fans subfacies. The sediments of areas on the south of Well Shuang 102 and the north of Well Shuangshen 3 what the percentage of sandstone can exceed 80%, and the thickness of sandstone is more than 200m, is a high-quality natural gas reservoir, and can be used as the main target area for natural gas evaluation and development in the study area. The muddy sediments are massive developed but sandstones are scarcely developed near the deep lake-semi-deep lake facies. The sediments of areas on the east of Well Manan 3 what the percentage content of sandstone is less than 20% and the thickness is less than 20m, is the most important hydrocarbon source rock in the study area. The practice of oil and gas exploration shows that the formation and distribution of oil and gas are strictly controlled by the temporal and spatial distribution of sedimentary systems and sedimentary microfacies and their diagenesis history. It is possible to further expand and deepen the understanding of the strata in the study area, and to screen the natural gas enrichment areas more accurately through the analysis and study of sedimentary facies, there are great significance to the exploration and development of natural gas.

Study on the Sediment Geochemical Data Unmixing Methods

Yuan Liu[1*]
1. School of Geosciences, China University of PetroleumEast China, Qingdao, Shandong, CHINA
E-mail: 1340283489@qq.com

Keywords: sediment mixing, unmixing model, sediment geochemical data, K-means

Sediment mixing in Source-to-Sink system can interfere with the analysis of source signals, thus affecting the deeper understanding of tectonism and climate change on the Earth's surface. At present, in order to analyze the geological information preserved in the sedimentary record, two models of unmixing sediment geochemical data have been proposed, namely the "top-down" mixing model and the "bottom-up" unmixing model. The "top-down" mixing model is to imitate the mixing process artificially in accordance with the law of conservation of matter, so as to obtain the contribution rate of each source region to the sediment in the sink region. This model is suitable for the watershed system with well-preserved situation in the whole area, where the researchers is familiar. The "bottom-up" unmixing model is to use only geochemical data of sediment in sink area to obtain original rock data of source area. This model is suitable for circumstances when the source areas are not well constrained and/or when a sufficient number of sediment geochemical data in sink areas are available. So far, the "top-down" mixing model has achieved good feedback, while the feedback of the "bottom-up" unmixing model is not ideal. The purpose of this study is to achieve the goal of provenance analysis and/or paleogeographic reconstruction, by modifying the existing "bottom-up" unmixing model of sediment geochemical data and/or using a new method to explore the model. We initially used K-means cluster algorithm to unmix a collected fluvial detrital geochronologic data set in northeast China, which included 13 samples and 1759 data, covering 7 rivers. The results show that the clustering algorithm is better for simple watershed, and the clustering effect of complex watershed depends on the setting of cluster number K. We expect to improve the K-means clustering algorithm to promote the development of sediment geochemical data unmixing methods.

Keywords: Northern South China SeaMeishan Formation, Submarine Fan, Types of turbidite fans, High-quality reservoir

The turbidite fans of Miocene Meishan Formation in the Qiongdongnan Basin are important targets for natural gas exploration in the northern South China Sea. The type of turbidite fans is closely related to the degree of reservoir development. During the deposition of the Meishan Formation, sea level continued to rise and sea area continued to expand. In the early stage of the lowstand system tract, affected by regional tectonic-sedimentary background and fault activity, six types of turbidite fans were developed: fault controlling intra-slope fan, terminal basin- floor fan, sag-controlling syn-depositional fault root basin floor fan, integral basin floor fan, canyon cutting basin floor fan and passive filling basin floor fan. In the late stage of the lowstand system tract, slope fans were mainly deposited in the continental slope area. During highstand system tract, shelf fans were mainly deposited on the shelf or at the shelf edge. Among them, fault controlling intra-slope fan, canyon-cutting basin floor fan and integral basin floor fan are important exploration targets with developed reservoirs. In comparison, sag-controlling syn-depositional fault root basin floor fan, shelf fan, slope fan has relatively higher risk of exploration due to poor sedimentary differentiation and high shale content. The terminal basin- floor fan and passive filling basin floor fan have fine grain sands with high shale content, thus need to be avoided in the hydrocarbon exploration. The development of different turbidite fan reservoirs follow certain patterns spatially in the northern South China Sea. In the western part of the basin, various types of fan reservoirs are developed due to sufficient provenance supply. However, the accretive continental slope in the middle section and the regressive continental slope in the eastern section are short of good quality reservoirs due to the long distance from the provenance area. Insufficient sediment supply leads to deposition of fine-grained debris with high shale content. The classification of turbidite fans and the understanding of reservoir development provide important theoretical guidance and are practically significant for the exploration of turbidite fan related reservoirs in the Meishan Formation, Qiongdongnan Basin.

Main controlling factors and effectiveness of turbidite fan reservoir of the Meishan Formation, Qiongdongnan Basin

Jianping Li[1*], Ziying Qiu[1]
1. Exploration and Development Research Institute, China National Offshore Oil Corporation Research Institute Ltd., Beijing, CHINA
E-mail: lijp@cnooc.com.cn

Keywords: Turbidite fan Reservoir, Main controlling factors, Reservoir effectiveness, Meishan Formation, Qiongdongnan Basin

The turbidite fan of the Miocene Meishan Formation in Qiongdongnan basin is a major contributor to natural gas in this area. The sedimentary mechanism, analysis of main reservoir controlling factors and advances in reservoir prediction techniques directly affect the increase of natural gas reserves and production in this area. Based on a large number of data from DST, formation fluid test, coring and rotary sidewall coring, referring to relevant enterprises standards, the turbidite fan reservoir of the Meishan Formation in Qiongdongnan basin is divided into four classes: high-quality, good, effective and tight. Those four types are corresponded to high-production capacity, commercial-production capacity, merely-production capacity and dry layer respectively. The research shows that the type and internal composition of turbidite fans , bottom current reworking and accumulation effectiveness are key factors affecting and restricting the success rate of reservoir prediction. Step fault basin-floor fan, incised valley basin- floor fan and integral basin-floor fan are three turbidite fan types with relatively developed reservoirs. Bottom current reworking is highly important to improve the reservoir quality of mid fan and distal fan in open flow environment. For the incised valley basin-floor fan, the lithologic lateral seal needs to be taken into account. For the integral basin-floor fan, the reservoir pinch-out needs to be mainly considered. At present, the accordance rate of reservoir prediction of Meishan turbidite fans in this area is very low. The methods proposed in this study will be of great value to improve the success rate of reservoir prediction.

Reservoir types and its petroleum significance of the Lower Cretaceous lacustrine carbonates in the eastern of Brazil

Lianqiao Xiong[1*], Xiaojun Xie[1], Haiqiang Bai[1]
1. Exploration and Development Research Institute, CNOOC Research Institute Ltd., Beijing, CHINA
E-mail: xionglq2@cnooc.com.cn

Keywords: lacustrine carbonates, silicification, dolomitization, reservoir, Lower Cretaceous

Giant commercial oilfield has been discovered in the Lower Cretaceous lacustrine carbonates in Great Campos Basin in the eastern of Brazil. However, huge amounts of silicon have been discovered in core samples, and some carbonates have altered to siliceous rock completely. Some studies have shown that these lacustrine carbonates developed on the central paleouplift of the lake basin. Algal reefs and particle shores have developed on the paleouplift, which was similar to the distally steepened carbonate ramp. These carbonates have experienced dolomitization, siliceous cementation and displacement during diagenetic process. Many scholars thought that silicon appeared in the carbonates could destroy the reservoir properties undoubtedly, which affect the reserve evaluation and development plan design. While some scholars also found that siliceous rocks could be reservoirs and could discover hydrocarbons. Reservoir types, relationship between silicon and carbonates, and hydrocarbon potential of the silicified carbonates in the Lower Cretaceous lacustrine carbonates in the eastern of Brazil require systematic studies. Based on the lithological analysis, integrating with the geochemical analysis, diagenetic evolution, reservoir types, and reservoir evolution of lacustrine carbonates have been studied.

Through the microscope observation, it found that giant quartz crystals filled the fractures in limestone, part of pores in framework limestone, and replaced part of the limestone framework. Grainstone debris stayed in the almost silicified rocks. Pores formed by the dissolution of silicous rocks have been discovered. Stomatal amygdaloid basalts developed below the carbonate strata, and carbonate xenolith has been found in basalts. Adularia was found in the baslt almond. Dumbbell shaped dolomite and saddle dolomite was discovered in the local basalt strata. The phenomenon observed above demonstrated that strata fluid with silicon entry the carbonate strata and then silicon precipitated in carbonates fractures and pores. In the local area, silicon displaced carbonate matrix. The strata fluid with silicon may have relationship with deep hydrothermal. During the diagenesis process, carbonates could be completely altered to siliceous rocks which could be dissolved by hydrothermal. Then the siliceous rock reservoirs formed. Primary porosity in the lacustrine carbonates was dominated by intergranular pores and residual intergranular pores. Secondary porosity includes mold pore and intercrystalline pore. Inter quartz crystalline pore and dissolved pore also developed in siliceous rocks. In the local area, expanded pores formed by fracture dissolution can be discovered. The main reservoir type is fracture-porosity reservoir. Through geochemical analysis, carbonates fractures filled with quartz developed inclusions. The peak homogenization temperature of inclusions distributed from 120-140 ℃. Part of limestone was dolomitizd. Integrated with the carbon and oxygen isotopes analysis of dolomites, oxygen isotope shift to negative direction.

It suggests that the underlying volcano uplifted and sprayed at the early deposition period of carbonates. After the deposition of carbonates, deep hydrothermal with silicon and magnesian reformed carbonates, which formed silicon cementation, replaced siliceous rocks, and dissolved siliceous rocks. Fracture-porosity reservoirs developed in carbonates and siliceous rocks in the Lower Cretaceous lacustrine carbonates in Campos Basin, indicating that siliceous rocks could be hydrocarbon reservoirs. Silicified carbonate strata also has hydrocarbon exploration potential.

Sequence stratigraphy and depositional model of shale in the lower section of Wufeng Formation and Longmaxi Formation in southern Sichuan Basin

Lingling Xu[1], Renfang Pan[1*]
1. School of Geosciences, Yangtze University, Wuhan, Hubei, CHINA
E-mail: rfpan@qq.com

Keywords: Wufeng formation, Longmaxi formation, sequence stratigraphy, depositional model

Cores, rock slices, paleontological fossils, well logging and geochemical data were used to analyze the Upper Ordovician (Katian) to the Lower Silurian (Rhuddanian) in order to explore the temporal and spatial evolution characteristics of the Wufeng-Longmaxi Formation in the southern Sichuan area. The sequence boundary identification and sequence division were carried out in the uplift stage, the sequence stratigraphic framework of the marine shale in this area was established, and the sedimentary evolution history of the Wufeng Formation-Longmaxi Formation was analyzed. A method for identifying the sequence boundary and dividing the fourth-order sequence of marine shale is established, which uses the graptolite sequence as the time scale, the logging response feature to reflect the formation layer stacking model, and the lithological changes, sedimentary structure and geochemical parameters to reflect the depositional environment. . The single-well vertical sequence and the well-connected profile show that the Wufeng Formation-Lower Longmaxi Formation experienced three transgression-regression cycles, with 3 largest marine flooding surfaces and 7 system tracts; regional tectonic subsidence and global sea level were discussed. The control effect of the rise and fall on the relative sea level rise and fall. The regional tectonic subsidence played a leading role in the depositional period of the Wufeng Formation, and the relative sea level rise and fall of the lower Longmaxi Formation was mainly controlled by the global sea level rise and fall. A marine shale sedimentary model with fourth-order sequence as unit was established under the influence of multiple factors such as compression structure, paleo-uplift, glacial climate, and terrigenous input.

Characteristics and Geological Significance of Organic-rich Dolomites from Upper Ordovician Wufeng -Lower Silurian Longmaxi Formations on The Eastern Side of Kangdian Ancient Land

Ankun Zhao[1], DOng Wang[1*]
1. energy department, china geological survey, chengdu, sichuan, CHINA
E-mail: wwwdong1222@qq.com

Keywords: Wufeng -Longmaxi Formations, Dolomite characteristics, shale

This paper focuses on the characteristics and geological significance of Marine organic-rich dolomite, which has received less attention at present. Based on the full collection of previous achievements and data, the Hanyuan section of Ya 'an in the southern margin of Sichuan Basin was selected for detailed observation, measurement and description, and field samples were collected for geochemistry, paleontology, mineralogy and other tests. The organic-rich dolomitic shale and argillaceous dolomite in the lower part of Hanyuan section in Ya 'an were identified through the measurement and analysis of shale outcrop samples from Wufeng Formation-Longmaxi Formations. According to the petrological composition, microscopic feature recognition and petrogeochemical analysis, the depositional environment of dolomite in the upper section of the profile is shallow shelf, oxidization-suboxidation environment, high palaeo-productivity but abundant terrigenous detrital supply. The sedimentary environment of the dolomite in the lower member is a shallower water body than the deep water shelf, a subreduction sulfide environment, a high palaeo-productivity and a lack of terrigenous debris supply hypoxia environment. By discussing the relationship between the origin of organic dolomite and the enrichment of organic matter in Wufeng and Longmaxi formations, it is proposed that the existence of rich organic matter dolomite is closely related to the prosperity of microorganisms, its distribution may be beneficial for the favorable environment for the formation of organic shale in the basin edge zone, and provide more abundant geological basis for the expanded shale gas exploration in Yangtze region.

Sedimentary Characteristics of Enping Formation in Huizhou 14 Sub-sag of Zhu I Depression and Its Indicative Significance to Source Rocks

KAI ZHAO[1*], Shenglan Wang[1], Chen Shen[1]
1. Research Institute of Petroleum Exploration and Development, CNOOC Research Institute, Beijing, CHINA, CHINA
E-mail: zhaokai9@cnooc.com.cn

Keywords: sedimentary facies, source rock, Huizhou 14 Sub-sag, Zhu I Depression

The middle-deep lacustrine source rocks of Wenchang Formation have always been the focus of exploration in Zhu I Depression, while the source rocks of Enping Formation have made weak contribution. However, Huizhou 14 Sub-sag is special. The thickness of Wenchang Formation in Huizhou 14 Sub-sag is small. But the Enping Formation develops thick sediments with large buried depth, which seems to have more favorable conditions for the development of source rocks. However, due to the unclear understanding of the sedimentary characteristics of Enping Formation and the development characteristics of source rocks, the petroleum exploration in Huizhou 14 Sub-sag has not achieved commercial success. In view of this, the sedimentary characteristics and source rock development of Enping Formation in Huizhou 14 Sub-sag are comprehensively studied using the data of drilling, logging, core and laboratory analysis, and the conclusions are as follows.

For the lower member of Enping Formation, the deposition occurred in the fault-subsidence period. The lithology is composed of sandstone interbedded with mudstone, without coal seam. Its sedimentary facies include braided river delta faces and shore shallow lake faces. The middle-shallow lacustrine source rocks are developed. By contrast, the deposition of the upper member of Enping Formation occurred in the depression period. The lithology is characterized by gray sandstone and mudstone intercalated with coal, mostly in the form of interbedding. The deposition model of shallow braided river delta facies and shore shallow lake facies is developed. The analysis shows that the source rock assemblage of swamp and shore shallow lake facies is developed in the upper member.

The development of source rocks are affected by sedimentary environment and closely related to sedimentary facies. The biomarker characteristics of Enping Formation indicate that the sedimentary environment was weak oxidation, and the source of organic matter is mainly higher plants, supplemented by aquatic algae. The content of planktonic algae is low, which proves that the water body was shallow during its deposition. Meanwhile, the content of planktonic algae in the lower member of Enping Formation is slightly higher than that in the upper member, which proves that the water body in the lower member was deeper than that in the upper member. The development of coal measure source rocks in the upper member shows that the sedimentation rate and deposition rate were relatively high, and the hydrostatic environment of mutual balance was achieved.

Based on these understanding, the distribution of source rocks of Enping Formation is predicted by using multi-attribute neural network method. The calculated hydrocarbon expulsion is 5.31×10^{8} tons, which proves that Huizhou 14 Sub-sag has a good exploration prospect.

The research is of great significance to the exploration of sub-sags dominated by Enping Formation source rocks in Zhu I Depression.

Fine-grained sedimentary investigation and shale lithofacies mapping Take Wufeng-Longmaxi sequences in the Sichuan Basin and its surrounding areas as an example

Zongquan Hu[1,2*], Tong Zhu[1,2], Wei Du[1,2], Ruyue Wang[1,2], Dongjun Feng[1,2]
1. Unconventional hydrocarbon and renewable energy research department, SINOPEC Petroleum Exploration and Production Institute, Beijing, CHINA
2. State Key Laboratory of Shale Oil and Gas Enrichment Mechanisms and Effective Development, SINOPEC, Beijing, CHINA
E-mail: huzongquan.syky@sinopec.com

Keywords: Fine grain deposition, Longmaxi formation, Shale facies, Terrigenous clast

Taking the Wufeng-Longmaxi Shale in the Sichuan Basin and its surrounding areas, the earliest commercial shale gas in China, as an example, this paper performs a series of investigations based on considerable drilling and outcrops, e.g., stratigraphic division and correlation, lithofacies classification and identification, deposition environment analysis, deposition model establishment, sedimentary microfacies-lithofacies mapping and favorable lithofacies prediction.

The study focuses on three key issues of sequence stratigraphy and sedimentology of fine-grained sedimentation, establishes lithofacies mapping technology based on inorganic and organic components and carries out systematic sedimentary microfacies-lithofacies mapping with well-divided third-order sequences as units, which aims to describe distribution and evolution of sedimentary microfacies-lithofacies as well as predict and evaluate high-quality shale distribution. Specific workflows are described as followings. Firstly, geology, log and geochemistry are combined to develop stratigraphic division methods for fine-grained deposits based on detailed sequence and system tract divisions using multiple parameters and to establish chronostratigraphic frameworks for refining sequences and system tracts. In this way, sequence stratigraphy of thin layers at fine-grained system can be interpreted. The sequence evolution of fine-grained deposits at the Wufeng Formation to Long-1 Member in Sichuan Basin and its surrounding area is characterized by cyclicity and periodicity, which can be divided into three third-order sequences, corresponding to three transgressive-regressive cycles, which are further subdivided into seven system tracts, i.e., seven sedimentary environment evolution stages. Secondary, a lithofacies division method for fine-grained deposits integrated inorganic and organic components is developed to identify and divide fine-grained sedimentary facies. Lithofacies classification criteria based on three terminal diagram of inorganic minerals is determined, where both inorganic mineral and organic matter contents as considered as classification parameters. The inorganic lithofacies are divided into 4 categories with 8 subclasses, while organic facies is divided into five levels based on organic matter content. Consequently, fine-grained sedimentary facies are comprehensively classified and named based on the principle “organic matter content determining quality and inorganic component content determining lithology”. Seven key lithofacies are combined and classified based on the comprehensive lithofacies classification. One good lithofacies and three fair lithofacies are determined to meet the needs of shale gas exploration and development. Thirdly, sequence stratigraphy and lithofacies in two directions, e.g., cutting and parallel to deep-water shelf, are compared to understand deep-water deposition model and lithofacies distribution. The deposition model of Wufeng-Longmaxi shale is established, suggesting that the shelf was deposited at the platform in Sichuan Basin and its surrounding areas during Wufeng-Longmaxi period. Primary mineral contents from palaeocontinent to shallow water shelf and then to deep water shelf is determined in an order: terrigenous clasts and clay, carbonate mineral, and quartz.

A lithofacies mapping technology based on inorganic components and organic components is established based on these three theoretical understanding of fine-grained sedimentation. Systematic sedimentary microfacies-lithofacies mapping is carried out for seven system tracts under the guidance of the established deposition model, which is based on quantitatively-mapped three principal mineral contents and organic matter content, reducing environment distribution mapped by environmental geochemical parameters as well as determined paleowater depth.

Tidal currents transporting terrestrial organic matter to the sea, evidence from the Eocene Pinghu Formation in the Xihu Depression, East China Sea Shelf Basin, China

Shanshan Zhou[1*]
1. Exploration and Development Research Institute, China National Offshore Oil Corporation Research Institute, Beijing, CHINA
E-mail: zhouss27@163.com

Keywords: tidal currents, terrestrial organic matter, neritic source rocks, biomarkers, palynofacies

Carbonaceous fragments and stripes were discovered in the Eocene Pinghu Formation neritic clastic rocks in the Xihu Depression, East China Sea Shelf Basin. The dark striated layers interspersed in the fine sandstones have an abnormally high total organic carbon content of 7.16%. The kerogen in the neritic mudstones is type II2, indicating that the organic source was dominated by terrestrial species with a limited contribution of aquatic organisms. Rivers are thought to transfer the terrestrial-derived organic matter debris into the sea (Saller et al., 2006; Deniau et al., 2010; Abbassi et al., 2014; Deng et al., 2019; Zhang et al., 2020), although other researchers have suggested that tidal currents can also transport organic matter into seas by disrupting marshes (Li et al., 2015). However, in the Xihu depression, these theories were under debate.

In this study, source rock samples of neritic, tidal flat (or lagoon), and delta front from the Pinghu Formation in the study area were collected and analyzed. Biomarkers and sedimentary organic matters in the neritic mudstones were compared to those in the tidal flat (or lagoon) and the delta front mudstones. The results confirm that the organic matter composition of the neritic mudstones is similar to the tidal flat (or lagoon) mudstones, indicating the supply of plant materials in tidal flat (or lagoon) is the primary organic matter source in the marine environment.

Trace element indexes confirm that the climate was warm and humid and plants flourished during the deposition period of the Pinghu Formation. In addition, the western slope of the Xihu Depression is flat with sags on it, which are favorable to the formation of marshes. The high gammacerane, high sulfur, and framboidal pyrite associated with the coal seam together reveal that the water is quiet and saline, which is favorable for organic matter preservation. The lithology assemblages of the tidal flat (or lagoon) sedimentary facies show frequent interbedding of coal, mudstone, and sandstone strata, indicating that hydrodynamic power increased suddenly and marshes were easily eliminated. These findings suggest that the tidal currents are the dominant mechanisms driving organic matter from the tidal to the neritic environment.

Keywords: Source to sink system, Rock-mineral analysis, Meishan Formation, Central depression, Isotope test, Turbidite

Large and medium-sized gas fields such as Lingshui 17-2 have been discovered in the Miocene Huangliu Formation-Pliocene Yinggehai Formation in the central depression of the Qiongdongnan Basin. The exploration of the mid-deep Meishan Formation has not yet been made a major breakthrough, due to the fact that the sand body distribution and the sand-controlling mechanism of the Meishan Formation are not well understood. This paper focuses on the turbidite fan sandstone of the Meishan Formation in the northwest of the central depression of the Qiongdongnan Basin. Microscopic thin section observation, rock and mineral composition statistics, and isotope test, were applied to analyze the elements of the "source sink" system and sand-controlling mechanism, combined with macro structural evolution and river channel development characterization. The result reveals that the turbidite fans of YC35-X well was transported and deposited from NW to SE along the No.1 fault, the No.13 fault and multi-stage channels of the Honghe fault zone with multi-provenance supply from the Hainan Island, the central Vietnam and the Honghe River. The turbidite fans of YC24-X and LS13-X well was transported and deposited from NNW to SSE along the No.5 fault, the No.3 fault, the No.2 fault and multi-stage channels with provenance supply from the Hainan Island. The turbidite fans of ST36-X well was transported and deposited from NE to SW along the No.5 fault, the No.6 fault, the No.2 fault and multi-stage channels with different branches of provenance supply from the Hainan Island. The source-to-sink system of the Meishan Formation in the northwestern of the central depression of the Qiongdongnan Basin is absolutely controlled by the provenance of the Hainan Island, which is manifested by multi-provenance supply from the Hainan Island, the Honghe River and the central Vietnam, converging along the inherited active-faults and multi-stage channels, and being deposited at the bottom of submarine fans. The northeast of the YC35-X and ST36-X turbidite fan is a favorable zone for the development of turbidite sand bodies of the Meishan Formation in the northwest of the central depression of the basin.

Provenance and sedimentary facies of Upper Triassic Mungaroo Formation in North Carnarvon Basin

Haiqiang Bai[1*]
1. Exploration and Development Research Department, CNOOC Research Institute, Beijing, CHINA
E-mail: baihq@cnooc.com.cn

Keywords: Provenance, sedimentary facies, Mungaroo Formation, North Carnarvon Basin

Based on the regional tectonics, seismic sedimentology and petrology, it is considered that there is no northern provenance in the Mugaroo Formation in the study area. The provenance mainly comes from the Australian craton, including the Ross highland and its basin in the southern Australian craton, and the Pilbara highland adjacent to the study area. The comprehensive analysis of drilling and logging, paleontological, core, thin sections, seismic and other data showed that the study area developed three types of sedimentary facies : fluvial, delta, and shore-shallow sea; sedimentary facies is generally northeast-southwest banded distribution, from south to north in turn developed fluvial face, delta face, shore and shallow sea face. Sequence stratigraphic study suggested that the Mungaroo Formation in the study area included 3 third-order sequences, such as SQ1, SQ2 and SQ3 from bottom to top. The reservoir mainly developed in the late stage of lowstand system tract and highstand system tract of third-order sequence. Among them, in the late stage of low-stand system tract and high-stand system tract, medium-thick layers rivers, medium-fine sandstones of delta facies and a small amount of thin coal seams are developed ; the transgressive system tract is dominated by thick-layer mud intercalated with thin-layer powder and fine sandstone, and local layers are frequently interbedded with thin limestone and coal seam. Comprehensive study showed that the provenance and relative sea level controlled the development of tidal-controlled delta in the study area (Fig. 1). With the relative sea level decline, from SQ1 to SQ3, the main body of tidal-controlled delta continues to move northward.

Seismic and Stratigraphic Correlation of Miocene Turbiditic Sandstone Reservoir in the Gharb Basin, Onshore Morocco

Zheng Wang[1], Jonathan Redfern[2*]
1. College of Marine Science and Technology, China University of Geosciences(Wuhan), Wuhan, Hubei, CHINA
2. Department of Earth and Environmental Sciences, The University of Manchester, Manchester, UNITED KINGDOM
E-mail: Jonathan.Redfern@manchester.ac.uk

Keywords: Gharb basin, Seismic and Stratigraphic Correlation, Sandstone Reservoir, Turbiditic sand, Biogenic gas

The Gharb basin is a westerly dipping foreland basin located in the external zone of the Rif fold belt, Morocco. Nappe migration in the Miocene formed the original foreland basin in which the sands were deposited. The Nappe continued to develop after the deposition of the Miocene marine turbiditic sandstones, developing one primary normal fault and several minor antithetic and synthetic normal faults that act as the traps for commercial biogenic gas.

In the study area, 21 wells have been drilled to produce biogenic gas, 10 of them were drilled during the 1960's and 70's. Since 2009, Circle Oil and SDX Energy Company drilled 12 wells in the area. The study has access to all the well data, plus a large 3D dataset provided by SDX. The study aims to assess the distribution of the main sandstone reservoirs, correlate the packages from the wells to the seismic data using structural mapping and amplitude analysis, and assess the depositional environment and controls on reservoir development.

The wells penetrate 5 sandstone intervals, 4 of them producing commercial gas flows. The sand intervals are named the Hoot Sandstone, Guebbas Sandstone, Gaddari Sandstone, Lower N'Zala Sandstone and Upper N'Zala Sandstone. Among these intervals, the Hoot Sandstone is the most prospective, with the main reservoir interval being a 10 metres thick sand, which has resulted in the largest discoveries.

The Hoot, Guebbas and Gaddari sandstones are heavily faulted by the later movement of Nappe, and interpretation of the 3D seismic data reveals a complicated structural compartmentalization of the reservoir. The operator, SDX, has drilled seven wells to produce the gas in the Hoot reservoir. However, the latest well drilled on a larger structure where other wells had previously been drilled, encountered a depleted reservoir. This study was also tasked to ascertain possible reasons why the well, KSR-16, was depleted, by undertaking a detailed interpretation of Hoot sandstone reservoir. Results suggest the well KSR-16 was within a reservoir segment connected to well KSR-8.

A correlation of the sandstone units has been made between the well data and seismic. Based on this correlation, the sandstone distribution has been mapped and deep-water paleoenvironmental models constructed. Many of the sandstone intervals show a distribution and thickness relationship to the syn-depositional structural pattern. This work provides useful information for sandstone distribution prediction and its relationship to faulting for further exploration in Gharb Basin.

Key Factors Affecting Reservoir Properties of Submarine Fans in the Meishan Formation of Lingshui Depression , western Qiongdongnan Basin

Jia Zhong[1*], Desheng Hu[1], Ming Li[1], Juan Liu[1], Liyuan Gong[1], Can Huang[1], Daojun Zhang[1]
1. Hainan Branch of CNOOC Ltd, China National Offshore Oil Limited Corporation, Haikou, Hainan Province, CHINA
E-mail: zhongjia2@cnooc.com.cn

Keywords: Qiongdongnan Basin,Lingshui depression, Meishan Formation, Submarine, Deepwater sandstone,Reservoir properties

Several giant deep-water gas field s (e.g., LS17-2, LS25-1) resoundingly discovered in the last decade confirm the superiority of gas accumulation in the deep-water sandstones of the Lingshui Depression, western Qiongdongnan Basin. Although the deep-water sandstones in the Lingshui Depression are generally large in body size, the reservoir properties vary distinctly with sandstone bodies. To better understand the mechanisms and critical factors that affect the reservoir properties of deep-water sandstones in the Lingshui Depression, an investigation based on the 3D seismic data, geophysical logs, and core samples that were recently collected from the submarine fans of the Meishan Formation was conducted. The seismic characterizations and the rare earth elements and heavy mineral assemblages of cores indicated that submarine fans of the Meishan Formation can be classified into two categories: 1) channel-lobe complex with sediments primarily sourced from the Hainan Island; 2) channel-levee complex with depositions mainly supplied from the Kunsong Uplift. The casting slice and scanning electron microscope observations suggested that both compositional and textural maturities of channel sandstones were generally higher than those of lobe or levee sandstones. Meanwhile, the porosity and permeability of channel sandstones were commonly higher relative to the lobe or levee sandstones, implying that hydrodynamic conditions during sediments transport were the primary factor affecting the reservoir properties. Diagenesis including the mechanical and geochemical compactions were also identified in the submarine fans. Mechanical compaction was inhibited by overpressure, particularly for sandstones spatially located in the depression center, contributing to the porosity of channel sandstones being >15% at a burial depth of ~4800m. Chemical compaction was dominated by carbonate cementation. Carbon and oxygen isotopes of carbonate cement suggested that carbonates were primarily sourced from the bioclastic limestone supplied by shelf collapse and partly from the deep pore fluids rich in calcium. Summarily, the hydrodynamic conditions during deposition and mechanical compaction during burial were the key factors that should be considered for the formation of high-quality reservoirs in the Submarine fans of the Lingshui Depression.

Temporal transformation trend of submarine-fan morphology and its allogenic/autogenic controlling factors

Osamu Takano[1*]
1. Technical Division, JAPEX Research Center, Chiba, JAPAN
E-mail: osamu.takano@japex.co.jp

Keywords: submarine-fan morphology, sandy radial fan, channel-levee system, controlling factor

After the late 1980's, variation on submarine-fan morphology has been discussed, and sandy radial fan and channel-levee systems have been recognized as morphological end members. Questions are whether submarine-fan morphology changes temporary within the long-term submarine-fan system development or not, and if so, what is the controlling factor on it. This study examined total eight examples of submarine-fan systems, developed in forearc and backarc basins of the NE and SW Japan arcs, in terms of morphological change trend, duration and its possible causes. As a result, in most cases, the morphological type of submarine-fan systems transformed from the sandy radial fan type to the channel-levee system type during their 2- to 10-million-year development life, except for a trough-fill turbidite setting. This temporal transformation trend might be caused by gradual decrease in coarser material supply due to tectonic waning in hinterlands, and by the increase of depositional surface gradient due to sediment wedge formation during sedimentation, resulting in the downstream-ward shift of the transition point between a channel and a depositional lobe, producing a channel-levee system-dominated condition.

Tectonic evolution and depositional response from rift through drift to foreland periods in the Lile basin, South China Sea

Xinong Xie[1*], Cheng Zhang[1], Jianxiang Pei[2]
1. Faculty of Marine Science and Technology, China University of Geosciences, Wuhan, Hubei, CHINA
2. Hainan Energy Co. Ltd., CNOOC , Haikou, Hainan, CHINA
E-mail: xnxie@cug.edu.cn

Keywords: Continental marginal basin, Lile basin, South China Sea

The Lile Basin is a Cenozoic passive continental basin in the south-central South China Sea, and its formation and evolution record the geological process from rifting to spreading in the South China Sea. The results show that the tectonic evolution of the Lile Basin has undergone three distinct stages, namely the Paleocene-Early Oligocene rift stage, the Late Oligocene-Early Miocene drift stage, and the Middle Miocene-Quaternary foreland stage. The tectonic evolution and sedimentary influx control the development of large reservoirs. During the Paleocene-Early Oligocene period, rifting forms along the NNW-SSE extension, the basin receives mainly sediment supplies from the north and west, and a series of fan-delta systems are developed, but in other sides a smaller fan-delta system develops. During the Late Oligocene-Early Miocene stage, with the South China Sea spreading and the Nansha Block away from the margin of South China, the Lile basin enter a drifting stage, marine carbonate deposits were widely developed due to far from the continental clastic sediment supply. Since the Middle Miocene, the South China Sea spreading has terminated and the Proto-South China Sea has completely disappeared, the basin moves into the foreland stage. The basin underwent a rapid subsidence due to the subduction and collision of the Philippine Sea Plate. The carbonate platforms in the northern part gradually submerge, and the muddy abyssal deposits with turbidite sandstones occur in the southern part. Hence, the tectonic evolution of the Lile Basin shows obvious differences in depositional infilling, and also records a wealth of information on the evolution of the South China Sea extension.

Research of delta characteristic of Source-to-Sink and sedimentary reservoirs in Northeastern Bozhong Sag dongying group II

Jian Wang[1*]
1. exploration and development, CNOOC Research Institude, Beijing, CHINA
E-mail: intosnow@163.com

Keywords: Northeastern Bozhong Sag, delta, Source-to-Sink system, sedimentary reservoirs

A large and Mega-thick delta is existing in Northeastern Bozhong Sag Dongying formation II. It has a low exploration degree and a large exploration potential. Research of the delta is of great significance in expanding the field of exploration. Main Reasons for Drilling Failure is the poor reservoir condition in the area, because of the thin reservoir thickness and low porosity and permeability, so a research of searching favorable reservoir development area is essential. The research is to prove the reservoir potential of the delta by the study of provenance, structural, sequence and sedimentary model characteristic. In the research, the research idea from source to sink is used. The sandstone distribution of the delta is characterized by the high resolution seismic attribute analysis and the horizoncube technique. In the research, seismic multi-attribute clustering analysis technology and neural network pattern recognition technology are widely used, which greatly improves the accuracy of the research The research proves that the granitic metamorphic rock area in northwest Bohai Bay Basin is the favorable provenancethe Dashihe delta is a more sand-rich sedimentary facies belt in the lower dongying group IIthe phase IV of Dashihe delta has the better reservoir condition in the area.

Occurrence forms and composite genesis mechanism of glauconites: A case study from the Neoproterozoic rocks in North China

Qin Zhang[1,2*], Hanyun Tian[1], Zeping Song[1], Donglian Lu[1]
1. College of Geosciences, China University of Petroleum(Beijing), Beijing, CHINA
2. State Key Laboratory of Petroleum Resources and Prospecting, China University of Petroleum(Beijing), Beijing, CHINA
E-mail: zhangqin@cup.edu.cn

Keywords: Glauconite, occurrence form, maturity, genesis mechanism, Neoproterozoic, North China

In recent years, more and more studies have found that the occurrence forms of glauconite are complex, and the single genesis proposed by the previous has been unable to explain the different occurrence forms of glauconites. The Neoproterozoic in North China has developed several sets of glauconite, but the occurrence forms and their genesis are still unclear.Taking the Neoproterozoic glauconite-bearing rocks in North China as an example, the occurrence forms, forming conditions and genesis of glauconite have been systematically studied through outcrops, thin sections, X-diffraction, SEM, electron probe and trace element experiments. The study shows that the glauconites have complex forms, including granular, colloidal, detrital pseudomorphic, pigment-infested and halo - rimmed. The glauconites were classified into five types based on the different color, morphology and chemical composition, namely green granular glauconite, yellow-green granular glauconite, yellow-brown granular glauconite, yellow colloidal form and dark brown detrital glauconite. The formation of glauconite is controlled by material sources and redox conditions. The iron components and glauconite developed in the underlying Xiamaling Formation provided the material source for the glauconites in the Changlongshan Formation. Green and yellow-green granular glauconites were formed in two different pseudomorphic replacement stages, and yellow-brown granular glauconites were formed by early pseudomorphic replacement or layer lattice genesis and later alteration. The colloidal glauconites were formed under the condition of authigenic cementation in the early stage, and most of them were oxidized and altered in the later stage. Dark brown detrital glauconites were formed by later re-transportation and allochthonous re-deposition of autochthonous authigenic glauconite or mica pseudomorphic glauconite by origin of layered lattice. A systematic classification of glauconites in the Neoproterozoic and the establishment of the evolution pattern of different glauconites can provide scientific basis for the restoration of paleogeographic environment and diagenetic sequences in North China or similar areas worldwide.

Tectonic control on turbidite sedimentation of Upper Jurassic sandstones in Western Central Graben, North Sea

CHEN Jingtan[1*]
1. Oversea Technical Support Center, CNOOC International Limited, Beijing, CHINA
E-mail: chenjt@cnooc.com.cn

Keywords: Western Central Graben, Upper Jurassic, turbidite, shoreface

In the UK Western Central Graben, due to high pressure and undercompaction, Upper Jurassic Feshney Member turbidite sandstones shows good reservoir quality when its buried depth is more than 4500m. However poor seismic imaging, it is difficult to predict the variation of Freshney Member sandstones, which leads to many wells' failure for hydrocarbon exploration.

Rifting created a faulted sag with thick marine claystone and turbidite sandstones, and uplifted margins with shoreface sandstones in the Late Jurassic. Based on the analysis of heavy minerals, composition of grains, and grain size, turbidite clastic sediments from re-deposition of shoreface sandstones in Multi-point source around uplifted margin. It has been found that thicker shoreface sandstones conversely resulted into thinner turbidite sandstones by several wells.

Based on thickness variation of Freshney Member, paleotopographic restoration shows southwest part is deepest with steep slope and northern part is shallowest with gentle slope in the sag. Salt movement and faulting action make shoreface deposition is unstable in the southwest margin, as a result, more sands slumped into deepwater area with thicker turbidite sandstones by steep slope. On the contrary, there is thinner northern part turbidite sandstones. Therefore tectonic mechanism controls turbidite fans development. According to this new cognition, the distribution of Freshney sandstone successfully predicted was from western margin in G Field which located the center of Western Central Graben.

E-mail: taojiang@cug.edu.cn

Keywords: Gas hydrates, Sand-rich reservoirs, Detrital zircon U-Pb dating, Provenance, South China Sea

Gas hydrates that occurred in coarse-grained sediments were drilled in the Qiongdongnan Basin for the first time, and this was also the first time sand-rich gas hydrate reservoirs were discovered in the northern South China Sea. To determine where the sands come from of the Quaternary gas hydrate reservoirs in the Qiongdongnan Basin, we integrate core-log-seismic data, major elements, and rare earth elements geochemistry as well as detrital zircon U–Pb geochronology to characterize the sand-rich gas hydrate reservoirs in detail.

It is clear that the gas hydrate saturation and physical properties of coarse-grained sand-rich gas hydrate reservoirs are better than those of fine-grained reservoirs. In addition, the gas hydrate saturation has an obvious positive correlation with the grain size of its host sediments, indicating that the newly discovered sand-rich gas hydrate reservoirs in the South China Sea have high resource potential. Furthermore, fine sand or even medium sand with some typical sedimentary structures of turbidity currents can be observed in the cores.

Geochemistry shows that sands are sourced from mature continental sedimentary rock provenances, and the detrital zircon U–Pb ages also indicate that the Quaternary sediments in the Qiongdongnan Basin were mainly influenced by the provenances of the Red River, the Truong Son Belt, and the Hainan Island. Combined with seismic geomorphology, it can be determined that the sediments from the northern Truong Son Belt and the Red River could be transported into the Qiongdongnan Basin, and then are deposited as submarine fan systems, forming sand-rich gas hydrate reservoirs.

Evaluation and exploration practice of Paleogene high quality reservoir in Panyu 4 Sag, Pearl River Mouth Basin

Li Zhen Sheng[1*]
1. Research Institute, Shenzhen Branch, CNOOC China Limited, Shenzhen, Guangdong, CHINA
E-mail: lizhsh11@cnooc.com.cn

Keywords: Panyu 4 Sag, Paleogene, reservoir evaluation

Panyu 4 Sag is a proven hydrocarbon rich Sag with high exploration degree and few and small remaining medium and shallow structures. Oil and gas exploration is facing the transformation from medium and shallow Neogene structural reservoir to deep Paleogene. After 15 years of three rounds of exploration, five Paleogene drilling wells have achieved poor results. Although sand shows abundant, the physical properties of the reservoir are poor and the distribution range of high-quality reservoirs is unclear, which restricts the exploration process of Paleogene Wenchang Formation. Aiming at this problem, the Paleogene reservoir conditions are systematically studied. Starting from the source-to-sink system, the differences of parent rocks in the three provenance areas around Panyu 4 Sag are analyzed, and the differential evolution model of deep reservoirs under different provenance systems is established. It is considered that the granite in Xijiang low uplift has the characteristics of high silica, high potassium oxide, small ratio of light rare earth to heavy rare earth, less dark minerals and high maturity of parent rock composition provided by Xijiang low uplift, It is a high-quality material source supply area with low rock debris content and strong anti compaction ability. Combined with the characteristics of regional tectonic activities, based on the restoration of the original basin, a structural sedimentary response model of "early fault control and late slope control" is proposed in the high-quality provenance supply area. It is considered that the early activity of Wenchang is strong and the late activity of Wenchang is weak, which is characterized by episodic activities. At the same time, episodic tectonic activities control the sedimentary characteristics of the area. The early stage of Wenchang is dominated by fan delta deposition and the late stage of Wenchang is dominated by braided river delta deposition. This understanding has promoted the exploration process of Paleogene in the gentle slope belt of Panyu 4 Sag, obtained multi-layer oil layers by drilling, and obtained oil samples in Wenchang Formation, opened a new situation of Paleogene exploration, and has certain guiding significance for the next Paleogene exploration of Panyu 4 Sag.

Characteristics of deep tight clastic rock reservoirs and genesis of relatively high-quality reservoirs: A case study of Paleogene in Panyu 4 Sag, Pearl River Mouth Basin

Li Zhang[1*]
1. Research Institute , Shenzhen Branch of CNOOC Ltd, ShenZhen, , CHINA
E-mail: zhangli117@cnooc.com.cn

Keywords: Pearl River Mouth Basin, Panyu 4 depression, paleogene wenchang formation, reservoir characteristic, genesis of relatively high-quality reservoirs

The clastic rock reservoirs of the deep Paleogene Wenchang Formation in the Panyu 4 sag in the Pearl River Mouth Basin are generally more than 3100 m deep, with strong heterogeneity and generally poor physical properties, with medium to ultra-low porosity and ultra-low permeability. Aiming at the problems in the study of the characteristics and genesis of deep tight and low permeability reservoirs , the characteristics of clastic rock reservoirs and the genesis of relatively high-quality reservoirs in Panyu4 sag were studied through core observation, casting thin section identification, scanning electron microscopy, physical property analysis, X-diffraction analysis, etc. with basin structure and provenance system as a constraint condition The research results show that: 1) The petrological characteristics, physical properties, pore throat structure, diagenesis and evolution of different provenance systems and sedimentary facies types of reservoirs are significantly different; 2) Compaction is the main controlling effect on the decrease of reservoir physical properties , dissolution improves the physical properties of the reservoir to a certain extent, and under these comprehensive controls, five types of low-permeability reservoirs are developed. 3) The northern steep slope zone of Panyu 4 sag mainly develops relatively high-quality reservoirs dominated by sedimentation, the southwestern gentle slope zone mainly develops high-quality reservoirs of feldspar dissolution and pore-increasing type dominated by diagenesis, and the northwest gentle slope zone mainly develops a relatively high-quality reservoir of quartz-rich and compaction-resistant reservoir dominated by the parent rock type.

Depositional characteristics and sedimentary sequences of Late Jurassic deep-water gravity flows in Eastern Moray Firth Basin, North Sea

Hongyu Du[1*]
1. Overseas technical support center, CNOOC International Limited, Beijing, CNOOC International Limited, CHINA
E-mail: duhy@cnooc.com.cn

Keywords: Moray Firth Basin, Late Jurassic, debris flow deposits, turbidity current deposits, sedimentary sequence, depositional mode of gravity flow

Through a large number of core observations, drilling/logging data analysis, and combined with gravity flow deposition theory, a systematic analysis was carried out on aspects of depositional characteristics, depositional processes, and sedimentary modes of Late Jurassic deep-water gravity flows in the northeastern Moray Firth Basin, North Sea. Research shows that the gravity flow deposits in the study area can be divided into gravel debris flow deposits, sandy debris flow deposits, argillaceous debris flow deposits, turbidity current and secondary slumping deposits. Among them, massive sandy debris flow deposits is most developed one. According to the vertical superposition mode of different or identical flow regimes in different stages during the gravity flow deposition, three vertical sequences have been established, and different deposition sequences correspond to their unique depositional environments. Sedimentary sequences dominated by debris flow deposits are usually found in restricted channels, sedimentary sequences dominated by debris flow deposits interbedded with turbidity current deposits are mostly developed in weakly restricted channels, and sedimentary sequences composed of debris flow and turbidity current interbeds are common in lobe complex.

2. college of geoscience, China University of Petroleum, Beijing, Beijing, CHINA
E-mail: liwj41@cnooc.com.cn

Keywords: Xihu Sag, Distributary Channel,Support Vector Regression,Reservoir Prediction.

X gas field is located in the central inversion structural belt of Xihu Sag, East China Sea basin. The main target layer H4 is in shallow water delta sedimentary environment. The dominant frequency of seismic data of the gas field is low (25Hz), while the buried depth of H4 layer is large (3300m ~ 3400m). The reservoir has low porosity and low permeability, and the consistency of sand body thickness predicted by conventional seismic inversion is low.

Aiming at the characteristics of full coverage of 3D seismic data and less drilling in X gas field, this paper makes up for the lack of sample points in SVR algorithm through forward and inverse modeling under the guidance of geological model and setting up virtual wells. Then, by extracting seismic attributes and optimizing sensitive attributes characterizing sand body thickness, SVR algorithm is used for multi-attribute fusion to complete the quantitative prediction of H4 sand body.

Based on the reservoir prediction results, it is proposed that H4 layer is a distributary channel deposit of shallow water delta meandering flow type, and further completed the dissection of sand body deposition model. After the development adjustment wells drilled, the coincidence between the actual drilled sand body thickness and the predicted sand body thickness is more than 84%.

This paper explores and obtains the quantitative reservoir prediction scheme of SVR algorithm constrained by geological model under the condition of few wells on the seawhich completes the accurate prediction of the middle and deep distributary channel reservoir in X gas field, and also has certain guiding significance for the reservoir description of the same type of oil and gas fields.

Reservoir Valuation and Effective Factors of Generation Capacity Research In long11 Sub-member of Longmaxi formation in Weiyuan area, south Sichuan

Xin Zhou[1*], Junxiang Li[1], Yuexiang Hao[1]

1. Shale Gas Exploration And Development Department, CNPC Chuanqing Drilling Engineering Company Limited , Chengdu, Sichuan, CHINA

E-mail: zx941115@163.com

Keywords: logging characteristic interval,stratigraphic division program,lithofacies,production distribution,shale gas

The electrical characteristics of the $Long_1^1$ sub-member in the Chuanqing block, which located in Weiyuan area of South Sichuan, have great lateral changes. Significant differences in the volume fracturing engineering effect and production also indicated variations in shale quality of $Long_1^1$ sub-member in the study area. To find the answer of these question, the stratigraphic identification standard and division program of logging characteristic intervals were established, based on the logging response of $Long_1^1$ sub-member in 12 evaluation wells . Then combined with several experimental methods, such as quantitative analysis of minerals by scanning electron microscope, canning imaging of backscattered two-dimensional multi-scale electron microscope, organic geochemical experiments and analysis of trace elements, the depositional environment, lithofacies , organic geochemical characteristics and key parameters of shale reservoir quality of logging characteristic intervals were analyzed. It is considered that there are No. 1~7 electrical characteristic intervals from bottom to top can be used to describe lateral variation of shale, which are developed completely around Well A in the middle of the block, the upper characteristic intervals was missing in the east area, and some lower characteristic intervals cannot be found in the west area of the block. Through dynamic data, the understanding of stratigraphic distribution regularities and quality differences in the horizontal direction of a single interval was verified. Finally, reliable conclusions about reservoir quality and productivity of characteristic intervals are formed. The neutron and density curves of No. 1, 2, 4, and 6 characteristic intervals are envelope-shaped and have high gas production potential, among them No. 1 and No. 2 intervals have strong mirror image characteristics and are excellent reservoirs. Those conclusions can be used to guide researches such as the selection of favorable areas in the middle and late stages of shale play development and some analysis of production distribution law in horizontal wells.

Shale lithofacies and reservoir characteristics of Wufeng Formation-lower Long 1 submember of Longmaxi Formation in western Changning

Chongjie Liao[1*]
1. School of Geoscience Technology, Southwest Petroleum University, Chengdu, SiChuan, CHINA
E-mail: chongjie98@163.com

Keywords: shale gas, lithofacies, reservoir characteristics, Longmaxi Formation, western Changning

Wufeng-longmaxi Formation shale in Changning area has made a major breakthrough which is a key target of shale gas exploration and development. In order to clarify the lithofacies differences, the vertical and horizontal distribution of lithofacies and influence factors of reservoir development in western Changning area, based on core, thin section observation, X-ray diffraction, logging curves and three-end member diagram of siliceous, minerals-carbonate, and minerals-clay minerals on shale of Wufeng Forming-lower Long 1 submember of Longmaxi Formation, the lithofacies of wufeng Formation- lower Long 1 submember of Longmaxi Formation in western Changning area are divided. On this basis, according to TOC, porosity and hydrocarbon content analysis of different lithofacies, the reservoir characteristics and controlling factors of various lithofacies in the study area are analyzed and predicted. The results show that there are seven lithofacies in the study area: siliceous shale facies, mixed siliceous shale facies, argy-siliceous shale facies, clay-siliceous shale facies, mixed shale facies, clay-siliceous shale facies and argy-siliceous shale facies. The siliceous shale facies mainly developed in sublayer-1 and sublayer-2 of Long 1 submember of Longmaxi Formation is the best lithofacies in the study area because of the abundant biosiliceous and abundant biosiliceous deposits in the depositional environment of stagnation and hypoxia reduction environment, resulting in high TOC content, high porosity and rich gas content of siliceous shale facies. Due to the destruction of anoxic environment in the middle and upper part of lower Long 1 submember of Longmaxi Formation, the mixed siliceous shale facies, greyish-siliceous shale facies, greyish-siliceous mixed shale facies and clay-siliceous mixed shale facies developed in the middle and upper part of lower Long 1 submember of Longmaxi Formation are the sub-optimal shale facies in the study area due to the deterioration of organic matter and pore conditions.

Characteristics and genetic mechanism of beach bar sedimentary system in the 2nd of Shahejie formation in Bohai Sea Area

Xiaojian Liu[1*], Yongjun Liu[1], Chenjie Wang[1], Yanhong Xu[1], Zhen Zhang[1]
1. Bohai Oilfield Research Institute, CNOOC China Limited, Tianjin Branch, Tianjin, Tianjin, CHINA
E-mail: liuxj14@cnooc.com.cn

Keywords: beach sand bodies, origin of high-quality reservoirs, formation mechanism, Bohai Sea

In recent years, there has been no major exploration discovery in the 2nd member of Shahejie Formation in Bohai Sea, which is mainly limited by the difficulties such as the exhaustion of structural trap and the large burial depth of reservoir3500m. Based on the "source-sink" theory, this study carries out the sedimentary system of E_2S_2, the genetic mechanism of high-quality reservoirs of deep / ultra deep clastic rocks and the tracing of lithologic traps, and finally predicts the distribution of high-quality reservoirs of E_2S_2. First, clarify the ternary sand control mechanism of "ancient material source, ancient landform and ancient hydrodynamic" of Lake wave transformed fan delta. Establish the development model of fan delta with Lake wave transformation in Shinan steep slope zone, and make it clear that the front edge of fan delta will form coastal beach dam after strong Lake wave transformation; Secondly, it reveals the genetic mechanism of "deep buried and high porosity" reservoir controlled by deep / ultra deep lake wave transformation and dominant minerals. It is innovatively proposed that high-quality reservoirs under deep / ultra deep conditions are jointly controlled by Lake wave transformation and "dominant minerals". The diagenetic dynamic mechanism of "mineral reservoir forming sequence" under Lake wave transformation and deep buried diagenesis is is established. It is clear that the fragmentation and dissolution of potassium feldspar is the basis for the clastic rock to break through the "lower limit depth of low permeability (3500m)" of the reservoir under deep / ultra deep conditions; Third, establish the fine tracking technology of Paleogene local provenance intermittent and multi-stage supply lithologic trap. The prestack random inversion technology constrained by structural model is used to track the deep / ultra deep lithologic traps, and the fine characterization of the plane characteristics of sand body is realized. The plane characteristics of the inversion results are consistent with the sedimentary model. The research results broaden the exploration direction of deep / ultra deep Paleogene clastic rocks in Bohai oilfield. It is proposed that the granite source supply area of K-rich feldspar and the medium coarse sandstone transformed by Lake wave in the E_2S_2 can be used as the practical direction of deep / ultra deep clastic rock exploration.

Sedimentary microfacies and sandbody distribution in shallow continental shelf: A case study of lower member of Silurian Kepingtage Formation in Tarim Basin

Fan Mingfei[1], Qu Jingjing[2*], Tian Miao[1], Liu Dawei[1]
1. Northwest Research Center of Exploration and Production, Sinopec Petroleum Exploration and Production Research Institute, Beijing, CHINA
2. School of physics, Peking University, Beijing, CHINA
E-mail: 2106588657@pku.edu.cn

Keywords: Shallow continental shelf, Shelf sand ridge, Sandbody distribution, Sedimentary Microfacies

The sandstones deposited on the shallow continental shelf are generally regarded as good reservoirs. In this paper, the sediments inside the lower member of Silurian Kepingtage Formation in Tarim Basin are taken as the study case to elaborate the corresponding microfacies and characterize the spatial distribution of sandstone in detail. We divide the depositions of the continental shelf sediments into 3 microfacies according to cores, well logs and seismic data here. These microfacies are shelf sand ridge, interridge sandstone and self-mud. The distribution of the sandbody of the former two microfacies is affected by sea level, hydrodynamics and paleogeomorphy. Specifically, the storm wave-drive sediments inside the shelf sand ridge are ranked in reverse graded order. And the major components are the medium sandstone and fine sandstone with a few inserted boulder clays. As the name suggests, interridge sandstones are mainly located between ridges due to the low hydrodynamic energy. The corresponding components inside are fine sandstone, siltstone and mud. Moreover, normal graded bedding, reverse graded bedding and massive texture are exhibited here. According to the vertical profile, the interval of interest can be identified as 3 sand-groups. As the seismic interpretation result shows, a large scaled shelf sand ridge with a thickness up to 30m, a height of 13km and a width of 5km is deposited in the NE direction in the sand-group. Its planar projection is an elliptic whose length-width ratio is 1/3 to 1/2. The shelf sand ridges are distributed as strips in the direction oblique with the shorelines. And the thickness is larger while the acient surface elevation is higher. The interridge sandstones here are small scaled fine-grained sediments with banded and irregular shapes. Notice that, the direction of the banded interridge sandstones is different from the sand ridges. The sandstones of shelf sand ridges are picked up as better reservoirs due to their relatively higher porosity and permeability. They are moving toward the continent due to the relative sea level rising.

The coupling relationship between the mantle-derived CO2 and hypogenic karstification in Baiyun sag of the Pearl River Mouth Basin, South China

Xuemei Wei[1*]
1. Key Laboratory of Tectonics and Petroleum Resources Ministry of education, China University of GeosciencesWuhan, Wuhan, Hubei, CHINA
E-mail: weixuemei2015@163.com

Keywords: Baiyun sag, mantle-derived CO2, stable oxygen and isotope, hypogenic karstification

Baiyun sag of Pearl river Mouth Basin is located in northern continental slope of south China Sea, it is characterized by high thermal background, three sets of source rocks and multi-stage magmatic activity, and a large amount of inorganic CO2 was found in the area and its surrounding areasThis article explores the filling of CO2 and transformation effect of fluid by the methods of observation of petrology, fluid inclusions and stable oxygen and isotope. Fluid inclusion test results show that there were three periods of mantle-derived CO2 charging in baiyun Depressionrespectively corresponding to baiyun movement (20.2 ~ 10.2 Ma), early Dongsha movement (9.3 ~ 6.1 Ma) and late Dongsha Movement (4.6 ~ 0Ma). According to the petrological observation, there are a lot of feldspar and calcite dissolution phenomena in sandstone reservoirs in this area, and the feldspar intergranular dissolution pores and intra-granular dissolution pores are developed. Around Baiyun sag, two carbonate cements annules and two abundant authigenic kaolinite precipitation zones are developed (which coincide with the area of gas Wells with or high CO2 content). The carbonate cements are mainly iron-bearing calcite cements of syngenetic and peneogenetic stages and chemical precipitates of hydrothermal fluids in late thermal burial stage. In addition, the hydrothermal authigenic minerals such as dawsonite, authigenic quartz, siderite, Fe-dolomite and albitite are observed in sandstone reservoirs. The values of δ13C and δ18O in the carbonate cements precipitated in the thermal burial stage are respectively range from -20.9‰ to -1.8‰(with an average of -5.26‰), and from -13.7‰ to -5.4‰(with an average of -10.66‰). The low carbon isotope indicates that there may be organic acid infiltration, and the low oxygen isotope demonstates that perhaps the fluid source is deep hydrothermal. Combined with the geological background of the area, it is speculated that the mantle-derived high-temperature CO2 migrated upward through deep and large faults or volcanic associated faults, and then migrated horizontally in the efficient transport layer, a series of hypogenic karstification which is beneficial to the development of deep secondary pore zone has taken place in sandstone reservoir, including solutional processes, and the precipitation of authentic kaolinite, quartz, dawsonite, calcite, dolomite, ankerite, siderite, albite and so on.

The Guiding Significance of the Sedimentary Facies Study to the Exploration in the Small-Scale Continental Rift Basin, Offshore Papua New Guinea

ying wang[1*], shun de miao[1], jian guang chen[1], dong Li[1]
1. Exploration research center, CNOOC INTERNATIONAL Ltd. Global Technology Supporting Center, Beijing, CHINA
E-mail: wangying8@cnooc.com.cn

Keywords: Deep-water, Gulf of Papua, frontier exploration, lacustrine rift basin sedimentary facies, quantitative prediction

The study area is located in the deep-water, offshore Papua New Guinea, which belongs to small-scale continental rift basins. The tectonic evolving history of the basin is complicated since it went through two rift and collision cycles. After the separation from the east margin of the Australian continent, the massif drifted northward and finalized in the forebulge zone of the Aure Foreland. The study area belongs to a frontier basin without a single well drilled in the surrounding. Thus, the focus of the exploration potential evaluation is on the study of the syn-rift source rock.

Based on the key questions of the source rock, from directionally to qualitatively and to quantitatively, this article used methods of analogy, characterization, and quantitative prediction firstly proposed techniques of high-quality source rock quantitative prediction, which quantitatively predicted the distribution area and deposition thickness of high-quality source rocks.

Starting from the source rock existence, the technique used oil seepages, structural reconstruction, and seismic facies analogy to determine the main analogous source rock strata intervals and evaluate the potentials of the basin. For the source rock characterization, this article used a four-step method: 1) analyzing the fault activity rate; 2) predicting sedimentary modes; 3) analyzing the sequence stratigraphy; and 4) seismic facies classification(figure 1). It determined the deposition background, distribution area and main stratigraphic intervals of high-quality source rocks(figure 2), and innovatively used relative acoustic impedance inversion NTG truncation method to quantitatively predict the shale thickness.

The results show that the Jurassic source rock in the study area is oil-prone. The high-quality semi-deep lacustrine facies source rocks have several hundred meterd thickness; and the shallow-shore lacustrine facies source rocks have an area of up to 100 km2figure 3. According to the resource calculation of different types of source rocks, the scale of hydrocarbon generation is determined.

Characteristics of favorable reservoir and its distribution prediction in the middle-deep layers in Baiyun sag, Pearl River Mouth Basin

XIE XIAOJUN[1*]
1. exploration and development research institution, CNOOC Research Institute Ltd., beijng, BEJING, CHINA
E-mail: xiexj@cnooc.com.cn

Keywords: Sweet point, diagenesis,controlling factors, distribution prediction,middle-deep strata,Baiyun sag

Middle-deep layers in Baiyun sag has great potential for unexplored hydrocarbon resources. Reservoirs in the middle-deep layers are generally low porosity and permeability. In order to describe the favorable reservoir characteristics, find the reservoir macro-controlling factors, and to predict the special distribution of the favorable reservoirs, Baiyun 5A structure in Baiyun sag was studied. Take middle-deep layers of Baiyun 5A structures for example, the microcosmic aspects such as reservoir lithology, reservoir properties, and constructive diagenesis and the macro aspects such as facies identification, prediction of progradation complex with thick sand, seismic inversion for sand and porosity, and fracture distribution recognition of reservoir are studied. Reservoir “sweet points” characteristics in the middle-deep layers, controlling factors that can be identified macroscopically, and special distribution of the “sweet points” are studied. It suggests that middle-coarse sandstones with big thickness in the distributary channels and underwater distributary channels in the Baiyun 5A structure developed secondary solution caves and microfractures, and these sandstones can be used as reservoir “sweet points”. Sand body thickness that represents its microfacies and fractures that represent the constructive diagenesis are controlling factors those can be identified macroscopically for reservoir “sweet points” prediction. Progradation complex with thick sand can be identified through the shape of “bump”, the superposed inside structure, and the low part of the microrelief in the seismic data. Composed the results of thick sand body identification, sand and porosity prediction, and fracture distribution recognition, the eastern part of the C block in the Baiyun 5A structure is recognized as the reservoir “sweet points”.

Facies Pattern of Large Contiguous Composite Sand and Great Exploration Significance in the Depression-Lacustrine Basina case from Lower Minghuazhen Formation of Laizhouwan Depression of Bohai Bay Basin

Xijia Sun[1*], Haifeng Yang[1], Wenlong Shi[1], Hang Wang[1], Gongli Liu[1]
1. Bohai oil research institute, CNOOC Ltd Tian Jin Branch, Tianjin, CHINA
E-mail: sunxj23@cnooc.com.cn

Keywords: Large Contiguous Composite Sand,Facies Pattern,Lower Minghuazhen Formation,Laizhouwan Depression

Laizhouwan Depression is located in the south of Bohai Bay Basin. The Lower Minghuazhen Formation is the shrinkage period of the depression-lacustrine basin, with weak tectonic movement, slow subsidence and obvious peneplanation. As an important target formation, the Lower Minghuazhen Formation is faced with unfavorable conditions such as no hydrocarbon sink structure, no faults, and thin drilled sand thickness, so no commercial oil and gas has been discovered after 30 years of exploration. With the continuous success of lithologic exploration in the surrounding area, the lithologic exploration based on the large contiguous composite sand has become a hotspot. The large contiguous composite sand has the complex sedimentary features, such as wide distribution area, large lateral variation, relatively thin thickness and sophisticated superposition relationship. The exploration process is restricted by the unclear sedimentary model and favorable reservoir development law.

Under the guidance of continental sequence stratigraphy and sedimentology, combined with 3d seismic data, core data, logging data, paleontological data, clay minerals data and other geological data, this paper comprehensively studies the large contiguous composite sand, and discusses the facies types, evolution law, controlling factors and hydrocarbon accumulation significance of the large contiguous composite sand. The results show that: (1) There are three types of large composite sand in the study area. The sheet-sand shallow water delta, which is characterized by the sheet sand with contiguous distribution, develop in the early stage. The formation of the sheet sand is related with the lake wave reconstruction. In the middle stage, the distributary-channel shallow water delta develops. It mainly consists of network connected channel sand and contiguous sheet sand. The fluvial facies develop in the late period, and the sand is isolated in thick layers. (2) Tectonic subsidence rate and paleoclimate variation are the main driving factors of sedimentary evolution. The structural gradient of the Lower Minghuazhen Formation is very slow, and the terrain slope is less than 0.1°. The paleontology data and the clay minerals data indicate the early stage is warm and humid climate. So the lake is large, and the wave transformation is relatively strong. It is conducive to the development of the sheet-sand shallow water delta. Although the accommodation space increases with the gradual increase of regional basin subsidence rate, the paleoclimate become dry and cold, which leads to the shrinkage of the lake, the decrease of source supply, and the gradual enhancement of fluviation. The shallow-water delta evolves from sheet sand type to distributary channel type, and finally fluvial facies developed. (3) Under the guidance of the facies model of large contiguous composite sand, several lithologic traps composed of large contiguous sand body are discovered in Bohai Oilfield, which realizes the lithologic exploration transformation from isolated channel to large contiguous sand, and effectively guides the lithologic exploration of the Lower Minghuazhen Formation of Laizhouwan Depression. KL10-2 oilfield, the largest lithologic oil field in the Lower Minghuazhen Formation of Bohai oilfield, has been successfully discovered.

Diagenetic mechanism of high-quality sedimentary microfacies by carbonate and kaolinite cements

Xin Li[1*]
1. CNOOC, CNOOC, Beiing, Beijing, CHINA
E-mail: lixin71@cnooc.com.cn

Keywords: offshore, Deep-buried, non-homogeneous, carbonate, kaolinite

Flow direction, dynamic and chemical properties change frequently in fluvial and tidal sedimentary environment, the reservoir mineral foundation, diagenetic process is complex and changeable, and the physical property is strong heterogeneity, which has always been the difficulty restricting its exploration and development. In this paper, Pinghu Formation in Xihu Depression of East Sea, China was taken as an example. Material basis, materiality pattern and main controlling factors were investigated in two high-energy sedimentary microphases, namely tidal channel and submerged divergent river channel. Methods were included core observation, pore penetration test, light microscopy, isotope and inclusions. The results showed that: (i) the upper/middle part of tidal channel possessed good physical properties with an average porosity of 18% and permeability of 120mD, while the bottom of tidal channel was dense with an average porosity of 4% and permeability of 0.05mD. The main reason for the inhomogeneity is that the bottom is dense due to carbonate cementation; (ii) the upper part of submerged diversion channel had good physical properties with an average porosity of 5% and permeability of 70mD, while the bottom of submerged diversion channel was dense with an average porosity of 1% and permeability of 0.05mD. The main reason for the inhomogeneity is that the bottom is dense due to kaolinite filling. The above analysis of the non-homogeneity of the main sedimentary microphase of the Pinghu Formation in the Xihu Depression is of great theoretical guidance and practical production value for deeper oil and gas exploration and development. It has important theoretical guiding significance to deepen the law and formation mechanism of reservoir heterogeneity under fluvial and tidal background.

Sedimentary characteristics and distribution prediction of the semi-deep and deep lacustrine facies source rocks of Wenchang Formation in the Shunde Sag, Pearl River Mouth Basin

Rui Sun[1*], Qingbo Zeng[1], Mo Ji[1], Haizhang Yang[1], Shuang Song[1], Jianrong Hao[1]
1. Exploration and Development Research Institute, CNOOC Research Institute Ltd., Beijing, CHINA
E-mail: sunrui7@cnooc.com.cn

Keywords: neural network, semi-deep and deep lacustrine facies, sedimentary characteristics, source rock, Wenchang Formation, Shunde Sag

The Shunde Sag in Pearl River Mouth Basin is located in the southwest of the Kaiping Sag, which has made a breakthrough in exploration, so the Shunde Sag is an important exploration breakthrough direction. The distribution and scale of the semi-deep and deep lacustrine facies source rocks in Eocene Wenchang Formation are the main problems in oil and gas exploration in the Shunde Sag. The sedimentary characteristics of Wenchang Formation in the Shunde Sag are analyzed through structural evolution analogy, seismic response characteristic analogy and statistics of fault activity rate. The study shows that the structural setting of the lower Wenchang Formation in the Shunde Sag is similar to the Kaiping Sag, and the faults controlling subsag sedimentation control the development range of the semi-deep and deep lacustrine facies. It is similar to the semi-deep and deep lacustrine facies source rocks in Wenchang Formation of Zhu I depression, and the seismic reflection of the semi-deep and deep lacustrine facies in Wenchang Formation of the Shunde Sag is mainly characterized by low frequency and continuity. The statistical results show that during the sedimentary period of the lower Wenchang Formation, the activity rates of faults controlling subsag sedimentation are greater than 100 m/Ma, which has the development background of the semi-deep and deep lacustrine facies. Comprehensive analysis shows that Wenchang Formation in the Shunde Sag is a river-lake sedimentary environment, mainly developing fan delta, braided river delta, shore-shallow lake and semi-deep and deep lacustrine facies. Constrained by sedimentary characteristics, the spatial distribution of the semi-deep and deep lacustrine facies source rocks in Wenchang Formation of the Shunde Sag was predicted by facies clustering analysis method based on seismic multi-attribute self-organizing map neural network.The study shows that the semi-deep and deep lacustrine facies began to develop from the sedimentary period of Wen 6 member, then Wen 5 member continued to expand, and Wen 4 member reached the largest scale, and the semi-deep and deep lacustrine facies shrank during the sedimentary period of the upper Wenchang Formation. The area of the semi-deep and deep lacustrine facies in Wen 4 member of the northern subsag of the Shunde Sag is 153 km^2 and the volume is 86.5 km^3. The research results can lay the foundation for resource evaluation and hydrocarbon accumulation research in the Shunde Sag, and provide the basis for the exploration target optimization.

Impact of depositional process and salt on reservoir property of deep-water sandstonesa case study from the Paleocene-Eocene Wilcox Formation in the Perdido belt, Burgos Basin

Chunyu Zhang[1*]
1. CNOOC Research Institute Ltd., CNOOC , Beijing, CHINA
E-mail: zcy21_jobs@163.com

Keywords: submarine system, gravity flow, salt, reservoir property, Perdido Belt

Deep-water sandstones overlain by allochthonous salt sheet in uneven thickness were deposited by various sediment gravity flows in the Perdido belt of the Burgos Basin. Cores and well logs, from 14 wells and high resolution 3D seismic data are used to reconstruct the sedimentary environments and depositional processes of the Wilcox Formation sandstones. A suits of petrographic and geochemical methods, including thins sections, X-ray diffraction(XRF), scanning electron microscope(SEM) and physical property test are conducted to study the reservoir property. The results reveal that depositional process and salt are the primary controls on reservoir property. Six bed types(high-density turbidite, low-density turbidite, hybrid event bed, debrite, slump deposit and bottom-current reworked bed) and five microfacies(channel, proximal lobe, distal lobe, slope and abyssal plain) are identified. The permeability in distal lobe(avg. 118.5mD) is almost twice as high as that in distal lobe(48.5mD). However, greater variations in reservoir property are observed for different bed types of different depositional processes. High-density turbidite, bottom-current reworked bed and the lower hybrid event bed exhibit approximately two orders of magnitude higher in permeability than that of the upper hybrid event bed, low-density turbidite and debrite. Petrograhpic analysis shows that the porosity decreases along with the increase of depth. However, it increases with greater depth when the sandstone is overlain by allochthonous salt sheet. Salt sheet is favorable for both the primary and secondary porosity preservation. Comparison between samples with and without overlying salt sheet exhibit similar reservoir property, porosity type and clay mineral in quite different depth, suggesting that thicker salt sheet with high thermal conductivity are beneficial for supressing the diagenesis.

The Cenozoic depositional system evolution and formative mechanism of Southern South China Sea basins

Wu Tang[1*]
1. Exploration and development department, CNOOC Research Institute Ltd., Beijing, CHINA
E-mail: tangwu3@cnooc.com.cn

Keywords: Southern South China Sea, Depositional systems,Difference,Controlling factors,Pro- South China Sea,South China Sea

In order to reveal the Cenozoic depositional system evolution and formative mechanism of basins, Southern South China Sea (SSCS), based on a joint geological, geophysical and geochemical dataset, this paper restored the Cenozoic paleogeography, illustrated depositional system evolution and discussed the controlling factors of basins of SSCS. The results show that there are three types of sedimentary basins in SSCS (including foreland, strike slip and drifting basins), with different sedimentary filling structures. The foreland basins form a depositional pattern of “early deepwater late shallow-water”, which suggests that these basins were dominated by deep-water depositional systems before Early Oligocene, with submarine fans developed. Later, the foreland basins were gradually dominated by shallow water depositional systems, with deltas and shallow marine facies developed, and the formation age of deltas gradually changed younger from west to east. The strike slip basins show the depositional architecture of "early lake and late sea”, which means the basins were dominated by the lacustrine deposits during Eocene, and they entered into marine depositional environment since Oligocene, with delta developed in the west part of the basin. The depositional evolution of drifting basins illustrate the characteristics of “early clastic and late carbonate”, which means the drifting basins were dominated by Eocene-Oligocene shallow marine clastic depositional systems, while carbonate platform started to develop since Early Oligocene, with early in the east and late in the west.

The above-mentioned depositional architecture differences in SSCS are controlled by a scissor-style closure of pro-SCS and progressive-style expansion of SCS. Specifically, the early deep-water sedimentary environment of basins in SSCS was controlled by the distribution of pro-SCS in Eocene. Then, as the scissor-style closure of pro-SCS from west to east during Oligocene to Early Miocene, the northwest of Borneo continued to rise, providing a large amount of clastic materials to the basins, leading to the development of large-scale deltas which younger from west to east. While, the distribution of early lacustrine sedimentation of strike slip basins were affected by paleo uplift and then the basins were transgressed from the northeast and gradually entered into marine sedimentary environment due to the expansion of SCS. Additionally, the expansion of SCS also controlled the sedimentary filling evolution of the drifting basins, which resulted in the basins breaking away from the South China continent and drifting southward. In turn, the drifting basin lack the supply of terrigenous clastic sediments and the development of large-scale deltas, forming a clear water environment which is conducive to the development of carbonate platform, the age of which younger from east to west.

Utilizing Cryptic Ichnotaxa in Core to Interpret Sedimentary Environments: Upper Montney Member, Northeastern British Columbia, Canada

Chenyang Feng[1*], Murray Gingras[2]
1. Department of Exploration, CNOOC Research Institute, Beijing, CHINA
2. Department of Earth and Atmospheric Sciences, University of Alberta, Edmonton, Alberta, CANADA
E-mail: 258078816@qq.com

Keywords: Trace-fossil types, Ichnotaxonomy, Ichnofacies, Lithofacies, Lower shoreface, Upper Montney Member

This study focuses on a new practice in using trace fossils that are not readily classified to the ichnogenus or ichnospecies levels to interpret sedimentary environments. Two lithofacies are identified from two cores representing the Upper Montney Member from northeastern British Columbia, Canada. Lithofacies 1 (L-1) is composed of highly bioturbated, bituminous, fine- to coarse-grained siltstone. Lithofacies 2 (L-2) consists of interlaminated dolomitic, medium- to coarse-grained siltstone and bituminous, fine-grained siltstone. Sediments in the studied cores are interpreted to be deposited within the fair-weather dominated lower shoreface settings. Owing in part to a lack of grain-size variability, trace fossils observed in both cores are poorly defined, making it difficult to determine the specific ichnospecies or ichnogenera. An alternative approach to the ichnotaxonomy is used, which is classifying trace fossils into types primarily based on their discernible orientation and shape. Herein, four types of trace fossils (Type a, b, c and d) are recognized. Type a and b are vertical to inclined, club to funnel shaped, unlined burrows, with infill typically structureless. They are mostly concentrated in L-1, commonly showing singular occurrence within tempestites, probably attributable to distal *Skolithos* to proximal *Cruziana* ichnofacies. Type c are circular to elliptical unlined burrows. The infill is occasionally vaguely meniscal. Largely, type c are densely distributed in L-1, especially within thick fair-weather deposits, possibly attributable to *Cruziana* ichnofacies. Type d appear as diminutive, circular to irregular dots. Infill always contrasts with host sediments. Type d are sporadically distributed in L-1 and L-2, interpreted to be *Planolites*-like trace fossils. On basis of these four types, L-1 exhibits the highest size-diversity index (SDI) (23-52) and bioturbation index (BI) (4-6). Both SDI and BI decrease gradually from L-1 to L-2, with L-2 largely smaller than 15 and 3. Overall, the sedimentological interpretation is collaborated by the trace fossil assemblage. And there was potentially an oxycline separating the proximal lower shoreface from the distal lower shoreface Thus, each trace-fossil type can represent a group of biogenic sedimentary structures that share ethological affinities, potentially fitted into the Seilacherian ichnofacies concepts. And ichnological data can be gathered from the identified types to interpret the physico-chemical stresses in sedimentary environments.

Differential characteristics of Paleogene sedimentary and hydrocarbon source in deep water area of northern South China Sea

Ying Chen[1*]
1. Research Institute of Exploration and Development, CNOOC Research Institute Ltd., Beijing, Beijing , CHINA
E-mail: chenying2@cnooc.com.cn

Keywords: marine source rocks, transitional facies source rocks,delta-bay systems; deposit source, the deepwater areas in the north continental margin, the South China Sea,basin structure

The differences of Paleogene tectonic geological settings in deep water area of the pearl River Mouth basin and Qiongdongnan Basin in the northern South China Sea lead to the formation of different sedimentary systems and source systems, and corresponding different oil and gas exploration directions.

The two adjacent basins are influenced by the evolution of the south China sea with the Paleogene tectonic evolution of east early-west night. In early Oligocene of major hydrocarbon source perioddeep water area of Pearl river mouth basin was the fault depression structure, with deep sags respectively have their uniform deposits and settlement centers. The basin accepted the large provenance injection of the ancient Pearl River system out of the basin and adjacent uplift belts in the basin, and developed large delta systems under the environment of the gulf. The deep water area of Qiongdongnan Basin is a faulted depression structure contemporarily, and many rows of small depressions with certain separation are developed in the steps and central lowlands on both sides. Under the influence of short-range provenance, such as the water systems in the south of Hainan Island and the River systems in Vietnam, the barrier coast system and a series of small fan deltas are developed in the enclosed and semi-enclosed bay environment.

The differences of delta systems between the east and west deep water areas have an important influence on the distribution pattern and types of source rocks in the bay. In the east, the large delta in the pearl River Estuary brought a strong terrigenous input, affected the whole bay greatly influenced by terrigenous organic matter, with generally higher abundance of organic matter in the source rocks and good types of source rocks. In the western deep water area, the deltas are small in scale and the influence range of terrigenous organic matter is limited, but the marine mudstone is wide in scope and thick, and the water body sealing is strong and the preservation condition of organic matter is good.

Coastal tempestite deposit of the western Zhu I Depression during the early-middle Miocene, Pearl River Mouth Basin

Guanmin WANG[1*], Yukun CHAI[2], Liang GAO[3], Rui ZHU[1]

E-mail: wangguanmin@upc.edu.cn

Keywords: Pearl River Mouth Basin, Tempestite deposit, Middle Miocene, the Ancient Pearl River DeltaEstuarine bar

The Pearl River Mouth Basin is a large petroliferous basin formed in the Paleogene, which is controlled by the NE trending synsedimentary fault zone. The structural unit of the basin has the characteristics of "three uplifts and two depressions". In the west of Zhu I Depression in the Pearl River Mouth Basin, there are secondary structural units such as Xijiang Sag, Enping Sag and Yangjiang Sag.

The Pearl River Mouth Basin experienced a Paleogene fault period and a Neogene depression period. In the sedimentary period of Pearl River Formation and Hanjiang Formation in the early and middle Miocene of Neogene, the ancient Pearl River Delta has been formed and progradated into Zhu I Depression on a large scale from northwest to Southeast. At this stage, the west part of Zhu I Depression is mainly located in the front of the ancient Pearl River Delta, and many underwater distributary channels and estuarine bar sand bodies are developed.

The root mean square amplitude attribute of the third-order sequence extraction of the Pearl River Formation and the Hanjiang Formation in the western part of the Zhu I Depression shows that there are two directions of sand body arrangement: One is the sand body distributed in a lobate and band shape from north to south, which represents the distributary channel and estuary bar deposits of the ancient Pearl River Delta; The second is the annular sand body, which surrounds the front of the lobate body of the ancient Pearl River Delta and is nearly vertical or oblique to the distributary channel at a large angle, oilfield scientists and technicians call it coastal sand ridge or distal bar, which belongs to the sand body caused by wave or ocean current transformation.

Through the detailed observation and analysis of cores, it is shown that these sand bodies distributed around the delta front do not belong to the real coastal sand ridge or distal bar. The particle size of sand body is generally 2-3φ, and usually contains 0-1φ coarse sand, with a single layer thickness can reach more than 10m, but these characteristics are not consistent with the medium and thin silt sand sediments reconstructed by the ocean current. Although there are some sedimentary features transformed by waves, such as wave cross bedding and broken biological fragments of different sizes, can be widely seen in the core, however, a large number of plant debris, desiccation cracks, plant root traces and other sedimentary phenomena above the water surface were not found in the core. On the contrary, there are many sedimentary structures related to tidal action, such as horizontal bedding and tidal bedding in the gray and light gray siltstone and mudstone interacting with the sand body. In addition, part of the sand body particle

size histogram presents double peaks or multi peaks, and the standard deviation is generally between 0.7-2.0. The probability accumulation curve is mainly two-stage, including three-stage or even multi-stage, with the impurity base content of 5-15%, and the impurity base content of some medium and fine sands can reach more than 25%, which shows that the sand body deposition is not a simple wave action. Bottom scouring structures are also common in the sand layer. In some core layers, the bioclastic mixed with sandy particles is not arranged in parallel, some coarse bioclastic are even vertical, and mixing structures can be seen in the silt. These phenomena point more to the intermittent tempestite deposition.

It can be compared that the wave action in the modern Pearl River Estuary is not prominent, and the Pearl River Delta is mainly tidal-dominated delta. However, the storm waves produced by typhoons that occur frequently every summer are the hydrodynamic conditions that cannot be ignored when the coastal debris materials are transformed and transported.

These storm induced ring belt sand bodies can show positive cycle and reverse cycle on GR logging curve, which are formed by the migration and progradation of sand bodies to the sea, and their positions correspond to the seaward side and the land side of the sand body respectively.

3. School of Built and Natural Environment, University of Derby, Derby, Derbyshire, UNITED KINGDOM

E-mail: Tanja.Unger@ruhr-uni-bochum.de

Keywords: Middle Devonian, Reef system, Sediment-stressed environment

In Earth's history, reef development reached an acme during the Middle and Late Devonian period. We present evidence from lower Givetian tabular biostromes in Western Germany, documenting a short-lived reefal interval in an otherwise clastic setting. Reefal biota and their host matrix are exposed in three dimensions along the walls and ceiling of the Klutert Cave (6 km accessible passages). Recently cleaned cave walls provide access to 26,000 m^2 of rock surface allowing detailed studies of the biostromes architecture. Stromatoporoids, rugose and tabulate corals are the main reef builders. Associated biota include crinoids, brachiopods, gastropods and cephalopods. Acid digestion data and other lines of evidence indicate that the reef developed in a sediment-stressed environment and collapsed when sediment influx crossed threshold limits.

Extracting data from literatures to construct knowledge database using DeepDive: A case study for stromatolites in the geological past

Yuangeng Huang[1], Xiaobo Zhang[2], Zhenhua Li[2*], Zhong-Qiang Chen[1]
1. State Key Laboratory of Biogeology and Environmental Geology, China University of Geosciences (Wuhan), Wuhan, Hubei, CHINA
2. School of Computer, China University of Geosciences (Wuhan), Wuhan, Hubei, CHINA
E-mail: yunzi90h@qq.com

Keywords: Information Extraction, Relation Extraction, DeepDive, Knowledge Base Construction, Stromatolite, Precambrian

In the field of Earth Science, a large amount of information is buried in various literature which are growing rapidly, so it becomes more and more difficult to manually pick up data swamped in literatures. To explore and summarize a feasible information extraction workflow and therefore further help geologists understand and master the series of text mining techniques, this work takes the construction of stromatolite knowledge from scientific literature as an example to demonstrate the whole extraction process step by step. Firstly, we collecting the stromatolite-related PDF documents and then converting them into text. Secondly, using a glossary of vocabulary and tags labeled by NLP (Natural Language Processing) software, we search for all possible candidate pairs from each sentence. Thirdly, each pair and its features are represented as a factor graph model, with a series of heuristic procedures used to score the weights of each pair's features training the probability of each candidate. This approach achieved 92%/464, 87%/778, 92%/846 and 93%/405 accuracy/distinct pairs on strata, facies, location and age with probability greater than 0.9 respectively from 3,750 scientific abstracts, and 90%/1734, 86%/2869, 90%/2055 and 91%/857 from 11,932 papers. At last, we got 10,072 unique data items after merging them. The newly obtained stromatolite knowledge database deciphers that stromatolites reached a pronounced peak in occurrence during Proterozoic (2500-541 Ma), followed by a distinct fall in earliest Phanerozoic and fluctuations during the Phanerozoic (541–0 Ma). Globally, seven stromatolite hotspots: western United States, eastern United States, western Europe, India, South Africa, northern China, and southern China are identified from the global dataset. Terrestrial stromatolites remained a low proportion (20%) in comparison with marine stromatolites from the Precambrian to Jurassic, and increased significantly in proportion from the Cretaceous to the present, up to 30-70%.

Anisian (Middle Triassic) stromatolites from Southwest China: biogeological features and implications for variations of filament size and diversity of Triassic cyanobacteria

Yuangeng Huang[1*], Zhong-Qiang Chen[1], Siqi Wu[1], Xueqian Feng[1]

1. State Key Laboratory of Biogeology and Environmental Geology, China University of Geosciences (Wuhan), Wuhan, Hubei, CHINA

E-mail: yg-huang@foxmail.com

Keywords: Bevocastria, filaments diameter, dissolved oxygen, atmospheric CO2

This study documents new stromatolite deposits from the Anisian succession of the Guanling Formation in the Boyun section of eastern Yunnan Province, southwestern China. The Boyun stromatolites are characterized by undulating laminations, which yield a variety of biostructures and abiotic grains, such as cyanobacteria Bevocastria and Renalcis, microclots, fecal pellets, coccoid-like spheroids, and authigenic quartz. Filamentous cyanobacteria Bevocastria are likely major builder constructing the Boyun stromatolite build-ups. Stromatolites in the Boyun section likely grew in an open, oxic marine environment, differing from the Early Triassic stromatolites that were mostly formed in relatively oxygen-poor conditions of shallow marine settings, strengthening the view that stromatolites are not necessarily indicative of harsh environments. In addition, the global dataset of cyanobacteria filament sizes through the Triassic deciphers that a pronounced increase in the diameter of filamentous cyanobacteria through the Early-Middle Triassic, followed by a decline during the Late Triassic. The developments of marine anoxia in the Early Triassic and Rhaetian coincided with the reduction in cyanobacteria filament diameter, suggesting a causal link between the two. Global data also show that the diversity of cyanobacteria broadly tracks the modeled estimates of O2 during the Triassic, but does not show a significant correlation relationship with any modeled estimates of CO2, indicating that their relationship might be more complex when CO2 levels are below 10 times as present atmospheric level.

A Study on the development characteristics of Early Permian (Cisuralian) reefs of the southwestern Tarim Block, northwest China

Yijun Wang[1*]
1. School of Geoscience and Technology, Southwest Petroleum University , Chengdu, Sichuan, CHINA
E-mail: 898789370@qq.com

Keywords: Permian,organic reefs,reef-building organisms,diagenesis,sea level

The Permian strata in Southwest Tarim Basin have organic reef with good exploration prospects. Based on outcrop observations and thin section examination of the Permian keziliqiman formation reef in Sangzhu section in Pishan County, Xinjiang, this paper explores the basic characteristics of the reef. Keziliqiman reef is a point reef that grew along the platform margin, and consists of a base, a core, a front, a back and a cap sub-facies. The lithology of the reef core close to the high-energy front is mainly coral skeleton rock, and that of the reef core close to the low-energy back is mainly sponge barrier rock. The development of the reef was subject to the rise and fall of the sea level; it emerged when the sea level rose in southwest Tarim Basin, and disappeared when the sea level fell rapidly. For the fall of the sea level reduced the Sangzhu area to a hot and dry supratidal zone where algae began to flourish, dolomitization intensified, and then reef building organisms died en masse. Paleontological and geochemical characteristics of the Sangzhu reef indicate that the sea-level fall in southwest Tarim Basin was probably related to the early Permian glaciation. When there were no more building organisms, the Keziliqiman reef began to be transformed by diagenesis. Overall, the impact of diagenetic transformation on it was rather small. Furthermore, its diagenetic process had more to do with marine fluids in its sedimentary period than with non-marine fluids, for non-marine fluids was powerful enough to affect biodetritus but powerless to affect argillaceous matrix.

Evolution of Cambrian carbonate platform in Tarim Basin: Analysis based on seismic sedimentology

WEI LIU[1*], Hongliu Zeng[2], Zhaohui Xu[1], Ying Bai[1]
1. Department of Resource Planning, PetroChina Research Institute of Petroleum Exploration & Development, BEIJING, CHINA
2. Bureau of Economic Geology, The University of Texas at Austin, Austin, Texas, UNITED STATES
E-mail: liuwei086@petrochina.com.cn

Keywords: carbonate platform evolution, sedimentary facies, Cambrian, seismic sedimentology

Three-dimensional (3-D) seismic data offers opportunity to exploit the growth pattern, paleoecology and reservoir heterogeneities of ancient carbonate platform systems. However, it is still very difficult to obtain Cambrian carbonate platform evolution and sedimentary facies information in Tarim Basin, because the carbonate rocks are deeply buried and seismic data resolution is low. In this study we try to use an enhanced interpretation workflow to improve facies interpretation in ultradeep (over 7000 m), high-velocity (6000-7000 m/s) carbonate rocks using low-frequency (up to 20 Hz) seismic data.

The study area named Xiaotangnan locates in middle of the east Cambrian platform margin and seismic surveys is about 800 square kilometers. The stacked, migrated seismic data is characterized by a frequency range of 10~60 Hz with a dominant frequency of 20Hz. Phase rotation, frequency decomposition, stratal slicing and RGB (red-green-blue) color blending are used to interpret platform architecture and facies.

The growth of Cambrian platform can be divided into two stages, ramp and rimmed platform. Erosion at the end of Sinian resulted in a gentle slope to the northeast in study area and above the unconformity a carbonate ramp developed in early Cambrian. Contour map of time-thickness (Txsd-Tg8) shows that there is no sudden change in deposit thickness in this period which also can be observed in seismic profiles. During this time, carbonate shoals are widely distributed and most of them are in irregular ellipse shape.

The transition from ramp to rimmed platform began at the end of Xiaoerbulake Formation. Slight rimmed architecture can be observed in seismic profile in this period. At the end of early Cambrian (Wusonggeer Formation), sharp shelf break is distinct in seismic profile and isopach map of Tg7-Txsd where a basin deepens and margin-slope become higher and steeper. Lagoon locates behind the platform margin where lobate tidal deltas were common. Platform interior is characterized by carbonate shoals. The middle Cambrian was the heyday of platform development, as a strongly prograding accretionary platform the edge migrated 3 km to the sea. Rimmed platform and arid climate lead to the deposition of evaporite in carbonate platform.

Seismic sedimentology provides an effective means for deep buried carbonate platform interpretation. Although drilling data is absent in this area, outcrops and modern sedimentary correlation analysis provide support for geological interpretation.

The ossicles and fragments of Ordovician crinoid and its palaeoecology from Tarim Basin, NW China

Hongxia Jiang[1*], Yanjia Yang[1], Yasheng Wu[2]
1. Hebei GEO University, Institute of Paleontology, Shijiazhuang, Hebei, CHINA
2. Chinese Academy of Sciences, Institute of Geology and Geophysics, Beijing, CHINA
E-mail: jianghx@hgu.edu.cn

Keywords: Tarim Basin, Ordovician, crinoid ossicle, paleoecology

Crinoid fragments and ossicles are very common in the carbonate rocks of the Ordovician in the Tarim Basin, in Xinjiang, northwestern China. Different from the previous studies of intact crinoid fossils, this study provides a comprehensive analysis of the types and contents of the crinoids stem fossils including ossicles and fragments, and the taphonomy of the symbiotic fossils from Ordovician cores of 6 wells, as well as the sedimentary environment is performed so as to understand the paleoecology of the crinoids. In the core samples there are 7 ossicles identified: cyclocyclic, pentagonopentalic, pentagonocyclic, ellipocyclic, pentagonoelliptic, corner pentagonopentalic, variabal pentagonalic. 4 ossicle assemblages are classified: Pentameri, Elliptici, Cyclici and Varii. According to the statistics of the shapes, size and percentage of the ossicles, combined with the taphonomic characteristics of the symbiotic fossil and analysis of the sedimentary environments, it is found that crinoids were absent from the community dominated by cyanobacteria and Tetradiid corals of the restricted lagoon environment. Very few slim crinoid ossicles occurred in the biota of gastropods and ostracods of the fine-grained bank facies covering the lagoon facies. Abundant crinoids and various symbiotic bryozoans, Solenopora, dasycladaceans and other organisms were present in the biota of the open platform facies. Both crinoids and bryozoans are filter feeders, and should have a symbiotic but competition relationship in most cases. However, in the Ordovician seas, their difference in body size determined the two groups belonging to different filter feeding groups, which eased the competition between them. In communities dominated by crinoids and bryozoans, crinoid ossicles are the most abundant, and all the four ossicle assemblages were present. Solenopora grew via photosynthesis and had no competition with crinoids. Their relationship with crinoids is a mutualism. The crinoid ossicles in the Solenopora-crinoid community are relatively simple, belonging to the Cyclici type, being big and dense, and their content is the highest. Crinoids are widely symbiotic with dasycladaceans. Due to the influence of the oncoids formed by filamentous cyanobacteria, the number and size of crinoid ossicles and fragments are fewer than dasycladaceans, but they are relatively richer and more diverse, including four types. Therefore, we suggest that the most suitable environment was the open platform for the crinoids in Ordovician of Tarim Basin, and the main controlling factors were hydrodynamic energy and water cleanliness. The higher the hydrodynamic energy was, the cleaner the water was, more flourishing the crinoid was. Low hydrodynamic energy and turbulent water turbidity were disadvantageous to crinoid.

Types and formation environment of lacustrine carbonate particles in Bohai Sea area

Longlong Guo[1], Qingbin Wang[1*], Liming Dai[1], Chong Feng[1], Wenjing Pan[1]
1. Bohai Petroleum Research Institute, China National Offshore Oil Corporation Limited, Tianjin, CHINA
E-mail: 370224565@qq.com

Keywords: Bohai, Lacustrine carbonate, Carbonate particles, Ooid, Shell

Carbonate particles related reservoir is a good reservoir of the shahejie formation in BoHai sea areas, in order to define the carbonate particles forming mechanism and forming environment, using rock-mineral analysis and paleontology, element geochemistry research method, on the sedimentary characteristics of the such carbonate particles have been studied in detail, according to the form and structure divides the particle type, the mechanism of formation and distribution of the carbonate particles were analyzed. According to the external morphology and internal structure, three particle types were identified: ooid, sheath particles and oocyte particles. The morphology of carbonate particles is influenced by many factors, including biological types, sedimentary environment and hydrodynamic conditions, as well as biochemical and physical effects.
Ooid formation is closely related to the filamentous cyanobacteria and coccoid cyanobacteria, dominant control filamentous cyanobacteria dark layer formation, as the early core particles of ooid, coccoid cyanobacteria were formed in the coastal and shallow water sedimentary environment rich in terrigenous clasts with strong hydrodynamics and developed in the water depth range of 0.5m-7m, which is an important structural type of granular carbonate rocks; sheath particles are formed by filamentous cyanobacteria and developed in shallow water and lacustrine environments with weak hydrodynamic conditions. They are the main structural components of microbialite. Ospherulites are controlled by coccoid cyanobacteria. They develop in shallow water environment with fast deposition rate and in water depth ranging from 4m to 10m. They are the main structural components of granular carbonate rocks. In addition, the parameters related to the shell and core of carbonate particles were statistically analyzed.It is found that there is no obvious correlation between the core of carbonate particles size and the depth of water, as well as the core-shell ratio (the ratio of the core size to the thickness of the shell). However, with the deepening of water depth, the smaller the thickness of carbonate particles shell, the larger the ratio of carbonate particles major axis and minor axis.

Paleogeographic features and reef-bank distribution of the Permian Changxing Formation-Triassic Feixianguan Formation in the Sichuan Basin

Shengyang Yao[1], Chuanlong Mou[2*], Xiuping Wang[2], Qiyu Wang[2]
1. Institute of Sedimentary Geology, Chengdu University of Technology, Chengdu, Sichuan, CHINA
2. Chengdu Center, China Geological Survey, Chengdu, Sichuan, CHINA
E-mail: cdmchuanlong@163.com

Keywords: Petrographic Palaeogeography, Sichuan Basin, Changxing Formation—Feixianguan Formation, Reef-bank

Reef-bank reservoirs have an essential position in global oil and gas exploration, and their oil and gas production accounts for about 50-60% of worldwide oil and gas production from carbonate reservoirs. The Permian Changxing Formation-Triassic Feixianguan Formation is an important formation in the Sichuan Basin for the development of reef-bank, and a large number of high-producing gas fields have been found in this formation. In this paper, through a large number of previous studies and field investigations, we subdivided the Changxing- Feixianguan phase of the Sichuan Basin into six periods according to the principle of "tectonic control of the basin, basin control of the face, and face control of the oil and gas", drew the corresponding petrographic paleogeography maps, highlighted the distribution of reefs and banks, and combined each oil and gas reservoir with reefs and banks. The systemic analysis shows that the petrographic paleogeography has an obvious controlling effect on oil and gas reservoirs, and the tectonic pattern of the Sichuan Basin between uplift and depression provides good conditions for the development of reefs and banks, and the reef and beach spreading patterns have strong regularity. At the same time, due to the high position of the banks, it is easy to be leached by atmospheric fresh water, and dolomitization occurs, which improves the reservoir capacity.

Evolutionary pattern of metazoan reefs after the Late Devonian extinctions

Le Yao[1*], Markus Aretz[2], Xiangdong Wang[3]
1. State Key Laboratory of Palaeobiology and Stratigraphy, Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences, Nanjing, Jiangsu, CHINA
2. Géosceinces Environnement Touloue, Université de Toulouse, Toulouse, Haute-Garonne, FRANCE
3. School of Earth Sciences and Engineering, Nanjing University, Nanjing, Jiangsu, CHINA
E-mail: lyao@nigpas.ac.cn

Keywords: coral reef, proliferation, mass extinction, glacial-interglacial climate, Mississippian

Metazoan reefs are very important ecosystems in marine environments due to their high biotic diversity and abundance. They are an excellent tool for tracking palaeoecological changes, especially through mass extinction transitions. Although metazoan reefs proliferated during most of the Phanerozoic, metazoan “reef gaps” and “reef-recovery intervals” with microbial resurgence often occurred after extinction events. The largest metazoan-reef ecosystems of the Phanerozoic flourished during the Middle-Late Devonian. They were formed by stromatoporoid sponges and corals. This reef association collapsed and disappeared during the Late Devonian Frasnian-Famennian and end-Devonian Hangenberg mass extinction events, respectively. Afterwards, the Mississippian is commonly believed to be dominated by microbial bioconstructions, such as the Waulsortian mounds. Few small, metazoan reefs of variable compositions were documented during the Middle-Late Mississippian (Visean to Serpukhovian). It is still unclear when metazoan-reef ecosystems recovered and whether a single evolutionary lineage for reef ecosystems appeared after the Late Devonian extinction events.

Based on the high-resolution reef database, four sub-intervals of the Mississippian metazoan reef evolution were distinguished: (1) metazoan “reef gap” phase without metazoan reefs during the Tournaisian; (2) metazoan reef re-establishment phase containing a few metazoan reefs from early Visean to the early late Visean; 3) metazoan reef proliferation phase with global coral reef flourishment reaching its peak in the middle part of the late Visean; and 4) metazoan reef collapse phase with a gradual decline in coral reef abundance during the latest Visean to Serpukhovian.

During the Tournaisian, a widespread marine anoxic event disturbed and further delayed initial phase of metazoan reef recovery. Later, during the Visean, recurrent glacial and interglacial climate may have stymied metazoan reef recovery during this time. However, the late Visean coral reef proliferation clearly shows that the Mississippian was not solely a period dominated by microbial reefs. Their development coincided with increased nektonic and benthic diversity, suggesting that stable marine ecosystems developed during this time. This situation is associated with warm conditions and high relative sea level. Then, with the onset of the major phase of the late Palaeozoic ice age (LPIA) and enhanced climate cooling starting in the latest Visean, and more or less coeval habitat destruction as consequence of the Variscan orogeny, coral reef ecosystems gradually collapsed and became very scarce in the Serpukhovian.

Lower Devonian reefs – The Emsian Château-Pignon biostrome from the Basque Country (Southern France)

Matthieu Saillol[1*], Markus Aretz[1], Elise Nardin[2]
1. Géoscience Environnement Toulouse, Université Toulouse III - Paul Sabatier, Toulouse, Occitanie, FRANCE
2. Géosciences Environnement Toulouse, CNRS, Toulouse, Occitanie, FRANCE
E-mail: matthieu.saillol@outlook.fr

Keywords: Lower Devonian, Patch-reef, Biostrome, Palaeoenvironment, Palaeoecology

While Silurian and Middle Devonian are well-known for their stromatoporoids-corals reefs development across the globe, the Lower Devonian reefs are less studied. In Southwestern Europe, they are scarce and mostly represented by patchy and biostromal geometries. Most of them have only been identified and summarily studied in larger-scale regional geological studies. Understanding what constraints (i.e. palaeoenvironment, palaeogeography, palaeoecology, etc.) impact reef development and their community structure is still a key question to deciphering reefs' evolution, especially in the Early Devonian.

Herein, we present the first results on the characterisation of the Château-Pignon biostrome (French Basque Country). The Château-Pignon biostrome is located South of Saint-Jean-Pied-de-Port (Hastateguy peak). Heddebaut (1973) called it “a biostrome like reefal limestone” without providing more details. Later, it was interpreted as channel deposits by Perlet (1986). Four field campaigns have been conducted to study and sample the potential reefal layers at Château-Pignon. Overall, the limestone body considered to represent the reefal facies is E-W oriented and measures 100 m in length and 30 m in thickness. Six main carbonate facies (FT1-6) have been determined. The base is characterized by slightly detrital (FT1) crinoidal wackestone to packstone, which formed in tide-influenced inner shelf environments. Then, tabulates corals, stromatoporoids and solitary rugose corals appear progressively in those shallow inner shelf (FT2: Floatstone with few bioconstructors). About 3 meters above section base, the abundance of bioconstructors increases and they start to form patches of heterogeneous composition and density, which are often 50 cm in diameter (FT3 Floatstone with bioconstructor, FT4 Floatstone with a high density of bioconstructors). Facies FT1-4 have a similar micritic matrix and most corals and sponges are reworked. In the upper third of the limestone body, a meter-thick bed is essentially composed of densely packed reworked bioconstructors (FT5 Bioconstructors rudstone). The core of the biostrome is a 1-2 m thick layer composed of densely grown thamnoporid colonies (tabulate corals) and stromatoporids (up to 100 cm in diameter) (FT6 Tabulate corals and stromatoporoids boundstone). The associated fauna comprises brachiopods and echinoderms, which are minly preserved as fragments of various sizes. Very rarely cephalopods can be documented.

Our preliminary results suggest that the Chateau-Pignon body corresponds to a sequence of short-lived, but mostly failed initiations of reef development of moderate-size, in an inner shelf depositional regime. Bioconstructors eventually formed a biostrome, favoured by a local increase in relative sea level. Further environmental parameters will be explored to better constrain the reef growth and the evolution of the community structure.

Late Permian Reef Buildup in the Upper Yangtze Region and Puguang Gas Field- Study on Typical Sedimentary Outcrops

Qianglu Chen[1*]
1. WUXI Research Institute of Petroleum Geology, Research Institute of Petroleum Exploration and Production, SINOPEC, Wuxi City, Jinagsu, CHINA
E-mail: chenql.syky@sinopec.com

Keywords: reef buildup,late Permian, upper yangtze region, puguang gas field, outcrop

The Yangtze region is one of the regions with the best stratigraphic record and the most abundant fossils of the Permian–Triassic in the East Tethys and even in the world. It records the evolution of the Paleotethys, the Permian–Triassic Boundary (PTB) mass extinction, the Emei tafrogenesis and other important geological events. The proposed field trip targets, locating in Upper Yangtze region, including the typical platform margin reefs of Late Permian and grain shoals of Early Triassic at Jiantianba in Lichuan County, at Panlongtong, and Puguang Oilfield in Xuanhan. It is shown how the sedimentological study serves oil and gas exploration successfully, leading to the discovery of the Puguang giant gas field. The Jiantianba outcrop reveals a complete sedimentary succession containing basin, slope, carbonate platform margin, and open-restricted platform deposits, where especially, the platform margin reef core can be observed with very clear assemblages of architecture units and a variety of identifiable microfacies(e.g., Filled-skeleton sponge framestone, Open-skeleton sponge framestone, Binding-skeleton sponge framestone, Segment or cluster bafflestone). Calcisponge is the main reef-building organism with abundant species and various forms. It is one of the most typical reefs of The Late Permian T in The Yangtze region. The platform margin zone across the Permian-Triassic biological mass extinction event is studied at the Panlongdong outcrop, revealing the typical platform margin sedimentary characteristics that the reefs of Changxing stage developed on the lower partT while the shoals of Feixianguan stage on the upper part of the section. Platform margin reef and shoal are superimposed and inherited spatially. The sedimentary evolution succession of reef base–reef core–reef cap is clear and complete. The platform margin shoal is mainly oolitic, and gravel intraclasts the second, with tabular and wedged cross-bedding developed. Puguang gas field is represented by the reef and shoal reservoirs with high porosity and high permeability of the Permian Changxing Formation and the Lower Triassic Feixianguan Formation. This discovery benefited from the breakthrough in The sedimentological study on sedimentary facies and favorable reservoirs. It provids a good reference for the exploration and development of ultra-deep buried carbonates gas fields in the world.

Keywords: Stalagmite,Indian summer monsoon,holocene

The Asian summer monsoon (including the Indian and East Asian monsoon), which which affects the live and production activities of one third of the world's population, plays an important role in the global climate system. Detailed studies of the monsoon changes during the Holocene in different regions are critically important for a better understanding of its future trend. Here, we reconstructed the accurately-dated, high-resolved Indian summer monsoon changes, covering the last 9000 years, by using four replicated stalagmites from Shenqi Cave in southwestern China. In general, the oxygen isotope changes of Shenqi (SQ) record are consistent with other stalagmite records from Oman, Indian and monsoonal China, following the northern Hemisphere summer insolation change during the Holocene. It indicates the covariations of the Indian summer monsoon and East Asian summer monsoon on orbital scale. Our record suggest the strongest Indian summer monsoon in southwestern China occurred in the early Holocene. The rapid declining of the Indian summer monsoon after 7000 a BP may be caused by the increase of the Arctic sea ice and ENSO frequence. Seven pronounced weak monsoon events were recorded at 8.27.65.65.35.04.02.3 ka BP in our stalagmites δ18O record, among which the 8.2 ka event was the most remarkable.

Facies architecture and palaeoecology of brachiopod-rich Visean (Mississippian) mud mounds from the Derbyshire Carbonate Platform (UK).

E-mail: alessandro.carniti@unimi.it

Keywords: mud mound, brachiopod, Mississippian, Visean, Derbyshire

Mud mounds are widespread in the upper Visean of the Derbyshire Carbonate Platform succession, outcropping in the Peak District (UK). In particular, mounds occur in the uppermost part of the Monsal Dale Limestone Formation. Derbyshire mounds are dominated by lime mud derived from in situ precipitation mediated by microbial mats on the seafloor, associated with siliceous sponges (‘automicrite’), and contain skeletal metazoan remains not forming a rigid framework (bryozoans, brachiopods, crinoids). Gutteridge (1990) described brachiopods as concentrated in storm-scoured pockets surrounded by a mound automicrite boundstone facies barren of shelly macrofauna.

Facies architecture was re-studied in several Derbyshire mud mounds developed in different settings on the platform: platform interior (Linen Dale), middle intraplatform ramp (Ricklow Quarry), outer ramp (Rheinstor Rock), platform margin (Pic Tor, High Tor, National Stone Centre). Metre-sized mounds are frequently associated to form decametre-sized complexes. The core of the complexes is similar in all the settings, being a clotted-peloidal micrite boundstone with fenestellid bryozoans, brachiopods, and siliceous sponges, unless for thicker cores where more accommodation space was available. This is indicative of the fact that there were no major changes in the mud mound biotic community in the different settings. Some differences may arise in the flank beds: in the platform interior (Linen Dale near Eyam) these consist of crinoidal peloidal grainstone – packstone, in the intraplatform middle ramp skeletal wackestone-packstone, in the outer ramp skeletal packstone – grainstone, at the platform margin fine wackestone - packstone with skeletal debris and chert towards the platform interior, while skeletal packstone beds with crinoids dip towards the basinal facies of the Widmerpool Gulf. These differences reflect the transition of the mound core facies to the surrounding off-mound facies.

Brachiopods are widespread in every mound facies, and no signs of storm scoured pockets were identified. However, some specimens are concentrated in skeletal grainstone patches in the mud mounds interpreted as the filling of cavities in the mound framework formed by bryozoans, siliceous sponges, and automicrite. Likely, the abundance of brachiopods contributed to the rigidity of the mounds. Brachiopod assemblages are dominated in terms of biovolume by productides, which is indicative of scarce and scattered food resources.

Middle Permian carbonates in Iran and the links between distribution pattern of the large test fusulinids and depositional environmental change during Guadalupian

Sakineh Arefifard[1*]
1. Geology, Lorestan University, Khorramabad, Lorestan, IRAN
E-mail: sarefifard@gmail.com

Keywords: Guadalupian, Iran, carbonates, depositional environments, fusulinids

The Middle Permian carbonates and significant events during this time interval have been studied by many geologists. The Guadalupian carbonates in east-central Iran are known as the Jamal Formation, located in Shotori and Bagh-e Vang Mountains and those in west-central Iran are named as the Surmaq Formation and lower parts of the Abadeh Formation in the Hambast Valley, Abadeh area, within Sanandaj-Sirjan Zone. The Guadalupian gray to cream medium- to thick-bedded carbonates of the Jamal Formation in the Shotori section are composed of the shallowing-upward successions but those in the Bagh-e Vang section contain the interbedding gray medium-bedded limestones and chert bands indicating a deep basin environment (Arefifard and Isaacson, 2011).

In Hambast Valley section, the Surmaq Formation is subdivided into three units (1-3) and consists mainly of light to dark gray medium-bedded shallow subtidal limestone in the Roadian-Wordian Unit 1 followed by the upper Wordian Unit 2 containing light gray thin- to medium-bedded deep basin limestone with chert bands interbeds. The dark gray medium- to thick-bedded shallow subtidal limestones of the upper Wordian-Capitanian Unit 3 overlies the Unit 2 of the Surmaq Formation. The overlying Abadeh Formation in the Hambast Valley section has a conformable contact with the Surmaq Formation and its lower part known as subunit 4a is composed of alteration of the gray to black shales and gray thin- to medium-bedded limestone indicative of a lagoon setting which are dated late Capitanian (Shahinfar et al., 2020). Considering the significance of end-Guadalupian extinction and its impact on organisms especially large test fusulinids, it is necessary to investigate the effect of the depositional environment change on the extinction of these organism at the end-Guadalupian.

Lager test fusulinid occurrences in the carbonates of the Shotori section are low, probably due to the paleotemprature of local ambient sea water above 36º centigrade which was not appropriate for the survival of these organisms. In Bagh-e Vang section, a deep basin environment was unfavorable for occurrence and growth of the large test fusulinids. In Hambast Valley section, the Roadian-Wordian Unit 1 of the Surmaq Formation yields abundant large test fusulinids. In the upper Wordian Unit 2 of the Surmaq Formation, limestones with chert bands interbeds are comparable with their coeval deposits in the Bagh-e Vang section and are lack of large test fusulinids. The cherts abundance in the Unit 2 of the Surmaq Formation and in the Middle Permian Jamal Formation of the Bagh-e Vang section are linked to Middle Permian chert event in South China and North America. These cherts were an indication of eutrophication conditions and high level of nutrients, providing unfavorable conditions for the life of large test fusulinids and their algal symbionts. It can be inferred that the climate change and the increase of nutrient input played major roles in the extinction of these organisms in the study areas of east and west central Iran.

Characteristics and evolution controlling factors of platform margin reef-shoal: a case study of Upper Carboniferous-Middle Permian in the northwest of Tarim Basin

Ke Sun[1*], Huixi Lin[1], Guanmin Wang[2], Qinghua Chen[2]
1. Northwest China exploration and Development Research Center, Sinopec Petroleum Exploration and development Research Institute, Beijing, CHINA
2. China University of Petroleum, School of Geosciences, Qingdao, Shangdong, CHINA
E-mail: sunke.syky@sinopec.com

Keywords: margin reef-shoal, characteristics, controlling factors, Upper Carboniferous-Middle Permian, Tarim Basin

Reef-shoal reservoirs play an important role in carbonate reservoirs and are prone to form high-yield oil and gas fields with huge reserves, such as the Ghawar oil field in Saudi Arabia, Zertan oil field in Libya, and Old Golden Lane oil field in Mexico[1]. In recent years, with breakthroughs in reef-shoal facies oil and gas fields of Upper Ordovician Lianglitage Formation in Tarim Basin, Triassic Changxing Formation and Feixianguan Formation in Sichuan Basin, such as Tazhong I Gas field, Puguang gas field and Yuanba gas field, the research interest of reef-shoal facies is increasing [2-6]. Studies show that the favorable area of reef-shoal body in Tarim Basin is $1.58\times10^4 km^2$, and the amount of oil and gas resources is more than $1.5\times10^9 t$, indicating its huge exploration potential [7]. Upper Carboniferous-Middle Permian platform margin reef-shoal reservoirs are one of the most important exploration targets for the northwestern margin of Tarim Basin. To obtain a clear understanding of the controlling factors for the platform margin reef-shoal development, field outcrops in the Wushi area, and northwestern margin of Tarim Basin had been studied in this article by field measurements, thin section identification, carbon and oxygen isotope testing, and ancient provenance analysis. Studies showed that the platform margin reefs in the Wushi area were dominated by algae reefs, and the platform margin shoals are dominated by bioclastic shoals and gravel shoals. The characteristics of algal bind inside grains were common. During the Zhaerjiake period, interbedded reefs and shoals were the main types, and platform marginal reefs were of the progressive type; During the Balediertage period, huge thick platform margin reefs were the main type, platform margin reefs were of accretion-weak progressive type. The development controlling factors of the platform margin reef-shoal are mainly relative sea-level change, palaeosource, and paleogeomorphy. Relative sea-level changes controlled the development characteristics and superposition mode of the platform margin reef-shoal; there were two sides of the influence of the palaeosource on the platform margin reef-shoal; the paleogeomorphology controlled the development position and spreading scale of platform margin reef-shoal. In the covering area, the platform margin reef-shoal reservoirs adjacent to the fault zone and with large sedimentary thickness might have a good prospect for hydrocarbon exploration.

Permian-Triassic Boundary Microbia: biological status & ecological position

Stephen Kershaw[1*]
1. Life Sciences, Brunel University London, Uxbridge, Middlesex, UNITED KINGDOM
E-mail: stephen.kershaw@brunel.ac.uk

Keywords: microbialite, calcimicrobe, Permian, Triassic, carbonate, diagenesis

Permian-Triassic boundary microbialites (PTBMs) are thin (ca 0.06 – 20 m) limestones directly after the end-Permian extinction horizon, concentrated in low latitude palaeogeographic positions and largely Tethyan. PTBMs' constructors are stromatolites and thrombolites when viewed at field scale, but in thin section many thrombolites are composed of calcimicrobes.

Palaeogeographic variations of PTBMs are principally:
1) South China Block (SCB) PTBMs (eastern Tethys): predominantly extensive calcimicrobe-constructed biostromes across shallow marine environments of the Yangtze Platform. PTBMs are pervasively recrystallised, making it difficult to ascertain their full constructing assemblage of microbialite forms. Diagenetic alteration is highly variable, even across distances of a few mm, but the dominant structure in best-preserved material is a lobate-form calcimicrobe similar to, but different from, Renalcis and Tarthinia, named a new taxon Calcilobes (which in SCB is C. wangshenghaii, Kershaw et al. 2021). In contrast to other calcimicrobes, Calcilobes is interpreted to have formed as individual solid round micritic blobs on the sea bed that amalgamated into a framework with geopetals. Dolomitisation is common in Calcilobesmasses, but is non-selective, occurring in both microbial lobes and interstitial sediment. SCB PTBMs also contain minor stromatolites that in some cases bear very small branching microbia called "Polybessurus-like fossils" (PLFs) in layers (Zhang et al. 2021). PLFs also occur as fragments in some thrombolites indicating some transport, yet overall the SCB PTBMs grew in low energy conditions, lack algae and may have formed in water a little deeper than modern coral reefs do. Uncertainty about conditions of formation of SCB PTBMs reflect evidence of both anoxic and oxygenated conditions in their sedimentary material.
2) Western Tethys PTBMs: mainly in Turkey & Iran in palaeogeographic positions including large Tethyan platforms in Cimmeria and northern Gondwana margins. Calcimicrobes are rare in western Tethys, PTBMs being stromatolites and thrombolites composed of clotted sediments. However, discovery of peculiar calcimicrobes in one site in Turkey reveal a different form of Calcilobes (Kershaw et al. 2012, Fig.12C,D, and in prep.). In Iran and Armenia are common occurrence of digitate stromatolites of presumed biogenic. Overall the form diversity of western Tethyan PTBMs is much greater than eastern Tethys, but reasons why the forms are geographically limited is not understood.

Despite substantial effort, major questions remain:
A) were the microbialites photosynthetic, thus cyanobacteria? We may surmise that the stromatolites have the best chance of being cyanobacteria but there is no proof in thrombolites or calcimicrobes, so interpretations including a primary production element, and oxygen production, are attractive but await confirmation.
B) What caused the PTBMs to appear so sharply, and to disappear (almost as sharply) so soon after the extinction, noting that biotic recovery from extinction took several million years? Interpretations of anoxic upwelling and raised bicarbonate levels in the oceans to drive carbonate microbialite production lack conclusive evidence.
C) Why are PTBM calcimicrobes apparently unique in the rock record (since the first microbialites ca. 3500Ma, the only occurrence of Calcilobes is in the PTBMs)?

PTBMs have a bright future: their enigmatic structure presents many research opportunities!

Keywords: Information Extraction,Carbonate,Limestone,Deepdive,Knowledge base construction

Carbonate rocks are the oldest sedimentary rock on earth, dating back to approximately 3.8 billion years ago. Limestone, as the most widely distributed carbonate rock, its temporal and spatial distribution can help us better understand the precipitation of carbonate minerals in the long-term history. Here, we use a novel method to efficiently extract information and generate the knowledge base from the published literature. First, we collect limestone-related PDF documents and convert them to text by using OCR (Optical Character Recognition) software. We use a glossary of vocabulary and tags labeled by NLP (Natural Language Processing) software, and all possible candidate pairs were searched from each sentence. Secondly, each pair and its features are represented as a factor graph model, with a set of heuristic procedures used to score the weights of each pair's features in order to train the probability of each candidate. Our results include 90%/6542, 92%/2377 and 85%/9225 accuracy/distinct pairs on strata, age and location with probability greater than 0.9 respectively from 27124 papers. After integrating the data, we ended up with 15,144 unique data items. Permian, Ordovician and Carboniferous are the three most commonly stated eras in our findings.
Limestone occurrence shows a low stand before Cambrian (541 Ma), then increases in Cambrian and reaches a subpeak in Ordovician (485-444 Ma). After a short decrease in Silurian-Devonian (444-359 Ma) it comes to a peak in Carboniferous-Permian (359-252 Ma), followed by a rapid fall at the Permian-Triassic boundary, finally descending to a relatively stable level with small fluctuations after Cretaceous (145 Ma). As for locations of limestone, China, the United States, Western Europe and Canada are the four hotpots identified by our data. OCR (Optical Character Recognition), NLP, and DeepDive are used in a pipeline procedure to extract important information from geological publications.

Microbial blooms triggered pyrite framboid enrichment and deoxygenation in microbialite systems after the end-Permian extinction

Zhong-Qiang Chen[1*], Yuheng Fang[1], Paul Wignall[2]

1. State Key Laboratory of Biogeology and Environmental Geology, China University of Geosciences (Wuhan), Wuhan, Hubei, CHINA

2. School of Earth and Environment, University of Leeds, Leeds, UNITED KINGDOM

E-mail: zhong.qiang.chen@cug.edu.cn

Keywords: South China, anoxia, dysoxic, Triassic

The widespread occurrence of microbialites immediately after the end-Permian extinction has attracted interest about their formation conditions. Microbialites are generally believed to be formed during microbial bloom in reducing conditions linked to the mass extinction. However, the cause-and-effect relationship between microbe bloom and reducing states of seawater has long been debated. Here, we report redox fluctuations across the Permian-Triassic boundary (PTB) to evaluate links between the two based on analyses of 17,306 pyrite framboid diameters and morphologies derived from 23 PTB sections from basin to platform settings in South China. During the end-Permian extinction, abundant tiny framboids indicate a widespread anoxia that was likely a direct cause of extinction. In the earliest Triassic (Hindeodus parvus conodont zone), pyrite framboids were absent in ramp to basin and shallow, nonmicrobialite platform sections. In contrast, the coeval microbialites yield abundant framboids indicative of dysoxia. The fact that framboids were only confined to PTB microbialites and absent in other habitats indicates that microbe bloom may have stimulated dysoxic watermass and triggered the framboid growth within microbe aggregates. Thus, the PTB microbialites were not built in reducing waters upwelled from deeper water masses, but instead, microbial proliferation caused local, dysoxia within shallow oxygenated platforms after the extinction. The new results also reject the inference that oxygen minimum zone (OMZ) may have controlled redox variations over the P-Tr transition, and also reveal that a widespread but transient de-oxygenation event was coeval with the end-Permian extinction and that the much more prolonged euxinic-anoxic conditions prevailed in the aftermath of the earliest Triassic extinction.

Cyanobacteria bloom on shallow platform in South China after the end-Permian mass extinction

Siqi Wu, Zhong-qiang Chen*, William Joseph Foster
1.
E-mail: zhong.qiang.chen@cug.edu.cn

Keywords: Microbialites, end-Permian mass extinction, cyanobacteria

The widespread development of Permian/Triassic boundary microbialites (PTBMs) are widely accepted as a sedimentary response to the mass extinction event. The major constituents of the microbial communities that precipitated these structures, however, remain unknown. Here, we report newly found columnar cyanobacteria from nine Permian/Triassic boundary microbialite successions in South China, which are interpreted as Pleurocapsales (a modern cyanobacterial clade having a strong calcifying capacity). These microfossils are abundant in Permian/Triassic boundary microbialites observed in South China, and four stages of the Pleurocapsales life cycle: baeocytes, juvenile column, mature column, and baeocyte-splitting are recorded, supporting a Pleurocapsale identification. The clustering branches give the Pleurocapsales potential in constructing frameworks to baffle water currents for the development of microbialites. Common occurrence, strong calcification capacity, and baffling framework indicate that Pleurocapsales are important in constructing Permian/Triassic boundary microbialites. Variation characteristics of Mg/(Mg+Ca) ratios from latest Permian to earliest Triassic in PTBMs and the micro-distribution of Mg between fossils and surrounding rock indicate enrichment of Mg by these cyanobacteria.

Characteristics and Differences of the Platform Margin Reef–shoal Complex Reservoir, Changxing Formation, Central Eastern Region, West of the Kaijiang-Liangping Trough

Yu Tang[1], Yunfeng Zhang[1,2*], Hongming Tang[1,2], Yaobin Sun[1]
1. School of Geoscience and Technology, Southwest Petroleum University, Chengdu, Sichuan, CHINA
2. Division of Key Laboratory of Carbonate Reservoirs, Southwest Petroleum University, Chengdu, Sichuan, CHINA
E-mail: zhyf@swpu.edu.cn

Keywords: Reef-shoal complex, Reservoir characteristics, Reservoir evolution, Changxing Formation, west of Kaijiang-Liangping Trough

In this study, the margin platform in the central eastern region to the west of the Kaijiang-Liangping Trough was divided into two areas: (1) the main central Longgang area, and (2) the eastern Longgang area, to determine the properties, genesis, patterns and differences of the reservoir. The main Longgang area is a steep-slope platform margin type. The reef–shoal complex growth close to the outer edge of the platform margin has a ridgeline shape, with multiple stages apparent in the vertical direction. The eastern part of the Longgang area is a gently sloping platform margin; the reef–shoal complex is the product of broad horizontal and vertical development. The former type of reservoir space contains constitutively selective intragrain dissolution pores, intergrain dissolution pores and non-constitutively selective dissolution fractures and structural fractures, producing low porosity and low permeability. The latter type consists mainly of intercrystal pores, intercrystal dissolved pores, intergrain dissolved pores and structural dissolution joints, resulting in a fracture-type reservoir possessing extremely low porosity and low permeability. Development of the reef–shoal complex reservoir was completely controlled by atmospheric freshwater dissolution, reflux infiltration and dolomitization, together with early diagenetic near-surface karstification, burial dissolution and buried dolomitization. The water body in the eastern Longgang area was relatively deep, resulting in weak atmospheric freshwater dissolution in the syngenetic stage, and weak near-surface dissolution in the early diagenetic stage. The high-quality reservoir is influenced by fractures and buried dissolution.

Criteria for recognizing microbial-caddisfly bioherms in lacustrine settings: Paleocene Second Member, Funing Formation, Subei Basin, East China

Xuewen Zhou[1*]
1. Northwest Research Center, Petroleum Exploration and Production Research Institute, SINOPEC, Beijing, CHINA
E-mail: zhouxw_zxw@outlook.com

Keywords: Trichopteran cases, Agglutinated polychaete tubes, Nested instar cases, Silk larval cases, Helix-shaped cases, Marine incursion

Paleogene carbonate successions from lacustrine basins across East China yield microbial bioherms containing abundant agglutinated fossil tubes. Historically, these have been interpreted as the dwellings of polychaetes introduced by marine incursions. This is problematic, because these tubes are associated with abundant non-marine fauna and algae. Diverse and exceptionally well-preserved fossil tubes from carbonate microbial bioherms were studied in outcrops and drill cores of the second member of the Paleocene Funing Formation, Subei Basin, East China. Detailed macro-, meso-, and micro-structural investigations of these tube-dominated bioherms reveal that the putative “marine polychaete tubes” better fit the morphologies and construction styles of lacustrine caddisfly (Insecta: Trichoptera) larval cases, eliminating the need for a marine influence on this lacustrine setting.

Individual caddisfly cases are commonly 10-25 mm in length and 1-2.5 mm in diameter, and form slightly curved, tapered tubes or coiled spirals. Twelve tubular case construction styles were further identified, based on caddisfly-case wall structures and dominant grain types. Caddisfly cases are commonly single-walled, with rarer nested instar cases comprising double- or triple-walls of different sizes. Most cases are fully agglutinated with neatly arranged, similarly sized and closely connected particles of clastic grains, carbonate particles, plant fragments, and phosphatic fish bones. Sparsely agglutinated cases are also present but much rarer, and conform to the silk larval cases of caddisflies.

The caddisfly cases appear as gregarious aggregations within carbonate microbial-bioherms. The microbial-caddisfly bioherms in this study are commonly developed on carbonate hardground or mudstone within the wave-washed, high-energy, shallow-lacustrine littoral zone and can be traced along the western paleolake margin of the Jinhu Depression of the Subei Basin for up to 60 km. The bioherms are composed of repeated microbial-caddisfly couplets, made up of randomly arranged and similarly sized caddisfly cases encrusted by domed, planar, columnar or cauliflower-like microbial layers. Cyclic microbial-caddisfly couplets fit well with caddisfly biology but are not known to occur with marine polychaetes. This is the first report of microbial-caddisfly bioherms in Cenozoic strata of China, and is the oldest Cenozoic record of caddisflies in China.

Late Ordovician Colospongia (“Sphinctozoa”, Porifera) from Tarim Basin reveals a shallow water origin of reef-building calcareous sponges

Yangge Zhu[1], Yasheng Wu[2], Lijing Liu[1*]
1. Geology, Northwest University, Xi'an, Shannxi, CHINA
2. Key Laboratory of Cenozoic Geology and Environment,, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, Beijing , CHINA
E-mail: liulijing@nwu.edu.cn

Keywords: Calcareous sponges, Sphinctozoans, Late Ordovician, Tarim Basin, reef

Calcareous sponges (including Sphinctozoa, Inozoa and Sclerospongiae) are important reef-builders in the Permian and Triassic. Although Sphinctozoans appeared in the Cambrian, there are few records about early Paleozoic reef-building calcareous sponges. At present, the earliest known record of a reef-building calcareous sponge is *Corymbospongia*, a multi-chambered sphinctozoan of the Sanqushan Formation in the late Katian, Zhejiang Province, China, and it is considered that the reef-building sphinctozoans may have originated from the relatively deep-water environment in the back arc basin of the Late Ordovician. We discovered a new species of sphinctozoan from the Late Ordovician early Katian Lianglitag Formation in the Tazhong area, Tarim Basin. The species is characterized by moniliform arrangement, hemispherical or spherical chambers, absence of a central tube and internal filling structures. We named it *Colospongia primitiva* sp. nov., belonging to the family Colospongiidae. *C. primitiva* is one of the important frame-building organisms in the *Tetradium*-?*Archaeolithoporella*-Sphinctozoan reef community. Sedimentary microfacies analysis shows that *C. primitiva* lived in the clear shallow water with weak hydrodynamic conditions in the platform interior, which is very close to the reef-building environment of *Colospongia* from the Permian and Triassic. Discovery of *C. primitiva* extends the appearance of *Colospongia* back from the Carboniferous to Ordovician, and it is the earliest known calcareous sponge involved in reef building. *C. primitiva* and Cambrian single-chambered *Blastulospongia* are the same structural characteristic type of low-grade sphinctozoans. Therefore, it is very likely that *C. primitiva* originated from Cambrian *Blastulospongia* and evolved into vertically stacked multi-chambers. The discovery of *C. primitiva* not only provides more evidence for the origin of *Colospongia* from *Blastulospongia*, but also reveals that *Colospongia* may not have changed much in the long-term evolution. Our discovery further enriches the diversity of reef-building sphinctozoans in the Ordovician, and for the first time shows that reef-building calcareous sponges may originate from the relatively shallow water environment of the platform interior and became a builder of shallow water reefs at least since the early Katian (Late Ordovician).

Comprehensive Geophysical Identification of Reef in Xisha Offshore

Taotao Yang[1*]
1. Offshore Research Center, PetroChina Hangzhou Research Institute of Geology, Hangzhou, Zhejiang, CHINA
E-mail: yangtt_hz@petrochina.com.cn

Keywords: Xisha offshore, reef, seismic identification, exploration prospect

Reef is organic construction of carbonate rock generating from reef-building organisms. As the most important reservoir type globally and main exploration prospect of South China Sea, reef reservoir has the characteristics of large reserves and high production. Xisha offshore, lying in the northern of South China Sea, has a good reef construction environment since Miocene and developed on a large scale. Based on the geology research of Xisha offshore, the geophysical corresponding characteristics of reef are synthetically analyzed. First the seismic reflection characteristics are introduced, including colliculus appearance, top interface's continuous reflection of strong amplitude, weakening continuous of bottom interface, unorganized internal reflection, lateral onlap, and draping overlying strata. Four geophysical characteristics are illustrated including high velocity, high wave impedance, no obvious abnormal gravity and abnormal low magnitude. Finally, the hydrocarbon geological condition is analyzed, and the conclusion obtained is that this area is a good hydrocarbon prospect and important exploration target of deepwater in future.

Oldest Phanerozoic calcimicrobial reefs (Cambrian Series 2) in Shandong Province, North China: calcimicrobe distribution and contribution to reef construction

Natsuko ADACHI[1*], Yoichi EZAKI[1], Hiroo NATSUKAWA[2], Jianbo LIU[3], Zhen YAN[4], Yuxuan CHEN[3]
1. Department of Geosciences, Osaka Metropolitan University, Osaka, JAPAN
2. Department of Geosciences, Osaka City University, Osaka, JAPAN
3. School of Earth and Space Science, Peking University, Beijing, CHINA
4. Institute of Geology, Chinese Academy of Geological Sciences, Beijing, CHINA
E-mail: nadachi@osaka-cu.ac.jp

Keywords: archaeocyath, calcimicrobe, Cambrian, North China, reef

Skeletal organisms first appeared at the end of the Ediacaran, and rapidly diversified in the Cambrian. Skeletal reef-builders (archaeocyaths) appeared during the late Terreneuvian, and had expanded their habitat by Cambrian Epoch 2. Calcimicrobes also became significant reef constructors during this interval. However, in contrast to archaeocyath-bearing reefs, purely calcimicrobial reefs without archaeocyaths have not yet been fully documented. Calcimicrobial reefs with highly diversified calcimicrobes occur in the Zhushadong Formation (Cambrian Series 2) in Shandong Province, North China; these are the earliest Phanerozoic microbial reefs reported from North China. This study examines the age-specific features of the modes of reef construction and calcimicrobe constituents by comparing the reefs in the Sunmayu and Jinhe sections.

In the Sunmayu section, the calcimicrobial reefs consist mainly of *Epiphyton* and *Kordephyton*, with subordinate *Tarthinia*, *Renalcis*, and *Bija*. The reef frameworks are constructed mainly by aggregations of *Epiphyton* and *Kordephyton*, and are encrusted by tubiform microbes. In some cases, the calcimicrobial assemblages exhibit a characteristic succession from a framework comprising *Kordephyton* and *Epiphyton*, to upward and lateral growth of *Epiphyton*, and finally to *Amgaina* aggregations. The interframework areas are filled with sparry cement and ooidal and peloidal grainstone. Bioclasts are very rare. In the Jinhe section, the calcimicrobial composition is similar to that in the Sunmayu section, although *Amgaina* does not occur. Reef frameworks are mainly constructed by *Epiphyton* and *Kordephyton*, with encrustation by tubiform microbes. Micritic masses with mesh-like fabrics representing keratose sponges occur locally within the frameworks. Unlike the Sunmayu section, the calcimicrobial reefs are in most cases intercalated with “nodular limestone”. The interframework areas are filled with lime mud containing bioclasts (trilobites, hyoliths, and sponge spicules). These areas are dominated by tubular or irregularly shaped voids of <1 mm in diameter, possibly related to burrows or decayed microbial matter. Those voids are infilled with spar cement and lime mud.

Epiphyton and *Kordephyton* were thus the main framework builders in the Zhushadong calcimicrobial reefs. Tubiform microbes in part acted as encrusters, enhancing framework rigidity, whereas *Renalcis*, *Tarthinia*, and *Bija* played minor roles as encrusters and consolidators. The reefs in the Sunmayu section, which are associated with spar cement and ooidal or peloidal grainstone, are inferred to have developed in a high-energy shoal setting. *Amgaina*, which acted as a final framework builder, might have exclusively inhabited higher-energy conditions, where other calcimicrobes could not live. In contrast, the calcimicrobial reefs in the Jinhe section, which occur within peloidal wackestone and lime mudstone, are interpreted to have formed in low- to moderate-energy subtidal settings. Their irregular microbial frameworks provided habitats for comparatively dominant reef-dwelling and burrowing organisms. Although archaeocyaths have not been reported from North China, the Zhushadong reefs contain almost the same calcimicrobes as coeval archaeocyath-bearing reefs. Calcimicrobes were thus distributed widely at that time and contributed greatly to microbial reefs irrespective of the presence or absence of skeletal reef-builders.

Stromatolite or keratolite? Hints from Early Silurian laminated microbialites, South China Block

Qijian LI[1*], Lin NA[1], Guan WANG[2], Yingyan MAO[1], Yue LI[1]

1. State Key Laboratory of Palaeobiology and Stratigraphy, Nanjing Institute of Geology and Palaeontology, Nanjing, Jiangsu, CHINA

2. Key Laboratory of Ocean and Marginal Sea Geology, South China Sea Institute of Oceanology, Guangzhou, Guangdong, CHINA

E-mail: qijianli@hotmail.com

Keywords: keratose sponge, Shihniulan Formation, Llandovery, vermicular fabric, spongiostromate structure

Putative keratose sponges in microbialites have attracted great attention not only from palaeontologists, but also from sedimentologists in the last few years. To distinguish from stromatolite, keratolite has been coined to refer to laminated carbonates dominated by keratose sponges. In northern Guizhou Province (Upper Yangtze Platform, South China Block), stromatolites have been described in the Lower Silurian (upper Aeronian, Llandovery) Shihniulan Formation. Due to the lack of attention, however, little is known about the complicated microstructures in these laminated microbialites. Here we investigated the well-preserved vermicular fabric-bearing “stromatolites” in the top part of the Shihniulan Formation at the Chayuan Section in Tongzi County, Guizhou Province. Small cylindrical and dome-shaped stromatolites occur in a 1.5-m-thick reef succession, with individual stromatolitic units generally less than 30-cm-thick. Microfacies analysis shows various fabrics with different microstructures, dominated by vermiform to spongiostromate structures and clotted textures in the layered deposits. The clotted textures are mainly composed of filamentous microbial fabrics. In contrast, the vermiform to spongiostromate structures share similarities with reported keratose sponges. The association of keratolite and stromatolite developed during a regression and was terminated by subsequent exposure of the seafloor. Our results provide the first case of interlayered keratolite–stromatolite consortia in the Silurian, suggesting that these laminated bioherms tend to grow in intertidal environments.

Biogenic Mg-calcite micropeloids within coral skeletons from Zhongsha atoll, South China Sea

Zhang Xiyang[1*]

1. Key Laboratory of Ocean and Marginal Sea Geology, South China Sea institute of the Oceanology, CAS, Guangzhou, Guangdong, CHINA

E-mail: zhangxiyang@scsio.ac.cn

Keywords: Mg-calcite, peloid, microbe, coral reef, Zhongsha

Micropeloids are common cement types in many limestones, and their formation mechanism is a matter of debate. Inorganic theory supported spontaneous nucleation and precipitation of Mg-calcite in the water column and then settled out of suspension as tiny particles, while the organic origin tended to bacterially-influenced precipitation. In this study, we drilled a shallow sedimentary core from the inundated reef flat in Zhongbei Shoal, north Zhongsha atoll, and probed into the internal relations between ongoing microbial activities and peloidal cements by petrological and geochemical analysis. Micropeloids, 20–100μm in size, occur as interstitial materials in the primary pores of the coral skeleton. Each peloid is assembled by abundant micron-sized rhombic microcrystals of High magnesium calcite (less than 2μm in size). Massive calcified algae/cyanobacteria in vivo were viewed within the peloidal cements, whose calcified sheaths comprised Mg-calcite rhombs, similar to the surrounding peloids. The same distribution modes of the rare earth element and high life-related element (V, Cd) content of the two Mg-calcite rhombs proved that Mg-calcite peloidal cements have a close linkage with microbial metabolism. This study gives a new insight into the organic origin of Mg-calcite peloids during early cementation and enhances the understanding of the pervasive microbial activities in tropical coral reefs.

"Keratose" demosponges in carbonates: comments and new data

Cui Luo[1*], Yu Pei[2], Joachim Reitner[2,3]
1. State Key Laboratory of Palaeobiology and Stratigraphy, Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences, Nanjing, Jiangsu, CHINA
2. Department of Geobiology, Geoscience Center, Georg-August-Universität Göttingen, Göttingen, Niedersachson, GERMANY
3. Academy of Science and Humanities, Academy of Science and Humanities, Göttingen, Niedersachsen, GERMANY
E-mail: cluo@nigpas.ac.cn

Keywords: keratosan, Porifera, non-spicular, metazoan

"Keratose" demosponge fossils were first recognized in Triassic and Devonian carbonates in 2014 (Luo & Reitner, 2014). Along with accumulating reports of similar structures from Phanerozoic carbonates, and recently even from the Neoproterozoic Little Dal Group (Turner, 2021), some researchers accepted the keratosan interpretation and started to address the role that "keratose" sponges played in reefs and other carbonate deposition systems (Lee & Riding, 2021; Pei et al., 2021). However, validation of this interpretation and the recognition criteria of these organisms are still unsettled questions to other workers. Alternative interpretations include lithistid sponges, Wedl tunnels, *Lithocodium*, and clotted micrites, etc. (e.g., Larmagnat & Neuweiler, 2015; Kershaw et al., 2021). Here, using samples from the Lower Triassic of Armenia and Tommotian of Siberia as examples, we reinforce our original point that "keratose" demosponges were indeed fossilized in some Phanerozoic carbonates. The morphological criteria, which were proposed in our earlier works during 2014–2016 (e.g., Luo & Reitner, 2016), are refined and shown to be useful for recognizing these fossils. Regarding taphonomic mechanisms, the preservation of "keratose" sponges is comparable with that of spicular taxa. The precipitation of automicrites and rapid burial by allomicrites can both mould the organic keratosan skeletons but result in different taphonomic features. Finally, we suggest that the morphology of most known keratosan fossils fit best in the Order Verongimorpha, and verongimorphs may have evolved at the latest by Cambrian Age 3. Nevertheless, in less favorable preservation, "keratose" sponge fossils can be confused with many structures of other origins due to their simple morphology. Broader cooperative efforts are required to forge more precise or quantitative criteria for the determination of these fossils.

Skeletal-cement-microbial hybrid carbonates in the Pennsylvanian: A case study in Guizhou, South China

Enpu Gong[1*], Wentao Huang[1,2], Yongli Zhang[1], Changqing Guan[1], Elias Samankassou[3]
1. Department of Geology, Northeastern University, Shenyang, Liaoning, CHINA
2. School of Ocean Sciences, China University of Geosciences, Beijing, Beijing, CHINA

E-mail: gongep@mail.neu.edu.cn

Keywords: Hybrid carbonates, Reefs, Paleoenvironment, Pennsylvanian, South China

Hybrid carbonates, defined as combinations of in situ abiotic, microbial and skeletal precipitates, have changed with biological and environmental conditions throughout geological history (Riding and Virgone, 2020). After a long dual-hybrid carbonate interval, the triple hybrid carbonates became prevalent in the late Pennsylvanian and lasted to mid-Triassic. Reefs from upper Moscovian-Kasimovian (mid-late Pennsylvanian) strata of Guizhou, South China consist of abundant skeletal organisms, microbial carbonates, and abiotic marine cements, which are classified as triple hybrid carbonates. Skeletal components (e.g., phylloid algae, colonial rugose coral *Ivanovia*) and stromatolitic microbial carbonates could build simple frameworks with the growth cavities filled by syndepositional marine cements, automicrite, and sediments. Microbial boundstones constituted by aragonitic cements (e.g., botryoidal cements) and microbial micrite layers are the critical contributor to the buildups as a constructor of the framework, a filler of the cavities, and hard substrate for the encrusting metazoans. The petrographic features suggest the reefs formed at a shelf margin to slope settings with active water circulation. The evolution of Carboniferous organic buildups was primarily driven by the changes in reef-building organisms, closely related to external conditions of the seawater chemistry and paleoclimate. The ubiquitous triple hybrid carbonates in the reefs from South China, consistent with Pennsylvanian tropical shallow-water reefs in their components, are proposed to have been derived from the interaction between decrease in atmospheric CO_2, seawater with high Mg^{2+}/Ca^{2+} ratio, warm tropical water, and the radiation of skeletal organisms in the Pennsylvanian (Fan et al., 2020).

The Spatial and Temporal Distribution of Cambrian Maze-Like Reefs in the North China Platform

Hao Xin[1], Jitao Chen[1*]
1. Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences, Nanjing , Jiangsu, CHINA
E-mail: jtchen@nigpas.ac.cn

Keywords: Maze-like reefs, Sponge, Paleoenvironment, Cambrian, North China Platform

Maze-like reefs, characterized by centimeter- to decimeter-scale branching structures, flourished during the Cambrian to early Ordovician on Laurentia and Gondwana. Maze-like reefs were identified across the North China Platform, and can be subdivided into branching maceriate reefs and columnar maceriate reefs. The maceria structures are made of sponges (e.g., keratosans and lithistids) and microbial components including *Girvanella*, *Renalcis*, and *Tarthinia*, whereas the interstitial material consists of lime mud with bioclasts and intraclasts. The temporal distribution of the maze-like reefs gradually becomes younger from the Drumian stage to the Jiangshanian stage from the northwestern part to the southeastern part of the North China Platform. Detailed facies analysis suggests that depositional environments may have played an essential role in the occurrence of the maze-like reefs in the North China Platform.

Faunal change across the Devonian-Carboniferous transition at Changtanzi section, Longmenshan area, South China

Kun Liang[1*]
1. State Key Laboratory of Palaeobiology and Stratigraphy, Nanjing Institute of Geology and Palaeontology, Chinese Academey of Sciences, Nanjing, Jiangsu Province, CHINA
E-mail: kliang@nigpas.ac.cn

Keywords: Hangenberg crisis, Carbonate microfacies, metazoan reef, stromatoporoid

This study reports the faunal and facies changes across the Devonian-Carboniferous transition at Changtanzi section, Longmenshan area of South China. Based on the revised stratigraphy, we find the occurrence of diverse organisms in the third member of the Changtanzi Formation, which is uppermost Famennian in age. The fossil assemblage is represented by 19 species of stromatoporoids and corals, including stromatoporoids (*Gerronostromaria angulatum*, *G. regulare*, *Platiferostroma crissum*, *Cystostroma zhonghuaense*, *C. hunanense*, *Stylostroma sichuanense*, *S. huanjiangense*, *S. hunanense*, *Labechia majiaobaensis*, *L. longmenshanensis*, *Labechilla* sp., *Spinostroma aggregatum*), tabulate corals (*Syringopora honanensis*, *S. longmenshanensis*, *Michelinia* sp., *Roemerolites* sp., *Fuchungopora multispinosa*, *F. huilongensis*), and rugose coral *Cystophrentis simplex*. In the uppermost of Changtanzi Formation, a biostrome built mainly by stromatoporoids and tabulate corals appeared, suggesting the recovery of the metazoan reef system, but it disappeared in the subsequent Hangenberg crisis during the D-C transition. Biotic recovery is observed in the lower Tournaisian Majiaoba Formation, represented by solitary rugose corals *Hebukophyllum* sp., *Neozaphrentis* sp. and *Uralinia* sp., as well as abundant brachiopods, gastropods and tube organisms, but the fossils belong to post-disaster fauna of low species-level diversity. This study indicates that the Hangenberg crisis caused sudden and significant influences to marine ecosystems, resulting in the disappearance of coral-stromatoporoid metazoan reefs.

EBSD, a new technique to understand the formation of stromatolite layers

Maria del Mar Simonet Roda[1*], Jeong-Hyun Lee[2]
1. Research Institute of Natural Sciences, Chungnam National University, Daejeon, KOREA, SOUTH
2. Department of Geological Sciences, Chungnam National University, Daejeon, KOREA, SOUTH
E-mail: simonetroda@gmail.com

Keywords: EBSD, EDS, carbonate, stromatolite, lake, biomineralization

During the last decade, Electron Backscatter Diffraction (EBSD) has been applied to various fields of geology and biomineralization. However, carbonates, one of the most common rock types on the Earth, have rarely been analyzed using EBSD. Until now, only biologically controlled carbonates such as mollusc and brachiopod shells or foraminifera have been studied under EBSD. In this study, we analyzed stromatolites using EBSD for the first time, in combination with Energy-dispersive X-ray spectroscopy (EDS). We analyzed Recent and Pleistocene stromatolites from the Ruidera Pools (Spain), and Cretaceous stromatolites from the Banyawol Formation (South Korea), all of which formed in arid lake environments. The data acquired from EBSD and EDS were complemented by petrographic observations as well as carbon and oxygen isotope analyses.

In both areas, stromatolites consist of alternating micritic and crystalline layers. In the stromatolites of the Ruidera Pools, the crystal co-orientations in both micritic and crystalline layers are very low, indicating a random distribution of the carbonate grains. Both layers mainly consist of low magnesium calcite devoid of siliciclastic grains, with constant elemental composition throughout the samples. In the micritic layers, EBSD misorientation maps show higher values concentrated in areas with smaller grains or in wavy well-defined fronts within bigger crystal units. The high misorientation values are interpreted as the incorporation of extracellular polymeric substances of microbial organisms into the crystal structure. On the contrary, the crystalline layers rarely show high misorientation values among the crystals, indicating abiotic precipitation.

Micritic layers in Banyawol stromatolites are poorly co-oriented and can be further subdivided into two different types based on their grain size, texture, and elemental composition; first, layers with heterogranular grains enriched in elements such as Al, Na, and Si, and second, layers with more homogeneous grains with more Mn. The former is interpreted to have deposited during the rainy seasons when detrital sediments were transported and trapped in stromatolite layers, whereas the latter would have formed in the dry season with more carbonate mineral precipitation. The misorientation value distribution of the Banyawol micritic layers is similar to those of the Ruidera Pools, suggesting the influence of microbial activity. The crystalline layers of Banyawol samples consist of upward-widening fan-shaped crystals. These fan-shaped crystals generally show low misorientation values, although vertically oriented narrow zones with high misorientation values are recognized. These fan-shaped crystals are reminiscent of cyanobacteria filaments observed within some modern stromatolites.

Overall, this study suggests that EBSD and EDS can provide a novel perspective on the biochemical mechanisms of modern and ancient stromatolite formation.

Carbonate-coated twigs in the Jinju Formation (Lower Cretaceous), southern Korea

Seunghoon Lee[1*], Jeong-Hyun Lee[1,2], Dong-Chan Lee[3]
1. Department of Astronomy, Space Science and Geology, Chungnam National University, Daejeon, KOREA, SOUTH
2. Department of Geological Sciences, Chungnam National University, Daejeon, KOREA, SOUTH
3. Department of Earth Sciences Education, Chungbuk National University, Cheongju, Chungcheongbuk-do, KOREA, SOUTH
E-mail: seunghoon.lee0826@gmail.com

Keywords: Carbonate-coated twigs, lake, stromatolite, oncoid

Distinctive cylindrical carbonate-coated twigs (CCTs), so-called “rod-shaped stromatolites (RSS)”, are reported from the Lower Cretaceous Jinju Formation in Sacheon, southern Korea, which are known to have formed under semi-arid lacustrine conditions. This study focuses on the CCTs collected from two localities of Bito Island and Seonjeon-ri to understand their formative processes and their paleoenvironmental implications. The CCTs are mostly cylindrical and are 1 to 5 cm in diameter and a few cm to >10 cm in length, and are generally similar in their macroscale morphologies regardless of their localities. In both localities, they consist of a central nucleus which is now mostly filled by sparite with minor detrital grains and micrite containing relict plant tissue, and outer micritic- to sparitic layers. The microstructures of the CCTs vary from site to site. The Bito Island CCTs show millimetric stromatolitic columns with laminated fabric in the inner part and thrombolitic fabric in the outer part. Laminated fabric contains undulatory convex-up micritic layers with abundant fossilized microbes such as branching tubular microbes resembling rivulariacean-type cyanobacteria and spherical algal mold (?) *Chlorellopsis*. Thrombolitic fabric is distinguished by millimetric branching digitates with faint laminations and abundant *Chlorellopsis*. In contrast, Seonjeon-ri CCTs are solely composed of millimetric stromatolitic columns of alternating clotted and fibrous layers, with rare fossilized microbes around the nucleus. Clotted fabric is characterized by sand-sized peloids with diffuse boundaries, and fibrous fabric consists of isopachous calcite crystal layers. Morphological characteristics of the fabrics suggest that laminated, thrombolitic and clotted fabrics are microbial in origin, whereas fibrous fabric would have formed by abiotic precipitation. It is interpreted that the microscopic differences between the Bito Island and Seonjeon-ri CCTs, despite their macroscopic similarities, resulted from varied effects of biotic and abiotic precipitations. The dominant precipitation process could have been controlled by temporal/regional differences such as water chemistry during the deposition of the Jinju Formation. This study thus suggests detailed microscopic analyses are required to understand the formative mechanisms of CCTs and their paleoenvironmental implications.

Sedimentary Characteristics of an Oolitic Beach of the Triassic Feixianguan Formation, East of Kaijiang-Liangping Trough, Sichuan Basin, China

Yang Li[1*]
1. School of Geoscience and Technology, Southwest Petroleum University, Chengdu, Sichuan, CHINA
E-mail: 1538336275@qq.com

Keywords: oolitic beach, sequence; rise and fall of sea level,Feixianguan Formation,Triassic, Kaijiang-Liangping trough, Sichuan Basin

The aim of this study is to clarify the temporal and spatial distribution characteristics of oolitic beach deposits and the controlling mechanism of sea level change on oolitic beach migration within the sequence stratigraphic framework of Triassic Feixianguan Formation on the east side of Kaijiang-Liangping trough in Sichuan Basin. Lithologic characteristics analysis, identification of sedimentary structural markers and division of sequence stratigraphic framework of sequence boundary have been carried out. The results show that: (1) Two third-order sequences (SQ1 and SQ2) are developed in Feixianguan Formation on the east side of Kaijiang-Liangping trough under the background of continuous regression, which can be further subdivided into five fourth-order sequences (I ~ V). (2) The oolitic beach of Feixianguan formation is mainly formed in sequence I to IV, and the oolitic beach in sequence II is the best, with large monomer thickness and good continuity, but the sedimentary thickness of beach body in sequence III, I and IV decreases in turn, and the worst shows discontinuous and sporadic distribution. (3) Oolitic beach has obvious lateral migration characteristics when vertical aggradation, migrating from the interior of the platform to the slope as a whole, and the characteristics of oolitic beach lateral migration from sequence I to sequence II are the most obvious. (4) The cause of vertical accretion and multi-stage superposition of oolitic beach in Feixianguan Formation in the study area is the synergistic change of high-frequency cycle in local geomorphic highland and carbonate production rate; while the hydrodynamic conditions suitable for beach growth change from local highlands to local depressions, resulting in the evolution of oolitic beach from vertical growth to lateral progradation, when the sea level drops below the base level. (5) On the plane, the oolitic beach of Feixianguan Formation in the study area is mainly distributed along the northwest southeast direction of the study area (i.e. the platform edge), the best areas are Tieshanpo and Puguang, followed by Dukouhe, Qilibei and Luojiazhai. The research results can provide a basis for the exploration of high-quality beach facies reservoirs of the Feixianguan Formation in the Kaijiang-Liangping trough area.

Sedimentary Characteristics of the Qixia Formation in the Shuangyushi area, northwest Sichuan Basin

BEI WANG[1*], LONGXIN LI[1], WEI LIU[1], YI JIANG[1], JUNJUN CAI[1], ZHANMEI ZHU[1], ZHENGLIN MAO[1], YUEYANG LI[1]

1. Research Institute of Petroleum Exploration and Development, PetroChina Southwest Oil & Gasfield Company, Chengdu, SICHUAN PROVINCE, CHINA

E-mail: wangbei08@petrochina.com.cn

Keywords: Shuangyushi area in Sichuan Basin,Lower Permian Qixia Formation,Ultra-deep gas reservoir,Sedimentary characteristics,The geological modeling of the sedimentary phase

Shuangyushi area is located in the front fold belt of Longmen Mountain on the north edge of Yangtze Craton in Sichuan Basin. The strata of the Lower Permian Qixia Formation in the study area are developed in the carbonate platform. Solid drilling in this area proves that the reservoir thickness is thin and mainly fracture-pore reservoir. Multiple well tests obtain high-yield industrial air flow of over one million square meters. The reservoir development is obviously controlled by the sedimentary characteristics, but the sedimentary phase type and space distribution characteristics are unclear, which affects the target deployment of the gas reservoir well position and development mode optimization. In this paper, using the core, sheet, well logging, logging and three-dimensional seismic data, with the research idea of "point-line-surface-body", on the basis of depicting the sedimentary phase type and horizontal and horizontal distribution, the research method combined deterministic modeling and stochastic modeling to carefully describe the characteristics of each sedimentary microphase. The research shows: (1) The form of the longitudinal sedimentary subphase platform edge beach, platform inner beach and open sea recognition mode, which further divides into five sedimentary microphase types. (2) The edge beach of the favorable phase zone is stable in transverse distribution, and mainly distributed in the longitudinal strata. The whole distribution is to north and east, and the development degree of microphase beach is high. (3) The sedimentary phase pattern of the study area was established, and the gas reservoir forms a wide and slow and high zone with relatively flat terrain and high landform. (4) The three-dimensional geological model of gas reservoir sedimentary phase in Shuangyushi area is established, and the spatial distribution characteristics of sedimentary phase were defined. The multi-dimensional research method is useful for the fine description of sedimentary phase features and reservoirs of similar superdeep complex carbonate gas reservoirs.

Stromatoporoids as indicators of pervasive sea-floor lithification in the middle Palaeozoic Era, and implications for reef formation

Stephen Kershaw[1*]
1. Life Sciences, Brunel University London, Uxbridge, Middlesex, UNITED KINGDOM
E-mail: stephen.kershaw@brunel.ac.uk

Keywords: Stromatoporoid, Palaeozoic, substrates, reefs

Stromatoporoids are abundant in shallow marine carbonate environments of middle Ordovician to Late Devonian strata, representing ca.100 million years. Stromatoporoids are benthic sessile hypercalcified sponges that grew on a range of substrates of clay-rich to pure carbonate, but rare in sandstones, so presumably largely required low sedimentation rates. Stromatoporoids were traditionally viewed as requiring a solid base, such as a shell fragment, for initial growth, after which they could spread on surrounding soft sediment (ambitopic ability). Certainly, stromatoporoids commonly started growth on hard objects, indeed some taxa preferentially encrusted hard substrates such as dead brachiopod and mollusc shells, other stromatoporoids and corals. Nevertheless, repeated observation shows stromatoporoids grew on sediment lacking hard objects, indicating ability to initiate directly on soft muddy surfaces. This capability may partly explain their success throughout their geological history.

However, a feature of stromatoporoid substrates that remained unexplained (best seen in vertical thin sections) is that the base of stromatoporoids very commonly is extremely irregular on a microscopic scale. The initial few laminations follow tiny basal irregularities in complete contact with underlying sediment, observed in stromatoporoids from middle Ordovician through to Late Devonian. How did this irregularity occur? There are two logical possibilities:

1) there was a basal primary cavity - the stromatoporoid base was not in contact with the substrate for much of its distance, potentially a mechanism to escape the choking effects of loose mud; then later the cavity was backfilled leaving no geopetal. Basal cavities with geopetal fills are common, so primary cavities certainly occurred.

2) the sea-floor sediment was partially to completely lithified, either directly on the sea floor, or a short distance below it, followed by current removal of loose sediment leaving a hard substrate that was eroded (perhaps bioeroded) prior to stromatoporoid growth, without evidence of infilled geopetal cavities. This sediment lacks layers or grain-size changes that might indicate successive generations of sedimentary fill, it is simply an amorphous sedimentary deposit upon which the stromatoporoid irregular basal surface sits. So the stromatoporoid encrusted a highly irregular solid surface.

An extension of Point 2 is the common occurrence of very deep basal cavities in stromatoporoid bases, explained only if the stromatoporoid encrusted a prominent object; some are little hills as upper surfaces of limestone beds, others are large lithoclasts. Commonly they are made of only sediment, in other cases they contain bioclasts, yet the pervasive character is stromatoporoid bases in direct contact with micrite sediment.

Comparisons with hardgrounds indicate that highly irregular basal stromatoporoid surfaces are no different from lithified sediment surfaces. Therefore I conclude that the sea floor where stromatoporoids are found was commonly lithified very early, so that stromatoporoids utilised hard sediment substrates. Stromatoporoids with irregular bases occur in level-bottom and reef environments, and reinforce the interpretation that reefs developed not just as dense organism accumulations, but were aided by early lithification as they developed, also explaining common cases of sharp reef margins. For further details see Kershaw et al. (2007, 2018, 2021).

Deciphering the variety of microcrystalline carbonate fabrics present in Ordovician sponge mounds, Tarim Basin, China

Yuefeng Shen[1*], Fritz Neuweiler[2]

1. School of Resources and Environmental Engineering, Hefei University of Technology, Hefei, Anhui, CHINA
2. Department of Geology and Geological Engineering, Laval University, Quebec City, Quebec, CANADA

E-mail: yuefengshen@hfut.edu.cn

Keywords: Carbonate rock fabric, cathodoluminescence, fluorescence, organomineralization, reef evolution

Microcrystalline to finely granular Ca-carbonate represents a major component of the total rock volume of Dariwillian calathid–demosponge carbonate mounds, western Tarim Basin, China. By petrographic means, these kinds of deposits range from microcrystalline sea-floor precipitates (automicrite) to multiple generations of infiltrated sediment accumulation (allomicrite). Here, we focus on the nature of automicrite distinguished by using a spreadsheet that contains six parameters and seventeen characters. There is an *in situ* peloidal–spiculiferous fabric (AM-1), an *in situ* peloidal fabric (AM-2), an *in situ* aphanitic–microtubular to microbioclastic fabric (AM-3), an *in situ* minipeloidal fabric (AM-4) and an *in situ* laminoid–cerebroid fabric (AM-5). Type AM-1 occurs with AM-2 being succeeded by an assemblage dominated by AM-3 and AM-4. Types AM-4 and AM-5 are separated by an erosional disconformity. AM-1 to AM-4 turn out to be non-microbial in origin. Instead, these automicrites represent relics of calcified metazoan tissues, such as siliceous sponges, non-spiculate sponges or even the basal attachment structures of stalked invertebrates. Fabric AM-5 is a microbial carbonate but is post-mound in origin forming a drape within a reefal framework established not until the formation of AM-4. Carbon and oxygen stable isotopic composition of automicrites plot within a range of 0.28‰ to 0.84‰ PDB for $\delta^{13}C$ and -7.23‰ to -5.23‰ PDB for $\delta^{18}O$. A total of 70% of the automicritic samples plot in or near to the field defining Middle Ordovician (Darriwilian) marine calcite. In addition, a good correlation of fluorescence and cathodoluminescence of automicrites indicates that induced and supported organomineralization produced automicrite, probably *via* the permineralization of non-living organic substrates adsorbing dissolved metal–humate complexes.

The Control of Fluids to Ordovician Reservoir in Shunbei Area, Tarim Basin,China

Yuwei Wang[1*]
1. Working Station for Postdoctoral Scientific Research, Shengli Oilfield, Dongying, Shandong, CHINA
E-mail: wangyuwei99@163.com

Keywords: fault-karst carbonate reservoir, Formation of reservoir,Fluid source, Ordovician, Shunbei area

The Shunbei area is located in the northern slope of Tazhong Uplift in the Tarim Basin. It is located in the Saddle between the Manjiaer Depression and the Awati Sag, the Shaya Uplift and the Katake Uplift. From north to the south, the tectonic units can be divided into the Shunbei gentle slope, the Shuntuoguole lower uplift and the Shunnan gentle slope. Among them, the Shunbei has made major breakthroughs in oil and gas exploration in recent years, with an exploration area of about 19,900 km2.

Using core observation, imaging logging and casting thin sections analysis, we identified the types of the Ordovician reservoir space in Shunbei area, and analyzed the types and sources of diagenetic fluids of different periods using fluid inclusion, carbon and oxygen isotopes and rare earth elements. Combined with logging data, seismic data and diagenetic phenomena, the controlling factors affecting reservoir formation and the controlling effect of karst fluids and faulting on reservoir formation are discussed.

The study believed that the Ordovician reservoirs in Shunbei area mainly develop fault-karst reservoirs, and the reservoir space is dominated by structural fractures, accompanied by the development of dissolved pores and vugs. Among them, the fractures are mainly single high-angle oblique fractures, the fracture width and porosity are not high, and micro fractures are mainly developed. There are five periods of fluid activities and three types of fluids acting on the Ordovician reservoirs in Shunbei area: the first and second periods are the mixed fluids of contemporaneous seawater and atmospheric freshwater; the third and forth periods are deep hydrothermal fluids; the fifth period is the evolution of formation water. Five periods of fluids mainly experienced two fluid-rock interaction systems: the evolution system of meteoric water-syngenetic seawater gravity flow and that of remote hydrotherm-syngenetic brine mixed upwelling flow driven by igneous activities. The formation of fault-karst carbonate reservoirs is the result of diagenetic karst superimposed on plutonic karst, based on the tectonic activities of strike-slip faults.

Keywords: Diagenetic fluids, Ultra-deep carbonate reservoir, Fault-fluid coupling, Ordovician, Tarim Basin

The formation and maintenance mechanism of high-quality carbonate reservoirs in deeply burial realms have received increasing attentions. A consensus is that high-quality carbonate reservoirs are largely attributed to secondary dissolution processes by various fluids that are correlated to fault activities, instead of primary porosity. However, how the fault-fluid coupling processes control the development of carbonate reservoirs remains to be unclear. To unravel this issue, we integrated the petrology, mineralogy, fluid inclusion, geochemistry, and logging data as well as seismic data in newly discovered Shunbei Oilfield (NW China) to constrain the diagenetic fluid types and formation mechanism of ultra-deep Ordovician reservoirs under the fault-fluid couplings.

Results show that strike-slip fault activity was absolutely the primary controlling factor in the development of high-porosity damage zones and dissolution-precipitation processes of various fluids. Various types of fluids, such as meteoric water, hydrothermal silicification, organic acids, and Ordovician formation water, are identified. Layered early dissolution pores leached by eogenetic meteoric water in high-energy facies provided basic channels for later fluid migration. The telogenetic coupling process of the fault-descending meteoric water during the I episode of Middle Caledonian contributes to developing multiple sets of epikarstic, phreatic, and deeper "fault-controlled karst" fracture-cave reservoirs at a depth of 0~430 m, making a great contribution to these Ordovician reservoirs. Subsequently, multi-stage re-opens of deep faults during Late Ordovician to Permian led to the upwelling of organic acids and silica-rich hydrothermal fluids which also created a certain amount of secondary porosity. Collectively, the formation of ultra-deep Ordovician "fault-controlled karst" reservoirs in the Shunbei Oilfield was considered to be an interplay of strike-slip faults and various fluids. A comprehensive development evolution model under the fault-fluid couplings is finally established, demonstrating that fault-fluid couplings play a major role in these ultra-deep reservoirs in the whole Shuntuoguole area.

The characteristics, evolution and constraints on reservoir quality of the eogenetic karst in the restricted-evaporative platform in Ordos Basin, North China

Kang Xie[1,2*], Xiucheng Tan[2], Shoukang Zhong[2]
1. School of Geographical and Earth sciences, Universuty of Glasgow, Glasgow, UNITED KINGDOM
2. School of Earth sciences, Southwest petroleum University, chengdu, Sichuan, CHINA
E-mail: Kangxie1023@gmail.com

Keywords: eogenetic karst, physical property inversion, gypsum-bearing dolomite, Ordovician Majiagou Formation, Ordos Basin

The evaporite–carbonate assemblages are often strongly influenced by karstification, which results in dissolution collapse and filling, leading to complex lithology and lithofacies. Therefore, it is difficult to study the transformation process and influence of karstification on this kind of reservoir. There are a great number of nodular evaporites and dolomite symbiosis in the upper Ordovician Majiagou Formation in the northwest of Ordos Basin, which is an ideal target to solve this problem. To improve the accuracy of this study, more than 600 representative core samples were collected, and their petrological and physical properties were comprehensively analysed. The results showed that: Under the background of the restricted-evaporative platform and influenced by the frequent sea-level eustacy, the high-frequency upward-shallowing sequence is developed in M54-M51sub-members of the Ordovician Majiagou Formation, and there are typical characteristics of karst development in the early diagenetic stage, such as selective dissolution, seepage filling, geopetal structure, and in-situ brecciation in the single upward-shallowing sequence.

Further analysis shows that influenced by the exposure time, the dissolution evolution of the eogenetic stage of the gypsum-dolomite assemblages can be divided into five continuous evolution stages: (1) fabric selective dissolution of soluble minerals stage, (2) spongy dissolution stage, (3) the formation of advantage channel and development of karst fissures stage, (4) vertical vadose and horizontal undercurrent dissolution stage (karst zoning), (5). excessive karst stage (overall brecciation). Based on the exposure time and the karst intensity represented by the five evolution stages, the karst dynamic evolution process has been established, and it is further found that the process has the characteristics of optimization and then destruction for reservoir reconstruction, so the reservoir optimization and inversion model of karst intensity control is proposed. The results not only help to understand the characteristics of karst evolution in the eogenetic karst stage and the influence of different karst intensities on reservoirs, but also provide theoretical support for the prediction of such reservoirs and provide new materials for the enrichment of karst geological theory.

Origin of giant Ordovician cavern reservoirs in the Halahatang oil field in Tarim Basin, NW China

Zhanfeng Qiao[1*], Anjiang Shen[1]

1. Key Laboratory of Carbonate Reservoir, PetroChina Hangzhou Research Institute of Geology, Hangzhou, Zhejiang, CHINA
E-mail: qiaozf_hz@petrochina.com.cn

Keywords: U–Pb dating, Clumped isotope, strike-slip fault, karst, Ordovician, Tarim Basin

Cavern and vug porosities in the Ordovician carbonates in the Halahatang oil field are currently hot targets for hydrocarbon exploration in the Tarim Basin, northwest China. Yet, crucially, the formation of cavern and vug porosities has not been fully understood due to multiphase fault-related and unconformity-related diagenetic alterations. Here, we integrated petrology observations and geochemical analyses (C, O, Sr isotopes, trace and rare earth elements, clumped isotope, and laser-based U-Pb dating), aiming at determining the timing for tectonic driven calcite precipitation which is closely tied to karstic reservoir development. Vug-filling calcites were emplaced at the late Caledonian (460.8±3.4 and 448.6±5.3 Ma) and early Hercynian (335±19 Ma). Megacrystalline calcites were precipitated from 324±23 to 300.9±4.8 Ma and 244.13±13 Ma to 240.5±4.1 Ma during the Hercynian. Three stages of fracture-filling calcites were predominantly precipitated at Early Hercynian (~364±53 Ma), Late Hercynian (282.9±5.4 Ma), and Yanshanian (~158±17 Ma), which are intimately grown with fracture-related cavern and vug porosities. Clumped isotopes suggest that these calcites were precipitated from formation fluids, with some localized hydrothermal fluid and meteoric water influxes. This study emphasizes that the main reservoir formation timing for the Halahatang oil field were correlated with the early Hercynian, late Hercynian, and Yanshanian tectonics. The outcomes from study might be able to guide the future hydrocarbon exploration in the Tarim Basin where similar tectonic background present.

Characteristics of carbonate karst assemblage and control of sedimentary factors in Dengying Formation, central Sichuan

1*

1. , , , , CHINA
E-mail: 281796744@qq.com

Keywords: Central Sichuan,Carbonate rock,The karst body,sedimentation

In recent years, with the continuous improvement of oil and gas prediction theory and exploitation technology, the exploration and development of carbonate reservoir in central Sichuan has been effectively promoted.Dengying Formation in Gaoshiti district of Sichuan Basin is a set of dolomite formation, which is affected by sedimentation, karst and tectonic evolution during the Tongwan Movement, and karst reservoirs are relatively developed.The study uses outcrop, core, logging and seismic data of Dengying Formation to carry out research on sedimentation, sequence, karst characteristics and paleogeomorphology restoration, and master the formation mechanism and combination characteristics of Dengying Formation karst reservoir.The formation mechanism of dissolution and pore development characteristics of reservoir are clarified, the main controlling factors of reservoir in different well areas are recognized, and the controlling effect of sedimentary factors is studied emphatically.The results show that the fourth Member of Dengying Formation has pore, cavity and cavity fracture reservoirs, and the formation of reservoirs has experienced sedimentary granulation, shelf formation, dissolution and expansion in peneogene, superimposed supergene karstification and burial karstification.The lower part of Deng4 formation is obviously controlled by sedimentation. Dissolution pores can be developed in the grain beach, but the continuity and scale are smaller than that of the supergene karst reservoir. If there are structural fractures, it will be more favorable.

Predicting dissolution patterns and incipient karst evaluation in complex fracture carbonate reservoir system:Insights from reactive transport modeling

Liu Hao Cheng[1], Dong Chun mei[1*], Lin Cheng yan[1]
1. Geoscience, China University of Petroleum East China , Qingdao, ShanDong, CHINA
E-mail: dongchunmei1@126.com

Keywords: reactive transport model, heterogeneity, fracture-caved carbonate reservoir, Dissolution mechanism, karst evaluation;

Karst features in limestone aquifers often exhibit highly heterogeneous patterns, which are strongly governed by structural complexities. Fracture network dominate preferential flow pathways and mass transfer. To understand the role of local reaction and dissolution transport processes in carbonate formation, we developed a reactive transport model by combining a two-scale pore-medium continuum model with a discrete fracture network that effectively quantify the role of dissolution on changing transport properties over a range of scales.

We provide quantitative insight into the early karstification evaluation with three different components: a prominent fracture embedded into a network of smaller fissures and porous matrix. The initial models geometry and parameters of matrix and fracture network model based on a typical core CT scan and outcrop data in Tarim basin. A systematic parameter study is carried out by varying the initial apertures of the fracture networks and heterogeneity of the rock matrix, key parameters such as flow rates, breakthrough times and densities, connectivity, topology and conductivity of fracture networks for the different models are compared.

Numerical experiments show that: (1)The preferential flow paths are closely related to the fracture network conductivity, topology and flow direction. (2)Patterns of local dissolution-induced alterations related to fracture permeability, hydraulic conductivity and extensive dissolution appeared in fracture tips and intersections. (3) The impacts of matrix can be significantly alleviated when fracture network enhances the connectivity and seepage capacity of matrix-fracture system.

Difference analysis of carbonate sedimentary system and karst reservoir of middle and Upper Ordovician in Tabei area, Tarim Basin

Li Fenglei[1*], Lin Chengyan [1], Ren Lihua[1], Zhang Guoyin[1]
1. School of Geosciences, China University of Petroleum, Qingdao , China, Shandong, CHINA
E-mail: lfl_winter@163.com

Keywords: carbonate sedimentary system, karst reservoir, karst stage, karst, palaeogeomorphology, platform margin reef beach

The carbonate karst reservoirs in the Tabei area have experienced multiple stages and various types of diagenesis, including cementation and filling, dissolution (or karst), silicification, pressure solution, fracturing and hydrothermal action. The main controlling factor of reservoir development is dissolution.Based on the comprehensive analysis of 3D seismic data, drilling, logging and Core experimental analysis data, the influence of carbonate sedimentary system and tectonic factors on karst distribution difference is analyzed vertically and horizontally.Based on the analysis of lithologic characteristics and freshwater karst characteristics of carbonate sedimentary system in three sets of middle and upper Ordovician strata in Northern Tarim.Combined with regional palaeogeomorphology characteristics, regional karst reservoirs are divided into three karst periods: Yijianfang Formation depositional discontinuity, Lianglitage depositional discontinuity and Sangtamu Formation exposure period.The comprehensive regional geological analysis shows that due to the tectonic movement, the carbonate rocks of the middle and upper Ordovician took place in a wide range of exposure at the end of the deposition period.

During the exposure period, a large number of ancient river system was developed with abundant water and large-scale dissolution conditions, which laid the foundation for large-scale interlayer karst.Because of the different sedimentary characteristics of carbonate rocks in different strata, the lithology is different, which determines the difference of formation dissolution.In general, the carbonate content gradually decreased from bottom to top, while the argillaceous content gradually increased, resulting in the best karst reservoir development in the late sedimentary period of Yijianfang Formation.In the Lianglitage formation, there is a high content of reef beach facies carbonate in the platform margin, while there is a high content of mud in other areas, which results in the difference of lateral development in the altered reservoir area.During the exposure period of the Sangtamu Formation, a large scale ancient drainage system was also formed and the Sangtamu formation is pinched to the north of the study area.Due to the continuous dissolution of carbonate strata in the north of pinching line, a large number of deep channels and residual mounds were formed, and some of them had the characteristics of karst paleogeomorphology.In the south of the pinchout line, the stratum thickness of the Sangtamu Formation increases gradually. Due to the high argillaceous content, effective reservoirs cannot be formed in the Sangtamu Formation, and surface fresh water cannot flow vertically into carbonate strata on a large scale, and the overall dissolution conditions are poor.Based on the above understanding, the matching relation between carbonate sedimentary system and karst reservoir distribution difference is clarified, and it is considered that favorable carbonate sedimentary environment and suitable palaeogeomorphic conditions are favorable conditions for carbonate karst reservoir development in Tabei area.

Intelligent identification of deep carbonate sedimentary microfacies based on decision tree

Song Hu[1*], Mi Liu[1], Chang Xiao Wang[1]
1. well logging technology research, Petroleum exploration and production research institute, Beijing, CHINA
E-mail: husong.syky@sinopec.com

Keywords: sedimentary microfacie, deep carbonate rock, Intelligent recognition, logging

Deep marine carbonate is an important field of oil and gas exploration and development, and the identification of sedimentary microfacies is the key to dessert evaluation. Taking the reef- shoal facies reservoir of Yuanba Changxing Formation in northwest china as an example, the reef-shoal facies reservoir has multiple stages of development and lateral superposition, with strong heterogeneity and sedimentary microfacies. The fine division is complicated. In order to improve the prediction efficiency and accuracy of reservoir sedimentary microfacies, firstly determined the division scheme of sedimentary microfacies combined with conventional logging, electrical imaging logging and geological data, and then defined the logging response characteristics of different microfacies, and an intelligent identification sample set of sedimentary microfacies is formed. Aiming at the problems of complex structure and low precision of missing attribute samples in the existing C4.5 decision tree algorithm, a new decision tree method based on Bayesian principle is proposed, which can reduce the uncertainty of tree building and improve the operation efficiency. The identification coincidence rate of 15 wells is 98%. The new method provides a reliable basis for the division of sedimentary microfacies of complex reef-beach carbonate rocks by using logging data.

Discovery and application of paleokarst in slow flow zone in Ordovician of Tahe Oilfield

1*

1. , , , , CHINA
E-mail: liuyongli526@126.com

Keywords: Internal fracture-cave bodies, Slow flow zone, Paleokarstification, Ordovician, Tahe oilfield

The Middle-Lower Ordovician carbonate reservoirs in the Tahe Oilfield have experienced paleokarstification during the Middle Caledonian-Hercynian orogenies, and developed typical karst landforms and fracture-cavity systems, which are highly comparable with modern karst areas. Since the discovery of Tahe Oilfield in 1997, many scholars have devoted a lot of work to the Ordovician paleokarst. However, due to the limitation of the degree of exploration and development, the early main research focus was the vadose zone and the phreatic zone within the ancient weathering crust 0-150m on top of the Middle-Lower Ordovician strata. With the deepening of deep exploration in the Tahe Oilfield, in 2014, it was discovered that there existed internal karst fracture-cave bodies in the western slope area, represented by Well Tashen 3, which are different from the previous studied epikarst fracture-cave bodies. Based on the interpretation results of high-precision 3D seismic data and drilling data, and referring to theories of modern karst hydrology, this paper describes the geometrical occurrence and distribution range of the inner fracture-cave bodies, and compares their characteristics with the epikarst fracture-cave bodies, and analyzes their occurrence conditions and hydrogeological properties. Therefore, it is pointed out that this set of internal fracture-cave bodies developed vertically in the range of 200-400m below the top surface of the Middle-Lower Ordovician strata, which are different from the typical epikarst zone, and should be slow-flow zone karstification under the phreatic zone. A "slow flow zone" paleokarst model is proposed characteristic of "planar input in the north, medium-deep pressure dissolution, and graded discharge in the south", and the hydrodynamic abrupt change zone developed intensively near the pinch-out line of upper Ordovician strata. The discovery and application of paleokarstification in the slow-flow zone and its associated internal fracture-cavity bodies provide basic theoretical and technical support for the exploration, development and sustainable development of the 100 million tons medium-deep Ordovician oil reservoir in the of Tahe oilfield, and further enrich the paleokarst theory represented by the Tahe oilfield.

Exploring fluid-rock interactions in fractures based on simulated experiments and numerical simulation

Qian Ding[1*]
1. Department of Basic Geology and Experiments, Petroleum Exploration and Devolopement Institution, SINOPEC, Beijing, CHINA
E-mail: dingqian.syky@sinopec.com

Keywords: channelization,dissolution, fracture,fluid-rock interaction;

It has always been a hot issue that scholars at home and abroad pay attention to the fluid-rock interaction in fractured systems. Fluid flows along fractures, dissolves rocks, precipitates new minerals, exchanges material and energy, changes the storage space, and affects the formation and distribution of carbonate reservoirs and hydrocarbon.

In order to further clarify the fluid-rock interaction process in the fracture system under specific geological background conditions, a series of dissolution simulation experiment based on the Yijianfang Formation in the Tarim Basin was designed and combined with numerical simulation tools such as ToughReact. We investigated geochemically induced alteration of fracture geometry in Yijianfang Formation limestone.

The interaction process of CO_2-acidified brine along fracture was identified. The influence of parameters such as temperature, pressure, fluid composition, and rock heterogeneity on fluid migration, ion exchange/diffusion was investigated. Ion diffusion characteristics in fracture and mineral dissolution/precipitation trends were calculated. This study shows that the fracture as the main flow channel makes the overall trend dominated by dissolution, the fracture volume increases, the sample permeability increases by orders of magnitude, and the porosity is also significantly improved. The overall mechanism is not because more rock dissolves, as would be commonly assumed, but because of accelerated fracture channelization.

Geo-modeling of paleo karstic underground river system in fractured-cavity carbonate reservoir based on geological knowledge base and MPG method

Xinrui Lyu[1*], Jianfang Sun[1], Fengying Xiao[1], Hongkai Li[1], Kelong Han[1], Xingwei Wu[1], Dongling Xia[1]
1. Petroleum Exploration and Production Research Institute, SINOPEC, Beijing, CHINA
E-mail: lvxr.syky@sinopec.com

Keywords: fracture-cavity carbonate reservoir, paleo karstic underground rivers, geological knowledge base, multi-point geostatistics method, training image, geological modeling

Paleo karstic underground river system is one of the three major karst types in Tahe oilfield. Controlled by multiple factors such as fractures, ground water level and lithological differences, the paleo underground river system has poor regularity with various shapes and complex structure. Currently, most people use seismic attributes to scuipt the spatial geometry of the river, but there are some differences between seismic predictions and outcrops in the width of the river, and it is also difficult to characterize the complex internal structure of the river system by using traditional two-point geostatistical methods. Multi-point geostatistical method (MPG) can better represent the developmental morphology and structural patterns of the target body through training images, and at the same time, multiple types of constrained data can be integrated during the construction of training images and modeling, which is a hot spot in the current research of modeling underground river systems. In this paper, geological knowledge base of paleo underground river system is constructed by integrating the outcrop information and reservoir description results. The training images are produced based on the modern karst pipeline and the predicted results of Tahe river system from knowledge base, the predicted width of paleo underground river is corrected by the cumulative probability curve method according to the width of modern karst pipes and their probability distribution. Considering the genesis main control factors, vertical structure and planar morphology of the underground river system, a training image pattern library of the paleo karst river system containing different main control factors is constructed. The training images both simulate the morphological and structural characteristics of typical modern subsurface rivers and reflect the characteristics of the geometric parameters of paleo underground rivers in Tahe area, which are suitable for modeling paleo karst river systems in fracture-cavity reservoirs. Meanwhile, probability body of karst-phase controlled underground river development is constructed based on the frequency of underground river development in different karst zones and different paleolandscapes, seismically constrained underground river development probability body is constructed using the statistical single-well seismic wave impedance and underground river frequency response relationship, and the PR model is used to fuse the two types form a comprehensive probability body of paleo river cave development. Based on the Sensim MPG algorithm, 3D underground river geological model of the S67-T615 is established with a comprehensive probability body as a multivariate constraint. The results show that the reliability of the model is verified by using 3 wells, compliance rate between model and well is increased from 67% to 81.8%, river width is corrected from 30-170 m to 10-50 m, which is more consistent with the reality. The new model realizes the characterization of the structure of the river from a single channel seismic body. New model includes 2 layers of main channels, 6 branch channels, 5 dissolution zones and falling water caves, which effectively characterizes the geometry shape and complex structure of paleo underground rivers, which improves the accuracy of the geological model.

Forgotten eustatic exposure before deep undersea: Paleokarst development of the uppermost second Maokouan member (Guadalupian), north Sichuan Basin, NW South China

Dancheng Zhu[1,2*], Huayao Zou[1,2]
1. State Key Laboratory of Petroleum Resources and Prospecting, China Universiry of Petroleum, Beijing, Changping, Beijing, CHINA
2. College of Geosciences, China Universiry of Petroleum, Beijing, Changping, Beijing, CHINA
E-mail: foreverimage@126.com

Keywords: Global regression, Paleokarst formation, Paleokarst reservoir, Maokou Formation, Sichuan Basin

The Guadalupian Maokouan limestone of the Sichuan Basin is famous for its gas-bearing paleokarst reservoir. Over the years, the uplift and eruption of Emeishan mantle plume has been considered as the formation mechanism of a long period exposure and paleokarst development of the Maokouan limestone at the end of Guadalupian. Besides, the impacts of the great late Guadalupian regression before plume activity (Shen et al., 2019) on the Maokouan exposure processes have been overlooked.

Collaborations of borehole, outcrop and seismic studies indicate the prevalence of paleokarst limestone at the uppermost part of the second Maokouan member, north Sichuan Basin. From the boreholes of southern hilly districts to the outcrops of mountainous north, the karst layers become thinner whereas the overlying marly limestones of the basal third Maokouan member turn into deep-water silicious mudstones and shales gradually, presenting a northward inclining paleotopography. Paleotopography and sedimentary facies are two major controlling factors of the karst development. As a result, the Maokouan paleokarst reservoirs of the north Sichuan Basin are concentrated in the bioclastic shoals of the southern districts.

The silicious, mud-rich deposits are water impervious layers that can exclude the source of paleokarst water from the top of Maokou Formation. Therefore, there should have been an elder unconformity before the deposition of the third Maokouan member, which was contemporaneous with the lowest stand of the Guadalupian global sea level. That is to say, there are two major unconformities in the Maokou Formation: the former one lied at the top of the second Maokouan member after the great late Guadalupian regression, and the latter one had a regional tectonic origin from the Emeishan plume activity, existing between the Maokou Formation and the Lopingian Wujiaping Formation. Since the paleokarst occurrences are much more frequent in the second Maokouan member than the third member, and the shallow carbonate platform shrinking upwards (Meng et al., 2021), it can be deduced that the preceding exposure process should have exerted a profounder influence on the Maokouan limestone than the final one, which is diverse from the previous consideration.

Karst morphological assemblage characteristics of epigenetic paleokarst fractured-vuggy reservoir before the extensive terrestrial plant growth and the macroscopic distribution law of oil and water

Cheng Zeng[1*], Haiying Li[2], Yun Wang[3]
1. The State Key Laboratory of Environmental Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences, Guiyang, Guizhou, CHINA
2. Petroleum Exploration and Production Research Institute, Sinopec Northwest Oilfield Company, Urumqi, Xijiang, CHINA
3. School of Geophysics and Information Technology, China University of Geosciences (Beijing), Beijing, CHINA
E-mail: zcchampion@qq.com

Keywords: Paleokarst landform assemblages, Terrestrial plant growth, Humid tropical/subtropical karst, Fractured-vuggy reservoir, Oil-water distribution

Epigenetic paleokarst reservoir controlled by paleokarst weathering crust is an important type of marine carbonate fractured-vuggy reservoir. In the practice of petroleum exploration and development in northern Tarim Basin, from the perspective of karst hydrogeology and according to the vertical zoning model of modern karst hydrodynamics, the epigenetic paleokarst reservoirs are divided into two subtypes: karst residual hill reservoir and karst paleo-subterranean river reservoir (Lu et al., 2018). Tarim basin is the largest oil-gas bearing basin in Western China. The thick marine carbonate rocks of Lower-Middle Ordovician experienced several tectonic movements and epigenic karstification stages during Caledonian and Hercynian Periods, forming various types of epigenic paleokarst reservoirs (Cai et al., 2020). Since the large-scale emergence of terrestrial plant life was covered by these karstification periods, it is of great geological significance to explore the impact of extensive terrestrial plant growth on the macro karst landform assemblages from the perspective of karst occurrence theory, and it also has important implications for the exploration and development of marine carbonate epigenetic paleokarst reservoirs.

The buried paleokarst landform assemblages in West District 10 of Tahe Oilfield during the first episode of karstification in the early Paleozoic was reconstructed by the high-quality, full-azimuthal 3D seismic technology. With previous geological, geochemical, and paleomagnetic data, from the perspective of karst genesis theory, the four conditions of lithologic structure, hydrodynamic force, climate and duration of karstification during the occurrence of paleokarst in this area are analyzed. Results show that in the early Paleozoic Period before the establishment of extensive terrestrial ecosystems, even if the lithology (pure carbonate rocks), climate (humid tropics/subtropics) and hydrogeological conditions (large uplift of carbonate blocks) were optimal, the karst landform assemblages of peak clusters and depressions could not be formed. Instead, the karst landform assemblages were relatively flat with shallow dish-shaped depressions. It is implicated that extensive terrestrial plant growth plays an important role in creating large-scale karst landform assemblages of peak clusters and depressions (Zeng et al., 2020a).

Compared with the heterogeneity of karst water-bearing medium in modern humid tropical or subtropical regions, it seems that the paleokarst water-bearing medium developed under similar karstification conditions is more uniform before the large-scale emergence of terrestrial plant. This also means that the paleokarst aquifer developed before the terrestrial plant growth has more obvious characteristics of stratoid weathered fissure aquifer. Therefore, after the stratoid paleokarst aquifer formed in the early Paleozoic was buried by mudstone caprock, the paleotectonic pattern between lateral hydrocarbon charging and fractured-vuggy body sealing generally established the macroscopic pattern of oil-water distribution (Zeng et al., 2020b). This has been gradually observed in the development practice of Tahe Oilfield.

Filling characteristics and forming conditions of pale-karst river in carbonate platform denudation zone: A case study from middle Ordovician S65 karst conduit in Tahe Oilfield

Chenhe Zhang[1], Zhiqian Gao[1*], Tailiang Fan[1], Jun Wu[1], Duan Wei[1]
1. School of Energy Resources, China University of Geosciences Beijing, Beijing, CHINA
E-mail: gzq@cugb.edu.cn

Keywords: Karst conduit,Platform denudation area,Filling characteristics,Formation condition,Tahe oilfield

The Ordovician karst river is widely distributed in Tahe Oilfield. However, the filling mechanism of karst river in the platform denudation area has not been deeply investigated due to its complex spatial distribution and strong heterogeneity. In this study, the development morphology and filling characteristics of the S65 karst conduit in the carbonate platform denudation area in Tahe oilfied were identified and the filling characteristics was summarized by comprehensive application of logging, core, seismic and laboratory data. Additionally, the formation condition was discussed and the filling pattern was established based on the ancient landscape, water system and other factors. These results show that: (1) The single mechanical (sand and mud) filling or the composite filling with mechanism and collapse breccia (sand-mud cemented collapse) distributes in the sinkhole, and the mudstone or muddy cemented breccia filling distributes in the narrow part of the conduit. (2) The filling of collapse breccia and sand or mud occurs in the intersection of the main conduit, the single collapse filling forms in the intersection of the branch conduit. (3) Chemical filling distributes in karst front, convex bank and narrow area of the conduit. (4) In lateral direction, the extension of pipeline was controlled by the paleo-slope and the position of karst conduit was determined by the faults distribution. In vertical direction, the greater differences between the thickness and resistivity of the top of surrounding rock and the bottom of tight layer, the easier to be dissolved and to form karst conduit.

Reservoir forming model and key technology of ultra deep marine carbonate fault solution

lu xinbian[1], wang yan[1*], hu wenge[1]
1. SINOPEC Northwest Oil Field Company, Exploration and Development Research Institute, Urumpi, Xinjiang Provice, CHINA
E-mail: wangyan19760902@163.com

Keywords: Ultra deep layer, Carbonate rock, Paleokarst, Tahe oilfield, Shunbei oil and gas field, Tarim Basin

By comparing and analyzing the geological background differences of karst and fault fracture in northern Tarim Basin, three types of fault controlled karst fracture cave reservoirs are proposed: over dissolution residual reservoir, fracture + strong dissolution reservoir and strong fracture + weak dissolution reservoir. Based on this, the fault solution reservoir forming model is established. The core connotation is: "fault solution controlled reservoir, plate fracture cave, deep fault controlled enrichment, vertical dredging, differential accumulation and segmented reservoir formation", It provides a new field for carbonate oil and gas exploration and development. Based on high-precision 3D seismic data, a fault solution description technology with "structural tensor + ant body + porosity inversion" and "residual wave impedance + discontinuity + automatic fracture extraction" as the core is formed, which realizes the characterization of the external contour and internal structure of fault solution reservoirs of different genetic types, with a coincidence rate of 91%. Key development technologies such as three-dimensional optimization of well layout in fault solution reservoir, multi-target in one well, optimization of drilling target and three-dimensional structure well pattern construction technology in plate reservoir have been further established, which effectively supports the efficient development of this type of oilfield. This achievement guides the deployment of more than 300 wells in deep ultra deep carbonate fault solution oil and gas reservoirs in Tahe Area and Shunbei area, implements 150 million tons of development reserves, and builds a production capacity of 3.2 million tons. It has significant economic and social benefits and has a good prospect of popularization and application. It can also provide reference for similar reservoirs at home and abroad.

E-mail: zhyf@swpu.edu.cn

Keywords: meteoric diagenesis, penecontemporaneous stage, platform margin shoal, Ordovician, Gucheng oilfield

The sedimentary facies of Yingshan Formation of Lower Ordovician in Gucheng area is a rimmed platform, and shoal in the the platform margin has the characteristics of large thickness, high proportion and multicycle. The dissolution of meteoric diagenesis in penecontemporaneous stage is an important diagenesis type of pore development in shoal, and the pore layer formed is an important exploration target area. The diagenesis types of meteoric fresh water in the penecontemporaneous stage of Yingshan Formation of Lower Ordovician in Gucheng area mainly include dissolution and cementation. The former is characterized by selective dissolution of the interior and edge of sand cutting in clastic grainstone, and formed harbor-shaped dissolution edge and intragranular dissolution, intergranular dissolution pore, mold pore and et al. The cement formed by cementation is mainly equiaxed granular and bladed calcite, and the cathodoluminescence of the cement is weak, and the trace elements are characterized by low Sr, Na, Mg and high Mn and Fe. Vertically, the dissolution in this area has cyclicity, and 10-13 cycles are developed, which is roughly consistent with the cyclicity of granular beach; It is mainly developed in the middle and upper part of shoal, and the dissolution degree is weakened and the cementation is enhanced in the bottom of the shoal. The vertical cycle of meteoric diagenesis is closely related to the shallowness and frequent exposure of shoal. Laterally, the amplitude frequency of C isotope in the platform margin is significantly higher than that in the open platform, which shows the characteristics of shallow water and sensitive response to sea level change in the platform margin shoal. Therefore, the exploration of this kind of reservoir should mainly look for the highland appearance of shoal on the platform margin.

Keywords: sedimentary microfacies, carbonate reservoirs, high-precision sequence framework, Yijianfang Formation

Abstract: It is of great significance for further exploration in deep-burial carbonates to clarify the distribution of sedimentary microfacies within the high-precision sequence framework and to analyze the influence of sequence stratigraphy and lithologic types on the karst carbonate reservoirs. Based on field outcrop, drilling cores, thin sections, full-bore microscan imaging (FMI) and conventional logging data, the high-precision sequence stratigraphy and sedimentary facies of the Yijianfang Formation in the Tahe Oilfield have been studied to clarify how they control the formation and distribution of carbonate intra-platform shoals. We have identified one third-order sequence, three fourth-order sequences, and then established the high-precision sequence stratigraphic framework. The depositional thicknesses of intra-platform shoal are large in the south and middle of the study area, and are thin in the west and north. In addition, we have identified eight lithofacies types (oolitic grainstone, intraclastic grainstone, bioclastic grainstone, bioclastic packstone, intraclastic packstone, intraclastic wackestone, bioclastic wackestone and mudstone) and four subsequent facies associations were then defined (inter-shoal sea, low-energy shoal, medium-energy shoal and high-energy shoal) within the sequence framework according to different hydrodynamic conditions. Based on the response difference of microfacies types between FMI and conventional logging, we have recognized four response models (blocky, linear, porphyritic and compound). According to the vertical thickness and lateral distribution of carbonate shoal reservoirs, we have concluded the favorable zones of carbonate shoal reservoirs are mainly distributed in the central, eastern and southern parts of the study area. This work provides a basis for predicting the distribution of favorable carbonate shoal reservoirs in deep-burial carbonates worldwide.

Discovery and application of paleokarst in slow flow zone in Ordovician of Tahe Oilfield

ming rui Zhao[1*]
1. Experimental Testing Technology Center, Sinopec Northwest Oilfield Company, Urumuqi City, Xinjiang, CHINA
E-mail: zhaorm2008@163.com

Keywords: 3D printing technology,Fractured-vuggy model,Characterization of fractures and vugs,Tahe Oilfield

The Ordovician reservoir in Tahe oilfield has various reservoir spaces, so it is difficult to achieve fine characterization of fracture cavity structure by making fracture cavity physical model based on acrylic or metal container. According to the characteristics of Ordovician reservoirs in Tahe oilfield, a fine imaging technology of carbonate fracture-vuggy reservoir is established, which is based on pre-stack time migration and target fine processing technology,based on the field rock with typical fracture and cavity characteristics, the digital 3D structure of typical core of basic fracture and cavity is proposed. The similarity of geometry, flow and connectivity between the field and the experimental model is compared, and the indoor fracture and cavity physical model which can characterize the fracture and cavity relationship of carbonate rock is established. Deepening the application of 3D printing, the digital 3D model of rock is transformed into the 3D physical model of typical fracture cavity structure, and the effective simulation of complex fracture cavity body is realized. The model breaks through the bottleneck of conventional visualization and pressure bearing, and has the characteristics of true three-dimensional, high pressure bearing capacity (up to 15MPa) and fine characterization, which provides strong support for the in-depth study of oil-water flow law in fractured vuggy reservoirs.

Seismic geomorphology of Ordovician paleo-karst in Ordos Basin

Zhang Hong[1*]
1. Geophysical center, Sinopec petroleum exploration and production research institution, Beijing, CHINA
E-mail: zhanghong.syky@sinopec.com

Keywords: paleokarst, paleogeomorphology, seismic geomorphology,carbonate reservoir,Ordos basin

The paleokarst reservoirs of weathered crust are developed on the top of the Ordovician Majiagou Formation in the Ordos basin.Karst paleogeomorphology is one of the factors controlling the reservoir distributions and quality. The residual layer thickness of the Ordovician Majiagou Formation were primarily used to map paleogeomorphology in the Ordos basin.However, the mapping results always are not enough to identify the complex paleokarst geomorphic units,such as erosion groove because it is very difficult to precisely calculate of the residual layer thickness of the Ordovician Majiagou Formation.Depending on three-dimensional seismic data with high horizontal resolution and logging,core data with high vertical resolution,we have applied the principle of seismic geomorphology to map Ordovician paleokarst geomorphic units using identified appropriate seismic attributes to highlight the characteristics of karst paleogeomorphology based on the analysis of the seismic responses of the paleokarst models and seismic-to-well calibration.The method in this presentation have applied in several study areas in the Ordos basin, which greatly improve the accuracy of paleogeomorphology characterization. The results have also provided imporatant indications of the paleokarst reservoir's internal and external architecture and assitted to predict high-quality carbonate reservoirs.Some drilled wells indicate that the mapping geomorphic units of Ordovician paleokarst are refined and reliable.

Characterization and geomodeling of Ordovician fault-controlled karst carbonate reservoirs in Tarim basin, China

Taizhong Duan[1], Wenbiao Zhang[1*], Zhiliang He[1], Qiqi Ma[1], Meng Li[1]
1. Geomodelling Group, Research Institute of Petroleum Exploration and Development, SINOPEC, Beijing, CHINA
E-mail: zwb.syky@sinopec.com

Keywords: Carbonate, Fault-controlled karst reservoir, Characterization, Geomodelling, Architecture elements, Deep learning

Fault-controlled karst carbonate reservoirs (FCKR) is one of the most important, deeply-buried Ordovician hydrocarbon reservoirs in Tarim basin, China, in which both faults-fractures and karsting features such as vugs and caverns contribute to the reservoir storage spaces. FCKR can further be recognized to be consisted of matrix, fractures, fault core complex, karsting caves, and vugs zone. Seismic texture or tension analysis can be used to recognize and distinguish fault-controlled karst systems from the surrounding matrix without faults; combined curvatures, anttracking and deep machine learning techniques used to recognize the subseismic faults-fractures, fault core complex and caves with higher accuracy and resolution. Geological rock type model is constructed compositely based on hierarchical architecture elements recognized in seismic data and further calibrated with well loggings. The improved relationship of porosity and elastic impedance is used to simulate reservoir porosity model, and all property models are readjusted and calibrated with dynamic data. Geological models built in Shunbei region demonstrate it useful to evaluate wells location before drilling and in production planning.

Comprehensive characterization of deep carbonate paleokarst fracture-cavity reservoirs by multiple means: A case study from the Ordovician Yingshan Formation in the Tahe Oilfield, Tarim Basin, Northwest China

xinyu Yan[1*]
1. Department of geology, Northwest University, Xi'an, Shaanxi, CHINA
E-mail: stella_yin77@163.com

Keywords: Paleokarst reservoirs characterization, Fracture-cavity complexes, Geophysical means, Tahe Oilfield, Tarim Basin

With the improvement of exploration theory and engineering technology, oil and gas exploration has been gradually expanding to deep and even ultra-deep areas around the world. The potential of the deep oil and gas resources in marine kraton basin of China is tremendous, and it is a hot area for research and exploration at present. Compared with shallow layers, deep layers are characterized by deep burial and ancient formation era and large time span, however, the development of deep carbonate paleokarst fracture-cavity reservoirs is almost independent of the burial depth and may form good oil and gas reservoirs. Not to be overlooked is that the multi-phase karst leaching and superimposed fault reconstruction have resulted in a series of problems such as having anisotropy in vertical and horizontal direction and very complex constructional characteristics of deep carbonate paleokarst fracture-cavity reservoirs. To address the above problems, this paper took the carbonate paleokarst fracture-cavity reservoirs of the Ordovician Yingshan Formation in the Tahe Oilfield as an example, (1) identified the small-scale dissolution pores and fractures by optimizing DEN, Vsh, GLLS, and ΔG parameters through logging cross-plot analysis, respectively; (2) divided and characterized different construction units of the reservoir according to karst zoning features by using imaging logging (FMI); and (3) carved fracture-cavity complexes based on 3D seismic multi-attribute to delineate reservoir distribution range. Eventually, a comprehensive multi-means characterization of deep carbonate paleokarst reservoirs had been achieved, and the development pattern of the paleokarst fracture-cavity reservoirs had been established. The results show that the deep carbonate paleokarst fracture-cavity reservoirs of the Ordovician Yingshan Formation in the main area of the Tahe Oilfield are mainly composed of fractures, pores, caves, and other storage spaces, which combine with each other to form a complex fracture-cavity system. The development characteristics of deep carbonate paleokarst fracture-cavity reservoirs are zoned. In the buried hill karst area, crust karst reservoir developed by unconformity karst action and the epikarst - vadose - runoff zones and their construction types are identified. In overlying-aquiclude confining karst area, a great number of bedding karst fracture-cavity complexes develop along the slope controlled by faults, and the development degree of fracture-cavity complexes gradually decreases laterally along the slope direction.

Subsalt karst development model controlled by fault- soluble lithofacies: A case study of middle-lower Majiagou Formation in Daniudi area

Haoxiang Lan[1], Wang X[1*], Meiyan Fu[1], Dong Wu[1], XIa Wang[1], Zhaoheng Liu[1]
1. College of Energy, Chengdu University of Technology, Chengdu, Sichuan, CHINA
E-mail: xuwang19@cdut.edu.cn

Keywords: Majiagou Formation, bedding karst, fault-controlled karst, Ordos Basin

Supergene karstification is widely developed in Majiagou Formation in Daniudi area, Ordos Basin, and karstic breccia can still be seen below Ma_5^6 sub-member. In order to explore the deep karst development model of Majiagou formation and clarify the paleokarst development mechanism below the aquiclude. the main controlling factors of karst development in the middle-lower Majiagou formation are analyzed and summarized based on the petrological, geophysical and geochemical data. The results show that the sedimentary facies in the Daniudi area evolve from evaporative platform to open platform to restricted platform, and the lithology changes from gypsum-salt rock to dolomite and limestone, partially contains gypsum, and soluble lithology is relatively developed; The faults are S-N, NW-SE trending, and are mainly tectonic faults formed in Caledonian and Yanshanian periods. The faults are zonal in plane and can be seen as "karst zone"; The strontium isotope ranges from 0.7086 to 0.7093, which is higher than that of the sea water in the same period, indicating the atmospheric freshwater karst in the epigenetic period, especially in the Ma_5^6 sub-member. Combined with the karstification of the Majiagou Formation, it presents the characteristics of continuous distribution on the plane and near-fault distribution in the vertical direction, and has a good coupling relationship with the plane distribution area of soluble lithofacies, propose a three-dimensional superimposed karst zone model controlled by "shallow lateral recharge + fault vertical and horizontal recharge + soluble lithofacies". In the shallow surface layer of the weathering crust, the lateral bedding karst superimposes the fault-controlled vertical karst, and the lower layer karst is comprehensively controlled by the fault and soluble lithofacies. This model breaks through the limitations of the previous near-surface karst model in the supergene period in Daniudi area, further clarifies the carbonate karst mechanism in deep karst zone below aquiclude, and expands the exploration of karst reservoirs.

E-mail: xuwang19@cdut.edu.cn

Keywords: Ordos Basin,Majiagou Formation,karstification, supergene karst,syngenetic corrosion

In Daniudi gas field, supergenetic karstification still exists in the deeper layers beneath the weathering crust at the top of Majiagou Formation, which is critical to develop reservoir spaces for deep tight carbonate rocks. At present, the karstification law of this formation is relatively limited, which seriously restricts the evaluation of karst reservoir. Based on the core, thin section, well logging and geochemical data, combined with regional tectonic and sedimentary background,the karstification mechanism of middle and lower Majiagou Formation was analyzed from the perspective of karst facies. Four types of karst facies with genetic significance were divided including fracture facies, collapse facies, transport facies and paste solution pinhole facies. Each karst facies indicates the intensity and controlling factors of karst development. The middle and lower Majiagou Formation developed supergene and contemporaneous karstification. The supergene karsts was characterized by lateral and vertical karst water superimposed transformation, which was mainly developed in $Ma5_{6\text{-}10}$ submember, especially in $M5_6$ submember. The contemporaneous karst was developed in $Ma5_7$, $Ma5_9$, Ma4 and Ma2 members, mainly due to the weak transformation of atmospheric fresh water in the relative regression period.The karst development mechanism under the constraint of sequence framework was established according to the factors of karst action, which provided theoretical support for the evaluation and exploration and development of middle and lower Majiagou Formation karst reservoir.

The effects of differential diagenesis on reservoir space of karst paleogeomorphology ---A case study of complex carbonate in Luxi uplift

Yajing zhao[1*], Hancheng Ji[1,2], Yanqing Shi[1,2], Zhibo Yang[1,2]
1. College of Geosciences, China University of Petroleum, Beijing, Beijing, CHINA
2. State Key Laboratory of Petroleum Resources and Prospecting, China University of Petroleum (Beijing), Beijing, CHINA
E-mail: zhaoyj202204@163.com

Keywords: Diagenesis, Reservoir space, Karst palaeogeomorphology, Luxi uplift

Differential diagenesis results in different space forms and physical properties of paleogeomorphic reservoirs. So analysis and study the different diagenesis, be helpful for effective evaluation of reservoir. An integrated study using cores ,thin sections, field outcrop, geological setting, and geochemistry was performed to investigate the characteristics, discuss the diagenesis, and study the influence factors of reservoir in Ordovician carbonates in Luxi uplift. It is found that there are obvious differences in reservoir diagenesis and porosity and permeability in different areas.The Luxi Uplift mainly experienced early Paleozoic to late Paleozoic and Meso-Cenozoic supergenetic karst. Karst highlands are mainly distributed in the east of Lanliao fault, showing strip distribution, and Karst Slopes and depressions are developed in turn to the East. The reservoir spaces are mainly fractures, fractured-caves and caves. The carbon and oxygen isotope values are highly negative, indicating that the karst highland is affected by atmospheric precipitation dissolution. High angle tectonic fractures, dissolution fractures and vertical tensile fractures-caves are developed. Some of them are filled with later buried calcit,with the temperature of cement inclusions is 100-130°C. The porosity of reservoir space is 14.57% and the permeability is $225.74\times10^{-3}\mu m^2$, with good vertical connectivity.The dissolution fluid in the steep slope zone is two directions: vertical and horizontal. Small caves formed at the intersection of fractures and near oval caves are developed. The filling material is calcite, with an average porosity of 13.06% and permeability of $184.95\times10^{-3}\mu m^2$. The vertical and horizontal connectivity of reservoir space is good. The karst gentle slope zone is mainly characterized by horizontal dissolution, cementation and filling, and develops horizontal tensile caves, which are mostly filled with calcite and mud. Karst depressions are eroded, cemented and filled by non directional calcium rich fluids, which are characterized by scattered solution pores and micro solution fractures. Substances carried in diagenetic fluids form granular calcite cement and argillaceous filling. Based on the above understanding, the differential diagenetic reservoir model of different karst paleogeomorphology is established.

E-mail: bo.steven.peng@gmail.com

Keywords: paleokarst,Paleozoic,geochemistry,stable isotope,Qaidam Basin,

The Paleozoic in the Qaidam Basin has developed several sets of carbonate formations, which have experienced multiple stages of uplift and denudation since the Late Paleozoic (Li Zongxing et al., 2016; Liu Kui et al., 2020), and the regional sedimentation hiatus creates favorable conditions for dissolution. This paper takes the Carboniferous fractures - caves and their fillings as the research target in Qaidam basin, and expounds the paleokarst evidence of petrology and geochemistry.

Most of the large carboniferous fractures and caves in the Qaidam Basin exist near the unconformity surface (<100m), except for a few high-angle/vertical fractures and cave. The petrological characteristics reveal that the fractures and caves traversed multiple formations, and the fillings of the caves with later reformation are similar to the characteristics of the dissolution in the epigenetic period .The characteristics of early cement in karstic fissures with ring bands under cathode ray are consistent with that of the phreatic zones of meteoric water recorded in the literature (Huang et al., 2010). The values of $\delta^{18}O$, which are close between the first-stage grey blackish calcareous fillings and granular limestone matrix , indicating surrounding rock should be the source of black calcium speleothems. More detailedly, the values of $\delta^{18}O$ for the first-stage grey blackish calcium speleothems of -9.60 to -8.45‰ (VPDB) are slightly negative compared with that of bioclastic and granular limestone of -8.78 to -7.72 ‰ (VPDB), possibly because that participation of atmospheric water in corrosion of fractures resulted in new sediments which are slightly more negative in the value of $\delta^{18}O$ than surrounding rock. As for the second-stage fine-middle idiomorphic granular calcite cement, its value of $\delta^{18}O$ is more negative and reaches to -13.20 to -11.04 ‰ (VPDB), but is higher than that of calcite deposited from formation water or hydrothermal liquid and similar to the value of calcite from meteoric fresh water (Li et al., 2014).Matrixes and first-stage grey blackish calcium speleothems have relatively concentrated and similar value ranges of $\delta^{13}C$, which are -0.22 to 3.51‰ (VPDB) and 0.32 to 3.72‰ (VPDB), respectively, and both are largely positive. The relatively expanded value range of $\delta^{13}C$ as for the second-stage fine-middle idiomorphic granular calcite cement is between -3.97 to 2.55‰ (VPDB), suggesting more influential factors involve in the diagenesis process.Fresh water inclusions recognized by raman spectrum are the most direct evidences for meteoric fresh water activities in the Carboniferous System, which are found in all speleothems of karstic fissures and caves, mostly in fine-middle crystalline dirty calcite fillings. The salinity converted from the freezing point temperature of the inclusions shows 0.18 to 0.53 wt% NaCl, which also in the fresh water range and corresponds to the Raman spectroscopy test results. The observation ambient temperature of this inclusion is constant at 24℃ to 25℃, and the freshwater inclusions are in single-phase liquid state. According to the $\delta^{18}O$ value of the fine-medium crystalline dirty calcite filling, the calculated fluid $\delta^{18}O$ values are -9.85 to -8.11‰(VPDB), which are close to that of the current range of atmospheric water.

Research on the simulation and evaluation method of logging response of fracture-vug reservoirs: A case study from the Ordovician in Tahe oilfield, Tarim Basin

Xiaochang Wang[1*], Jun Li[1], Song Hu[1], Qiangfu Kong[1]
1. Well Logging Department, Petroleum Exploration & Production Research Institution, SINOPEC, Beijing, CHINA
E-mail: wangxc.syky@sinopec.com

Keywords: well logging, fracture-vug reservoirs, reservoir types, porosity, simulation, interpretation and evaluation

Fracture-vug reservoirs are rich in oil and gas resources, and various types of reservoir spaces are developed by karstification. The pore scales vary greatly, and the filling conditions are complex, thereby resulting in complex logging responses. Therefore, the logging interpretation and evaluation of fracture-vug reservoirs have always been one of the difficult problems in the field of logging research. In view of the difficulty of logging interpretation and evaluation, a set of effective, practical and characteristic logging fine interpretation and evaluation technology for different types of fracture-vug reservoirs have been developed. A set of reduced-scale dual lateral logging response physical simulation system is established to carry out physical simulation, and the three-dimensional finite element method is used to perform the numerical simulation of dual lateral logging response. The combination of the physical simulation system and simulation method produce the dual lateral logging response of fracture-vug reservoirs feature. A logging identification method for fracture-vug reservoir types is established by using the cross-graph decision tree method. A porosity model and a vug and fracture filling identification chart are established by the idea of classification, respectively. A fracture porosity calculation method is established based on the results of numerical simulation. Digital core method is used to establish the permeability model. The classification chart of reservoir level is developed. Finally, the formed logging interpretation methods are organized to form the logging processing interpretation specification for fracture-vug reservoirs, and the logging processing interpretation module is compiled. The processing and interpretation of well data could provide continuous and fine reservoir parameters, afford necessary information for predicting the location of high-quality fracture-vug reservoirs and calculating reserves, and give a reference for logging interpretation and evaluation of the same type of reservoirs.

Discovery and significance of Ordovician paleo-karst caves in shallow drilling on the southern Ordos Basin

Xiaohui Jin[1], Juntao Zhang[1], Dongsheng Sun[1*], Qian Ding[1], Jiaqi Yang[2]
1. SINOPEC Exploration and Production Research Institute, Beijing, Laboratory of Structural and Sedimentological Reservoir Geology, Beijing, CHINA
2. China University of Geosciences, Beijing, School of Energy Resource, Beijing, CHINA
E-mail: sunds.syky@sinopec.com

Keywords: geochemistry, mudstone, cave, Pingliang Formation, Benxi Formation, southern Ordos Basin

The Ordovician sedimentary and karst environment are completely different in the southern margin and central-eastern of the Ordos Basin, and karst reservoir characteristics also are completely different. A shallow drill designed in the southern margin revealed the existence of karst caves filled clastic rock. The shallow drilling encountered two sets of strata in the Benxi Formation and the Pingliang Formation. The lithology of the Benxi Formation is bauxite mudstone. The Pingliang Formation is mainly composed of granstone and algal limestone, in which there are multiple sets of mudstone layers. Using mineral composition, major elements, trace elements and rare earth elements, the source, weathering alteration degree, redox environment, climate and paleo-tectonic environment of the two sets of mudstones were compared and analyzed. Among them, the mudstones of the Benxi Formation represent a higher degree of weathering. The mudstones in the Pingliang Formation are more reductive than the mudstones of the Benxi Formation; the sedimentary environment of the two sets of mudstones was the transitional sedimentary environment of the sea and land in the Late Paleozoic, with frequent climate changes and similar tectonic backgrounds. Mudstone in the Pingliang Formation was formed in a relatively reducing underground environment, wet karst development stage, and southern Ordos basin uplift stage. The composition is terrigenous clastics that have undergone weathering alteration, representing caves and underground river deposits in the pre-Carboniferous karst period. Combined with the widespread development of upper and lower fractures in the mudstone section, it indicates that there was a karst fracture-cave system in southern Ordos basin. Although shallow drilling encountered caves representing collapse and destruction, it can be inferred that there may be residuals in the southern Ordos basin at a suitable paleomorphological location. The fractured caves are the areas that are worth looking forward to for future oil and gas exploration.

Keywords: Karstification, Dolomite reservoir, Upper Cambrian, Tarim Basin

The upper Cambrian dolomite is one of the main potential hydrocarbon producing horizons in northern Tarim Basin. Detailed petrographic and geochemical studies indicate that the genesis of various dolomites is different [1,2] and the development of dolomite reservoirs is still in dispute[3,4].Our research on the cores from TS2 well,YQ6 well and others indicates that karstification probably had played an important role in the development of dolomite reservoirs. A plenty of corrosion pores and fractures are distributed around unconformity, sedimentary discontinuity or strike-slip faults. There is just the significant evidence for karstification that a fracture-cavity filled with sandstones and mudstones was drilled at the depth of 6842m~6846m in TS2 well in platform. It suggest that the fracture-cavity is influenced by terrigenous clastic materials relating to meteoric fresh water on the basis of further mineralogical analysis. We proposed the other strong evidence is that there is a typical vertical percolating zone with massive karst breccias existing in YQ6 well and a plenty of immiscibility inclusions dominantly at 30℃~75℃ in the calcite or dolomite cements, which are the indicator of karstification. It means that a new hypothesis of ultra-deep meteoric fresh water dissolution model may provide a reasonable interpretation about the formation of the upper Cambrian dolomite reservoirs although the exposion period was relatively short. This study provides a useful analogue to understand the development of dolomite reservoirs at deep depth in Tarim basin and elsewhere.

Keywords: magnesium isotope, karstification, paleo-weathering crust, Ordos Basin

Magnesium, as an important constituent element of dolomite, is directly involved in the formation process of dolomite (Zenger et al., 1994). As the first step and one of the most important steps in the global element cycle, the karstification promotes the fractionation of different isotopes (Dessert et al., 2015), and the karst formation are also an important reservoir in dolomite (He et al., 2020). In recent years, with the rise of high-precision Mg isotope experiments, new perspectives have been provided for the continental weathering (e.g. Ning et al., 2020; Gao et al., 2016; Pokrovsky et al., 2011; Peng et al., 2016). In order to improve the fractionation mechanism of Mg isotopes, the Middle Ordovician Majiagou Formation in Ordos was selected as an example, a systematic study was carried out on the influence of the ancient dolomite strata by karstification, and the effect of Mg isotopes on the influence of strong weathering was explored. Combined with petrographic characteristics, C, O, and Mg isotope fractionation, and element concentration characteristics, the results show that Ma51+2 was in the vertical vadose zone, Ma53+4 was in the horizontal underflow zone, and Ma55 was in the deep slow–flow zone. There are two types of dolomitization and three kinds of Mg isotope fractionation trends in the study area.

Various factors control the different trends of δ26Mgdol in karst crust. In the vertical vadose zone, the main control of Mg isotope fractionation is weathering. The δ26Mgdol gradually enriched with the increase of weather intensity, and finally showed downward decrease profile. In the horizontal underflow zone, fluids and late diagenesis jointly control the fractionation of δ26Mgdol, then showed unchanged downward while obviously negative. In the deep slow–flow zone is not restricted by later diagenesis, the main reason for the fractionation was the brine–reflux dolomitization mode, which led to the increase of δ26Mgdol formed later.

Keywords: paleokarst reservoirs,geological model,description method

Paleokarst oil and gas reservoirs are one of the most important fields of oil and gas exploration and development in China. In the past half century, abundant oil and gas resources have been discovered in the paleokarst reservoirs from the Proterozoic to the Cenozoic. It has become two theoretical and technical problems that the industry is concerned about. How to analyze the genetic mechanism of paleokarst reservoirs and establish a geological model? How to describe the reservoir space in detail to support exploration and development?

There are dozens of classification schemes about karstification, and there is a tendency of pan karstification. It should return to the original definition of karstification and highlight the three basic characteristics of paleokarst reservoirs:

geographical environment of long-term exposure of carbonate formations controlled by the third sequence boundaries and up; a fluid environment dominated by terrestrial atmospheric freshwater and coastal mixed water; reservoir space dominated by dissolved pores-fractures-cavities. Through the analysis of typical oil and gas reservoirs in the Tarim, Sichuan, Ordos and Bohai Bay basins, the surface-controlled (Ordos Basin, Ordovician), surface-fault-controlled (Tahe Basin, Ordovician), and surface-face-controlled (Sichuan Basin, Dengying Formation) models were established respectively.

Paleokarst reservoir description methods include: geological analysis, logging, seismic, geological modeling and so on. The content of geological analysis is to establish a detailed genetic geological model through systematic analysis of structure, strata, lithofacies, fluids etc. The content of logging analysis is to identify the storage space type of paleokarst reservoirs and evaluate the reservoirs based on logging data. The content of the seismic description is based on the pre-stack and post-stack seismic data, describing the structure and paleomorphology, stratigraphic structure and lithofacies, and identifying the size and distribution of fractures and caves. The content of geological modeling is to quantitatively describe the boundary, internal structure, physical properties and fluid distribution of paleokarst reservoirs through the integration of multiple disciplines and the support of knowledge data bases. Due to the strong heterogeneity of paleokarst reservoirs and the increasing depth of exploration and development, it is necessary to introduce methods such as big data and artificial intelligence, and establish a multidisciplinary integrated working mechanism to continuously improve the efficiency and effect of exploration and development.

Research progress of Carbonate fault-karst reservoirs and its volume ——Take the Tarim Basin as an example

Qianglu Chen[1*]

1. WUXI Research Institute of Petroleum Geology, Research Institute of Petroleum Exploration and Production, SINOPEC, Wuxi City, Jinagsu, CHINA

E-mail: chenql.syky@sinopec.com

Keywords: carbonate rock, fault-karst reservoir, water-rock interaction, reservoir volume, Tarim Basin

The fault-karst reservoir is a concept model proposed in the exploration research on the southern slope of the Tabei uplift. It refers to the fracture-cave reservoir mainly formed karst reformation in the non-carbonate exposed area with faults as the prerequisite.It is different from conventional epigenetic karst reservoirs. In the transition zone between the Tabei uplift and the Tazhong uplift in the Tarim Basin, the Middle Ordovician limestone and the overlying Upper Ordovician mudstone are continuous deposition, and the mudstone is more than 1000m thick. In recent years, high-yield oil and gas reservoirs with “fault-karst bodies” buried deeper than 6000 m have been discovered in this area. Most of the studies have mainly discussed the control effect of faults on the formation of reservoirs, but few studies have been done about the source of fluids and the transformation effect of fluids on reservoirs. Based on drilling data from multiple wells, This paper researched fluid identification and water-rock interaction by rock-mineral-geochemical analysis. Evidence from inclusions, carbon-oxygen isotopes, and strontium isotopes indicates that there are three types of CO2-rich, S-rich and Si-rich hydrothermal fluids. CO2-rich and S-rich fluids have weak effects on reservoir stimulation and contribute to reservoir space Smaller. Si-rich hydrothermal fluids are widespread and strongly reform carbonate rocks. Through the water-rock reaction experiment of silicon-rich fluid and carbonate rock by using fused silica capillaries, combined with regional geological conditions, the reservoir transformation model of deep carbonate formation dissolution-shallow filling is proposed. The silica-bearing hydrothermal fluid migrates upward along the deep and large faults, passing through the Sinian-Lower Ordovician dolomite layer, where the siliceous components will react with the dolomite to form magnesium-rich silicate and CO2. CO2 is an important acidic component, which is conducive to the dissolution of shallow carbonate and the preservation of pores. Decrease in fluid temperature and pressure, and the presence of CO2 result in the precipitation of quartz, forming large amounts of intercrystalline pores. The CaCO3 produced by the dissolution of the surrounding rock was carried into the shallow part of the fault zone to form calcite veins to fill the existing fault fissures. The activities of hydrothermal fluids are restricted by the geothermal field and the distribution of faults. Based on the reformation mechanism of hydrothermal fluids on reservoirs, favorable reservoir development zones and intervals in the Tarim Basin are proposed and confirmed by drilling.

Ultra deep fault control type reservoir of oil and gas enrichment regularity and development way

Zhijiang Kang[1*], Shoutao Peng[1], Kunyan Liu[1], Fengying Xiao[1], Xiaote Huang[1]
1. Petroleum Exploration and Production Research Institute, China Petroleum & Chemical Corporation, Changping, Beijing, CHINA
E-mail: kangzj.syky@sinopec.com

Keywords: Ultra deep reservoir,fault control type reservoir,Oil and gas enrichment regularity,Oilfield development

Marine Ultra deep fault control reservoir is carbonate rocks is important reservoir type, is also important reservoirs in the recent increase in oil reserve and production in China. Large strike-slip faults control the karst cave, Fracture, holes, discrete distribution, dimension change is big, distribution regularity of understanding difficult. Through the research on static data and development practice, reveals the fault system, karst system, Hydrocarbon Migration Path system is the main controlling factors of oil and gas enrichment: Along the large strike-slip faults vertical oil column height (300-700m), compared with the weathering crust karst , curved shape rivers cave and surface hole growth is less, north east to the main fault Extrusion torsion part tension torsion part and Fault crossing areas in different directions are favorable. Paleogeomorphology slope, Fault connected with the ancient river cave and fracture growth satisfactorily. Along the fault zone of longitudinal cutting depth, strong continuity, outline the space larger volume is good filling system, oil column height. The geological modeling method of "fault control and step-by-step constraint" and the reservoir numerical simulation technology of discrete fracture cave deformation medium are established. Forecasts the development of injection water, gas and nitrogen gas injection effect. Low parts injection water, high parts production, earlier to keep formation pressure, prevent water channeling along the fracture, water injection scheme has been implemented, the effect is better, improve the oil recovery 2-5%.

Controlling effect of Ordovician thrust fault on meteoric karstification in Tahe Oilfield

Heng Zhang[1*]
1. School of Earth Resources, China University of Geosciences, Wuhan, Wuhan, Hubei, CHINA
E-mail: cughzhang@163.com

Keywords: thrust fault, nose-like structure, paleokarst conduit, meteoric karstification, Tahe Oilfield

Tahe Oilfield is the first marine carbonate petroleum reservoir discovered in the Paleozoic in China. Due to the superimposition of meteoric karstification from the Middle Caledonian to the Early Hercynian, a large paleokarst conduit system was generated on the karst platform in the Tahe oilfield. It is one of the most important objects of hydrocarbon development in this area. However, the formation process and main controlling factors of the paleokarst conduits are still unknown. Based on three-dimensional seismic data, drilling and coring data, the thrust-fault system and paleokarst fracture-cave reservoirs in this area were described, the paleo-structural conditions in the Middle and Lower Ordovician were restored, and the controlling effect of thrust-fault on meteoric karstification was discussed. The following results were obtained. 1) The thrust fault system is developed in S80 well region of the Tahe Oilfield, which extends in NNE direction and goes through from the Upper Cambrian to the Middle and Lower Ordovician in vertical. 2) The paleo-structures of the Middle and Lower Ordovician are generally characterized by NE-SW extending nose-like structure, and secondary nose-like structures are formed on both sides of the thrust fault and dip southward. 3) Large paleokarst conduit developed in the Middle and Lower Ordovician, which shows single branch or labyrinth morphology on the plane. And it extends from south to north, mainly distribute between the T74 and T76 interfaces vertically, and has a multi-layer structure. The paleokarst conduit is mainly distributed in the hanging wall of the thrust fault. Compared with the footwall, the development and preservation degree of paleokarst fracture-caves revealed by drilling data is obviously higher. 4) The thrust fault formed in the Middle Caledonian leads to the folding and deformation of the Middle and Lower Ordovician strata. This results in the formation of synclinal structure between secondary nose-like structures, which influences the confluence range of meteoric water from the Middle Caledonian to the Early Hercynian. Furthermore, the thrust fault has obvious water-blocking characteristics, which makes the hanging wall of the thrust fault rich in karst water locally, and promotes the spatial differentiation of the meteoric karstification. These results are of great significance for understanding the formation mechanism of paleokarst reservoirs.

Geochemical Characteristics of a Ordovician Carbonate Cave in Keping Area, Tarim Basin

Chen Li[1], Jian Wei Feng[1*]
1. School of Earth Science and technology, China University of Petroleum (East China), Qingdao, Shandong Province, CHINA
E-mail: 1113082765@qq.com

Keywords: carbonate rock,carbon and oxygen isotopes,strontium isotope,karst,Tarim Basin

Affected by multi-stage tectonic movement and fluid activity events, the Ordovician carbonate strata develop complex karst in Tarim Basin. The geochemical characteristics of carbon oxygen isotope and strontium isotope of typical outcrops in Yijianfang in Keping area are analyzed. The results show that the range of filling $\delta^{18}O$ value is -10 ‰ ~ -6 ‰, and the range of $\delta^{13}C$ value is -0.3 ‰ ~ 0.5 ‰, which is slightly different from the surrounding rock.The paleosalinity value is more than 120, indicating that the sediments are marine origin and formed in the middle and late Caledonian. The $\delta^{13}C$ value of the filling in the cave is less than -0.5 ‰, and the paleosalinity value is less than 120, indicating that the sediments are formed by atmospheric freshwater. The obvious negative $\delta^{18}O$ may be due to the influence of late Hercynian hydrothermal activity or the rise of temperature under burial conditions. According to the strontium isotope test, the $^{87}Sr/^{86}Sr$ value of the filling in the cave is between 0.70955 and 0.7106, which is larger than the $^{87}Sr/^{86}Sr$ value of the O_1 formation of the Tarim Ordovician. The $^{87}Sr/^{86}Sr$ value of surrounding rock ranges from 0.7089 to 0.70922, which is close to the $^{87}Sr/^{86}Sr$ value of Ordovician O_1 stratum, and the formation environment of fillings in this area can be judged accordingly. When the $^{87}Sr/^{86}Sr$ value is significantly higher than 0.7091, it indicates that the filling material and siliceous layer are formed under the action of late Hercynian hydrothermal activity. When the value is slightly higher, the filling is formed in the shallow burial stage due to the effect of formation water or the dissolution fluid carrying strontium. To sum up, the formation of cave is affected by Caledonian movement and Hercynian movement. The filling of surrounding rock and cave is the product of late Hercynian heating fluid, which can provide important research ideas and basis for the prediction of carbonate cave reservoir and reservoir development.

Carbonate Formation Feature Detection from New-Generation Oil-Based Mud Microresistivity Image Logs

Jing Mo[1*]
1. A&I, Schlumberger, chengdu, Sichuan, CHINA
E-mail: JMO@slb.com

Keywords: Vug and Fracture, Carbonate Reservoir, Strata Feature

The Permian Sinian Dengying carbonate formation is one of the main conventional gas production intervals of Sichuan Basin. Vug and cave is the main reservoir space and open fracture is the key to increase permeability. Fracture-vuggy wells typically produce more than 100×104m3/day natural gas and less than 10 ×104m3/day in poor reservoirs. It suggests the formation characterization is key important to Sinian Dengying carbonate reservoirs.

Water-based microresistivity image logs application is relatively mature, However, since those carbonate rocks in Sichuan basin are basically deep or even ultra-deep strata, oil-based mud drilling fluid system has been applied in large scale with a slim hole. What's more, regional study shows that the response of conventional curves to those carbonate reservoirs is often multi-solution. Not only the vug and open fracture will lead to resistivity decrease, but also the formation structure or induced fracuture. The new-generation oil-based microresistivity image logs provide high resolution images with high borehole coverage. It can provide abundant information about vug, open fracture and formation structure to identify different geological significance of resistivity decline.

There are 1 well has new-generation oil-based microresistivity image logs, and then measured water-based microresistivity image logs after replacing mud. The comparation among core data and two different mud system microresistivity image logs in the same interval shows that new-generation oil-based microresistivity image logs can truly reflect vug, fracture and strata structure feature. Due to different principles of measurement, new-generation oil-based microresistivity image logs is more sensitive to strata structure. The size of the fracture and vug has different response on the oil-based mud electrical image logs. The longitudinal width greater than 10cm is characterized by high resistance, 5cm-10cm is characterized by high resistance or low resistivity, and less than 5cm is characterized by low resistivity.

The case study presents how to understand vug, fracture and strata structure feature on new-generation oil-based microresistivity image logs through core and water-based mud microresistivity image logs data calibration. And then, in oil-based mud well, different geological significance of resistivity decline can be realized. It has great guiding significance for reservoir evaluation and fluid identification. Better understanding of reservoir characterization was instructive for acid fracturing design of carbonate gas reservoir as well.

Characteristics and Sedimentary Evolution of Late Ediacaran-Early Cambrian: Insights from Microbialites, Chert, and Phosphorite in South China

Chenyang Bai[1,2*], Bingsong Yu[3], Shujun Han[3], Zhenhuan Shen[3], Ye Wang[4]

4. College of Resource Environmental Engineering, Guizhou University, Guiyang, Guizhou, CHINA
E-mail: Baicy@cugb.edu.cn

Keywords: Ediacaran-Cambrian transition, Microbialites, Chert, Phosphorite, Sedimentary evolution model

The Ediacaran-Cambrian (E-C) transition period witnessed one of the most important environmental changes in Earth's history. The western margin of the South China Block (SCB), a shallow-water environment, shows a complete sedimentary record of the E-C transition. The lithologies of E-C transition layers are complex; therefore, analyzing the source and formation mechanism in different lithologies and mircofacies can help reveal the sedimentary evolution of the E-C transition. Through the profile surveys, it was found that the lithologies of the western margin of the SCB in E-C transition layers are dominated by dolostone, microbialites, chert, and phosphorite. Synthesizing petrological and geochemical evidence, it is determined that microbialites have stromatolitic, thrombolytic, cavities, and sporadic microbial structures. The different structures of microbialites indicate as light difference in hydrodynamic and water chemical conditions. Microcrystalline dolomites form in the syngenesis stage, and the meso- to macrocrystalline and sparry dolomites form in the burial diagenesis stage. The siliceous component is a hot-water source and is carried by upwelling into shallow-water environments. The phosphoric component is mainly controlled by biological activity and upwelling. In the increasing tectonic activity background of the E-C transition period, cyclical upwelling carries more deep source materials into the shallow-water of platform environments, which result in increases in siliceous components and mass microbial death. With mass microbial death, the phosphoric component is enriched in deep-water environments. Then the siliceous- and phosphoric-rich fluids are carried by upwelling and enter the shallow-water environments again. The phosphoric component eventually enter the small shelly animals and deposited in the phosphoric-rich layers of the earliest Cambrian period.

A new model for formation of primary dolomite by subaqueous hydrothermal venting

Zhe Yang[1*]
1. Division of Geology and Mineral Resources, Beijing Research Insititute of Uranium Geology, Beijing , Beijing, CHINA
E-mail: yangzhe_cup@126.com

Keywords: primary dolomites, lacustrine dolomites, rifting basins, northern China

Dolomite is a common constituent of much of the sedimentary record, a host for hydrocarbons and ore minerals, and has attracted immense research interest as an indicator of carbon and magnesium cycles, paleoclimate and the chemical history of seawater. However, modern dolomites are rare in earth surface environment and the processes governing dolomite formation are an actively debated topic of current research.

Our research is motivated by observations of high-temperature dolomite occurring within numerous continental rift basins in northern China, associated with powerful volcanism. These dolomites deposited proximal to normal faults extending from the basement and is interbedded with terrestrially derived lacustrine mudstone. Sedimentological and petrographic characteristics of dolomites reflect their formation in primary and hydrothermal origin. Recently, many batch reactor experiments have successfully synthesized dolomites in the laboratory suggesting that, with a favourable fluid composition, temperatures above 100 ℃ are sufficient to overcome kinetic barriers to nucleation and growth of ordered dolomite. Therefore, integrating our recent field observations with recent experimental results, we suggest that a high heat flow, such as would occur during rifting, could drive convective mixing between hydrothermal and lake waters at temperatures known to facilitate dolomite precipitation. We tend to propose a new model to explain the formation of high-temperature primary dolomites, combining an understanding of the fundamental physics of subaqueous hydrothermal eruptions and known geochemical constraints on the stoichiometry, ordering and Sr and C isotopic composition of the dolomites.

This model has wider application for formations of dolomite in high heat-flux settings such as rifting basins worldwide, as well as implications for high-temperature ore genesis. Furthermore, our work serves to motivate researchers by highlighting the importance of coupling physical and chemical requirements for reactions such as dolomite formation, which will be key not just to understanding dolomitization in rift settings.

Multiphase Dolomitization and Dolomite Reservoir Characteristics in Lower Cambrian, Aksu Area, Tarim Basin, China

Ying Bai[1*]

1. Institute of Petroleum and Natural Gas Geology, Research Institute of Petroleum Exploration and development, Beijing, BEIJING, CHINA

E-mail: baiying81@163.com

Keywords: Dolomitization, Reservoir, Cambrian, Tarim Basin

The Lower Cambrian Xiaoerbulake Formation in the northwestern Tarim Basin consists of a sequence of platform carbonates that are extensively dolomitized. These compound dolomitization reservoirs have significant gas exploration potential, but relevant occurrence and distribution are unclear. This study collected core samples covering dolomite reservoirs from the Xiaoerbulake Formation in the Aksu area. A combination of petrology, fluid-inclusion assemblage microthermometry, and geochemistry data was used to define the dolomitization process and its impact on reservoirs.

The initial microbial dolomitization occurs in restricted environments, characterized by microbial dolostone with depleted $\delta^{13}C$ values. These microbialites were of seawater origin, and they share the same REE (Rare Earth Element) patterns and $\delta^{18}O$ values with limestone from seawater. Micritic dolostone from lagoon and sabkha showing the highest $\delta^{18}O$ values represents sabkha and reflux dolomitization. Besides, some fine crystalline dolostone has a high homogenous temperature. However, its isotopic values fall into the relevant ranges of micritic dolostone, implying the influence of reflux seawater seeping deep into the ground. These samples are mainly near or located in the porous platform margin reef and shoal. Most of the medium to coarse crystalline dolostone came from burial hydrothermal dolomitization, with a homogenous temperature up to 170 ℃. However, relative REE patterns indicate that the direct dolomitization fluids are brine and terrigenous water. Thus hydrothermal fluid may play an essential role in forming dissolved pores filled with medium to coarse crystalline dolostone later.

It is concluded that microbial dolomitization generated moldic and breccia pores, and microbial reservoirs of high porosity and permeability. While in fine crystalline dolomite reservoirs, intercrystalline and oversized dissolved porosities are related to sabkha and reflux dolomitization. This work has shown that deeply buried dolomite reservoirs have good porosities, shedding light on the future petroleum exploration in deeply buried sedimentary basins.

Microstructure of ancient and modern dolomite supports the presence of microbial mediation

Tian Xia[1], Mengze Liu[1*]
1. School of Ocean Sciences, China University of Geosciences, Beijing, Beijing, CHINA
E-mail: lmz0348@163.com

Keywords: dolomite, microbially mediated, microstructure

Dolomite is a common rock in Precambrian strata but only forms in small amounts in modern strata. So far, scientists have still not been able to synthesize dolomite with a 1:1 ratio of Ca^{2+} to Mg^{2+} under normal temperature and pressure. The question of the origin of dolomite has become a huge problem for scientists.

White clasts and globular deposits can be observed in the modern dolomites of the Abu Dhabi Bank. Scanning electron microscope shows that these spheres are partly formed by needle-type minerals and partly composed of rhombohedral crystals (Bontognali et al,2010). Warthmann et al. found dumbbell-type and cauliflower-type dolomite structures in their observations of dolomites mineralized with microbial assistance. They also found dumbbell-shaped pores in dolomite, a structure that suggests that microbially mediated dolomite may be the precursor to ordered dolomite (Warthmann et al.,2000). Dolomite from the Tibetan Plateau (Li et al.,2020) occurs as subspherical and spherical crystals. These crystals are dispersed in the sediment or adhered to the surface of feldspars to form nodular dolomite layers.

The study of ancient dolomites in the Tarim Basin could also find evidence for the presence of microorganisms (You et al.,2013). Microcrystalline dolomite with high euhedral-granular can be observed in the dark layers. The observation of fluorescence microscope for the dark layer shows the possibility that the dark layer is rich in organic matter and a large number of microorganisms exist. Scanning electron microscope observation of the microstructure of the dark layer dolomite can see rhombic dolomite in a relatively good crystalline state and a certain amount of poorly crystallized spherical dolomite. Many spherical grains can be observed on the surface of dolomite crystals at the micron scale, and the dissection of dolomite crystals can reveal a large number of aggregates of small spherical grains.

Currently, three main contributions of microorganisms to the dolomite precipitation process are considered. First, the charged cell surface is easily enriched with metal cations around the surface, creating partial saturation and promoting the nucleation of mineral crystals for production on the microbial surface. Second, the EPS secreted by microorganisms can reduce the activation energy of dolomite precipitation and overcome the kinetic problems. Third, microorganisms change the chemical properties of the solution during the metabolic process to form a high pH environment suitable for dolomite precipitation (Zhang et al.,2015). Moreover, some recent studies have shown that the presence of microorganisms may change the rheological properties of the water column and favor the dolomite precipitation (López H M et al.,2015).

The microstructure of ancient dolomite, which is very similar to that of modern dolomite, largely suggests that microorganisms played a role in dolomite formation. Although the role played by microorganisms in the formation of dolomite is not clearly conclusive, a comparison of the microstructural features of modern dolomite and ancient dolomite can further verify that a large number of ancient dolomites were most likely formed under the process of microbial involvement.

Study on the formation mechanism and identification marks of microbial dolomite

1*

1. , , , , CHINA
E-mail: 738534341@qq.com

Keywords: Carbonate rock,Microbial dolomite,Formation mechanism,Carbon isotope

Abstract: Dolomite is a common carbonate rock, which is widely distributed in carbonate platform. As for its cause, many mechanisms have been proposed by predecessors, but there is no hard evidence for many of them. Recent research results show that dolomite can be precipitated by microorganisms at room temperature to form microbial dolomite. In the early diagenetic process, microorganisms participate in the sulfate reduction reaction and methane anaerobic oxidation reaction, and overcome the thermodynamic obstacles by reducing the concentration of SO_4^{2-} in water, forming CO_3^{2-} and HCO_3^- , increasing alkalinity and pH value, and then precipitate dolomite. In the methanogenesisreaction, CO_3^{2-} and HCO_3^- are formed in the reaction. However, microorganisms in aerobic respiration change the surrounding microenvironment through metabolism to increase pH value and release CO_2 to increase CO_3^{2-} , leading to the medium supersaturation of carbonate to promote dolomite precipitation. The four organic genetic models can aggregate Mg^{2+} and Ca^{2+} in solution to maximize the precipitation of dolomite. Microbial activity and organic matter in the process of dolomite formation is the most important factors affecting the formation of dolomite, and four kinds of organic origin purpose of this article is a systematic mode of basic principle and key data, the formation mechanism of dolomite in carbon isotope characteristics of identification of organic origin dolomite, so as to provide new method and train of thought for the formation of dolomite.

Stable Carbon and Oxygen Isotopic Characteristics of Dolomite from Ediacaran Dengying Formation in Southeastern Sichuan Basin: A Case Study of Well L1

Yifen Wu[1*]

1. School of Ocean Sciences, China University of Geosciences(Beijing), Beijing, Beijing Municipality, CHINA
E-mail: 1011182108@cugb.edu.cn

Keywords: dolomite, geochemical characteristics, Dengying Formation, Sichuan Basin

The stable carbon and oxygen isotope chemistry is an important method used for researching the genesis of dolomite. The oxygen isotope composition of dolomite is dependent on temperature and the original oxygen isotopic composition of fluid, while the carbon isotope composition is affected by the admixture of different sources of carbon, making the dolomite in variable diagenetic conditions have different characteristics of carbon and oxygen isotope. As an important high-quality reservoir, the study of dolomite from Dengying formation has been widely concerned. However, due to the complex diagenetic evolution history and other factors, exploration in the study area is still in a low level. By means of thin section identification and carbon and oxygen isotope analysis, the forming environment of dolomite in well L1 is studied. The sample mainly adopts fine and medium grained crystalline dolomite. 1.The average values of $\delta^{13}C_{PDB}$ and $\delta^{18}O_{PDB}$ are about 2.88‰ and -5.55‰, respectively. It is consistent with the results of previous studies on Dengying Formation in Sichuan Basin. 2.According to the formula proposed by Keith and Weber distinguishing marine brine and freshwater limestone, the Z value representing salinity averages at 127.30, indicating the dolomite in study area was in marine brine during sedimentary period. The conversion of $\delta^{18}O_{PDB}$ (PDB scale) to $\delta 18O_{V\text{-}SMOW}$ (V-SMOW scale) is based on the formula proposed by Coplen. Assuming that the seawater temperature in the Dengying Age was 30 ℃ and $\delta^{18}O_{water}$ is - 6.4 ‰, the reconstruction of paleotemperature shows that the seawater temperature at that time was about 27.6 ℃, which is closed to the assumed value. 3.Previous studies have found spherical dolomite similar to the morphological characteristics of modern precipitated dolomite was developed in the 4th member of Dengying. Nevertheless, the significantly positive $\delta^{13}C$ value and the $\delta^{18}O$ value that comes between - 6.7 and 5.6 ‰ are closed to the figure of methanogenic microorganisms mediated dolomite.The points above lead to a conclusion that the diagenesis of dolomite in study area is related to methanogenic microorganisms.

The Cambrian Carbon Isotope Excursions in the Tarim Basin and Its Sedimentary Significance

Fan Xu[1*], Changsong Lin[1], Hao Li[1], Xuqiao Wu[1], Yan Yi[2], Zhenhong Wang[2], Xing Zhang[2]
1. School of Ocean Sciences, China University of Geosciences, Beijing, Beijing, CHINA
2. Research Institute of Petroleum Exploration and Development, Tarim Oilfield Company, Korla, Xinjiang, CHINA
E-mail: 3011190005@cugb.edu.cn

Keywords: carbon isotope, geological event, Cambrian, Tarim Basin, depositional evolution

By analyzing the existing $\delta^{13}C$ data of the Cambrian in the Tarim Basin, four obvious carbon isotope excursion (CIE) events are identified. From bottom to top, the order is: (1) BAsal Cambrian Carbon isotope Excursion, BACE, ca. 541Ma, maximum ~ -10‰; (2) Redlichiid-Olenellid Extinction Carbon isotope Excursion, ROECE, ca. 509Ma, maximum ~ -14‰; (3) Drumian carbon isotope excursion, DICE, ca. 506.5~503 Ma, maximum ~ -3‰; (4) Top of Cambrian Excursion, TOCE, ca. 485.4Ma, maximum ~ -7‰. These four CIEs are correlated with coeval tectonic-volcanic activities, bioevents and paleoceanographic/paleoclimatic changes. The specific is as follows. "BACE" corresponds to the expansion of the South Tianshan Ocean, the oceanic anoxic event and the Ediacaran organisms extinction, and a set of black rock series are deposited in the basin. "ROECE" corresponds to the global trilobite extinction, and climate changes from wet to dry, in which lagoon-facies evaporites and lime-/dolo- shale replaced the restricted tidal-flat facies carbonate rocks. Moreover, there might be some volcanic activities. "DICE" corresponds to the climate change from dry to wet and transgression in the same period with evaporites no longer. "TOCE" corresponds to the transgression while the open tidal flat limestone gradually replace the thick dolomite. Considering the biological, climatic and tectonic events at that time, combined with the equal changes of the upper and lower lithofacies, logging facies, and earthquakes of these four excursions, they can be regarded as the secondary sequence interface of the Cambrian in the Tarim Basin. The identification of such CIEs helps to define the Cambrian stratigraphic framework in the Tarim Basin. The origins and sedimentary responses of the CIEs influence the lithofacies, well-logging and seismic facies in the basin. Therefore, these 4 CIEs can be regarded as the secondary sequence boundary of the basin scale, which contributes to understand the depositional evolution.

Microbial dolomite of ultra-deep Early Cambrian in the Tarim Basin

Fan Xu[1*], Changsong Lin[1], Hao Li[1], Xuqiao Wu[1], Xinxin Wang[2], Hong Lou[2], Xiaoxue Wang[2]
1. School of Ocean Sciences, China University of Geosciences, Beijing, Beijing, CHINA
2. Research Institute of Petroleum Exploration and Development, Tarim Oilfield Company, Korla, Xinjiang, CHINA
E-mail: 3011190005@cugb.edu.cn

Keywords: microbial dolomite, ultra-deep, Lower Cambrian, Tarim Basin

There are widely discussions about microbial dolomite patterns as an important insight to solve the "dolomite problem". This study is the first to introduce the microbial dolomite found in the ultra-deep Lower Cambrian in the Tarim Basin. The sample is cored from the Wusongger Formation in WXH1, located in the northern Tarim Basin, with a depth of about 7355~7358m. Macroscopically, a large number of dark horizontal laminae are developed, with a thickness of about 1~2mm. The color between the laminae is lighter, but the cross section is still dark gray. It has the total characteristics of stromatolites. After acid dripping, bubbles are generated violently, and the lithology is limestone. Microscopically, obvious red-black band differentiation can be seen in the stained slices. The red is micrite calcite, and the black is not stained. It is shown in the fluorescence photos that the unstained has a strong fluorescence effect, while the fluorescence effect of calcite is very weak. Under the scanning electron microscope (SEM) and analyzed by energy dispersive spectroscopy (EDS), a large number of rhombohedral crystals and ring-shaped mineral aggregates were distributed in the unstained part, in which the Mg/Ca ratio was close to 1:1. The above characteristics all indicate that the undyed part is dolomite. Macro and micro petrographic studies indicate that it was deposited in a hydrostatic environment near the redox zone, as confirmed by elemental geochemical data. To sum up, dolomite is more likely to precipitate with a large amount of organic matter in the environment, or in an environment that is conducive to the preservation of organic matter. In other words, active microbes and/or organics might be a trigger for dolomite formation. This is the first instance of suspected microbial dolomite found in ultra-deep marine strata, in which the degree of rock preservation is better than that in outcrops. In the future, the microenvironment of these dolomite precipitations can be studied through the more precise techniques to reveal the influence of ancient organic matter on dolomite precipitation.

Keywords: Zhaowei Formation,Niyuan Formation,Organic matter,I/(Ca+Mg),hydroxylated surface

The origin of dolomite, known as “the Dolomite Problem”, has plagued geologists for more than a century. Though recent laboratory studies have revealed that biotic or abiotic substances containing carboxyl or hydroxyl groups could induce proto-dolomite precipitation, their applications to ancient dolomites are still difficult. Ribbon carbonate, a type of carbonate rock with centimeter- to decimeter- scaled alternating of limestone and marlstone layers with the latter rich in dolomite, provides an ideal window into exploring dolomite origin. To address this issue, ribbon carbonates from the Neoproterozoic Zhaowei and Niyuan formations in Xu-Huai area were selected as the target in this study. Comprehensive sedimentological, mineralogical and geochemical analyses were carried out in this study, using SEM, EDS, and MC-ICP-MS. The ribbon carbonates are mainly composed of calcite carbonate mud, with non-zero I/(Ca+Mg) values, and are occasionally associated with hummocky cross-bedding, indicating their deposition in an open marine environment with water-depth close to storm wave base. The carbonate mud in them was likely precipitated from a moderately oxygenated water column. Therefore, variations in salinity were unlikely to result in the differential dolomitization through the mediation by halophilic archaea with high-density carboxyl groups on its cell surface. Pyrite grain is rare in both the limestone and marlstone layers, indicating that bacterial sulfate reduction may not be the primary control for the dolomitization either. The positive correlation between Al and Mg/Ca ratio, and the close spatial association between clay minerals and dolomite crystals, suggest that clay minerals may have played an important role in promoting dolomite precipitation. Previous experiments show that clay minerals with hydroxylated surfaces facilitate dehydration of Mg-H_2O complexes, and can serve as sites for dolomite nucleation. As organic matter is often closely associated with clay minerals, it is difficult to evaluate separately the contribution of organic matter to dolomite formation. Clay mineral and organic matter may have both contributed to dolomite precipitation in marlstone layers. This study provided the first geological evidence for clay mineral-mediated dolomite precipitation, and will further help to elucidate the origin of dolomite in deep time.

Deposition Model and Main Factors Controlling Depositional Processes for Microbialites in the Fourth Member, Dengying Formation, Central Sichuan Basin

Anpeng Li[1], Da Gao[1*]
1. School of Geosciences, Yangtze University, Caidian District, Wuhan, Hubei, CHINA
E-mail: gaoda18@gmail.com

Keywords: microbialite, sequence stratigraphy, deposition model, Dengying Formation, Sichuan Basin

In the late Ediacaran period, Dengying Formation in Central Sichuan basin developed continuous and thick microbial carbonates on the carbonate platform, with complex and diverse sedimentary characteristics. At the same time, it is easy to form high-quality oil and gas reservoirs. Therefore, the research on the classification of microbial carbonates types, sedimentary environment, reservoir characteristics and genesis is not only a hot and difficult point in the field of sedimentology, but also one of the focuses in the field of oil and gas geology (Liu et al., 2016; Luo, 2013; Wang et al., 2018). A detailed deposition microfacies analysis was carried out on macrostructures and microfabricsShapiro, 2000Han et al., 2009 using data from drill cores and thin sections. The fourth member of the Dengying Formation in central Sichuan Basin includes mainly eight types of lithofacies which are gray-black horizontal-bedding micritic dolomite, dark-gray wrinkle-laminated dolomite, light-gray wackestone to packstone dolomite, light-gray packstone to grainstone dolomite, thrombolite, stromatolite, thin-bedded micritic dolomite, and breccia. The stromatolite can be further divided into wavy-laminated agglutinated stromatolite, wavy-laminated skeletal stromatolite, and flat-laminated fine-grained stromatolite. According to the stacking patterns, these lithofacies are grouped into four types of lithofacies associations, which are subtidal-restricted lagoon deposition, subtidal thrombolites, shallow-subtidal to intertidal stromatolites to shoal complex, and intertidal stromatolites. Based on the macrostructures, microfabrics, and vertical sequence of the microbialites, the deposition model for the microbialites in the fourth member of Dengying Formation is established. The thrombolites were mainly deposited in the subtidal environment below the wave base, with low hydrodynamic. The clots were locally formed by microbial trapping and binding small grains. The wavy-laminated agglutinated stromatolites were mainly deposited in the lower part of intertidal zone, in which various types of microbe flourish. They were formed by microbial trapping and binding ooids and peloids under strong waves and tides. The wavy-laminated skeletal stromatolites were mainly deposited in the upper part of intertidal zone with moderate hydrodynamic dominated by the tide. The sponge structure were formed by microbial inducing precipitation and in situ calcification, and trapping and binding a small amount of pellets. The flat-laminated fine-grained stromatolites were mainly deposited in the upper intertidal zone, and deposition processes are predominantly microbial inducing precipitation. According to the core and logging characteristics, the fourth member of Dengying Formation can be divided into five microfacies: tidal flat limited lagoon, shoals, stromatolite mound, thrombolites mound and mound-shoals. On the basis of microfacies division, the sequence framework of the fourth member of Dengying Formation is established, and the distribution law of microbial carbonates is found out. The microfacies distribution in the sequence stratigraphic framework shows that microbial mounds and shoals were located mainly in the upper part of the sequences, which became better-developed from bottom to top in this member of the Dengying Formation. The mound-shoals were more developed at the platform margin, decreasing in scale and continuity at the restricted platform.

Research progress on the microbial genesis of cold-seep dolomite

Mengze Liu[1], Tian Xia[1*]
1. School of Ocean Sciences, China University of Geosciences,Beijing, Beijing, CHINA
E-mail: xtsummer0105@163.com

Keywords: seep dolomite, carbon isotope, microbial mechanism, methane-oxidizing bacteria

Dolomite genesis is a long-term concern in sedimentology. Recently, the perspective that microbial activity promotes dolomite precipitation has rapidly developed. Protodolomite had been discovered in hydrocarbon seeps, which provides new thoughts for solving the problem. (Zhao et al., 2021)

In Japan, the Kuroshima Knoll is a typical area for developing cold-seep dolomite in the modern submarine cold-seep system. The chimney-shaped dolomite is mainly cylindrical, circular, and spiral and is formed by cementing sand and mud with dolomite and calcite on the seafloor of Kuroshima Knoll, Japan. The dolomite crystals in the chimney are tiny, and the contents range from 79.2 to 83.2 wt.%. Its $\delta^{13}C$ is -43.6‰ to -17.0‰, $\delta^{18}O$ is 5.66‰ to 7.92‰ (PDB)(Takeuchi et al., 2007; Wang et al., 2022). Takeuchi et al. suggested that methane is produced by methane fermentation of the organic matter in the Shimajiri Group. This methane forms the methane hydrate layer under the seafloor. When pressure or temperature changes, methane hydrate dissociates, causing methane to seep with the light carbon and the heavy $\delta^{18}O$. Microorganisms oxidize this methane from the depths to form methane-oxidizing bacteria dolomite. (Takeuchi et al., 2007).

The formation mechanism of methane oxidation bacteria dolomite is to use methane oxidation bacteria to oxidize methane, reduce the concentration of SO_4^{2-} in water, form CO_3^{2-} and HCO_3^-, increase alkalinity and pH, overcome thermodynamic barriers, and thereby precipitate dolomite(Moore et al.,2004; Wang et al., 2022). The $\delta^{13}C$ of methane oxidized microbial dolomite is usually below -5‰ and can reach -20‰ (PDB)(Bontognali et al.,2008). The $\delta^{13}C$ of this type of dolomite overlaps with that of sulfate-reducing microbial dolomite, but if it is below -10‰ (PDB), it is methane-oxidizing microbial dolomite(Wang et al., 2022).

Ancient cold-seep carbonates containing large amounts of dolomite were developed in Taiwan. Cold seep dolomite occurs as chimneys or lenses in shales of the Early Pleistocene Yanshukeng formation exposed in Chiayi County, southwestern Taiwan, with dolomite as the carbonate mineral and a large number of cold-seep biogenic fossils. The $\delta^{13}C$ of dolomite ranges from -27.08‰ to -10.58‰, indicating that the carbon source may be a mixture of methane and seawater carbon sources. The mean values of Ni/Co and the distribution pattern of REE indicate that the cold seep dolomite was formed in a weakly reducing sedimentary environment(Zhao et al., 2021).

Based on the analysis of the origin of dolomite chimneys distributed in the modern sediments of Kuroshima Knoll, Japan (Takeuchi et al., 2007), combined with the existing knowledge about methane oxidation and anaerobic oxidation of methane (AOM) and the study of the sedimentary environment of the Early Pliocene cold seep dolomite at Chiahsien, Taiwan. It can be speculated that in the weakly reducing depositional environment, methane anaerobic oxidizing bacteria promote the consumption of SO_4^{2-} and the increase of HCO_3^-, which, together with the active microbial action, favor the precipitation of cold-seep dolomite and provide new thoughts to solve the dolomite genesis(Zhao et al., 2021).

Keywords: Crystal Structure, Origin of dolomites, Dengying Formation, Sichuan Basin

The origin of ancient massive dolostones, with a thickness >100 m and a platform-wide distribution in the Dengying Formation of the Yangtze platform, is the intractable issue of the 'Dolomite Problem' that cannot be demonstrated by any existing dolomitization models.Here we report that dolomites of different sizes have different structural characteristics. Based on the exploration of dolostones from outcropscoresand thin sections in the Dengying Formation of Sichuan Basin, three types of dolomite were identified micritic dolomite(3μm)(type D1), silty dolomite3-100μm(type D2) and medium-fine crystalline dolomite100μm(type D3), and ten subtypes because of structural and structural differences. The comparative studies of crystal structure and geochemistry were carried out by utilizing X-ray diffraction and geochemical analysis. Results show that: type D1 is mainly characterized by Primary sedimentary structures, such as massive structures, algal lamina, algal mass, sand debris, stromatolites, etc. which cathodoluminescence(CL) is dull red, crystal parameters (a,c) are small, CaO-MgO positive correlation and Fe/Mn value are high. The Sr/Mn values are low, and the ranges of carbon isotope (δ18C) are similar to that of the seawater at that time. The low negative oxygen isotope (δ18O) (>−10‰), and Strontium isotope (δ18Sr) value is similar to that of the seawater in the late Sinian period. The above researches indicate that it can deposit or be early-dolomitized at the nature of seawater; Type D2 is mainly composed of massive and algal structures. Its CL characteristics are bright red, the a and c are relatively large, and CaO-MgO is negatively correlated. The δ18C values are similar to that of micrite dolomite, and the δ18O values are highly negative (<−10‰). The ranges of strontium isotope are similar to that of type D2. The above research indicates that type D2, experiencing High-temperature burial diagenesis occurs in recrystallization, but its element components not be changed by other fluids; Type D3 mainly distributes in voids, and the CL characteristics are bright red or bright dark interphase rhombohedral shape. The order degree of type D3 is the largest, and CaO-MgO is negatively correlated. The Fe / Mn values are the lowest, and the Sr/Mn values are the highest. The carbon isotope is more positive than the sedimentary seawater value in the late Sinian period, and the oxygen isotope is high and negative (<-10‰). The above research indicates that it is formed by multi-stage diagenesis in the late diagenetic stage under the action of multiphase fluids.

Paleoclimate and paleo-oceanic environment of the formation of Cambrian dolomite in Keping area, Tarim Basin

Kehui Zhang[1*]
1. School of Ocean Sciences, China University of GeosciencesBeijing, Beijing, CHINA
E-mail: xjuer@126.com

Keywords: Tarim Basin,Cambrian,dolomitization,paleo-climate,paleo-ocean,aragonite sea

The Cambrian to Lower Ordovician in the Tarim Basin is a large-scale carbonate platform, in which evidence of microbial-mediated primary dolomite in the ancient Sabha environment is found in the thick Cambrian dolomite strata (You et al., 2013, 2014, 2015, 2018a, 2018b). In recent years, attention has been paid to the formation of dolomite under the background of paleoclimate and paleooceanography. According to the survey, the Tarim block was located in the lower latitudes of the southern hemisphere during the Cambrian period(Huang et al.,2020). Although the sudden change of the global sea level in the Cambrian period may indicate the existence of glaciers, the whole Cambrian period was dominated by a warm "greenhouse" climate. (Babcock et al., 2015). According to measurements of seawater temperature in modern tropical regions, the surface temperature of seawater generally does not exceed 30 °C (Meckler et al., 2015). The temperature of the water for precipitation of dolomite is 30-35 °C. The Awatage Formation in the Keping area in the northwest of the Tarim Basin predominately was deposited in a shallow evaporative environment. The beds are composed of micritic and fine-grained dolomite. They were deposited in the inter-supratidal zone of the lower sabkha and are characterized by frequent sub-aerial exposure surfaces, anhydrite nodules or gypsum pseudomorphs. It was formed in a strong oxidative depositional environment, and was in a strong arid and evaporative environment during this period. The Mg/Ca ratio and Ca2+ concentration of seawater play an important role in microbial precipitation of dolomite. The study shows that the Tarim Ediacaran-Middle Cambrian is a typical glacial-aragonite sea deposit under the background of dry-hot/dry paleoclimate. The dry-hot/dry paleoclimate background and the glacial-aragonite sea deposits have the highest salinity of the diagenetic medium, which in turn affects the degree of dolomitization, resulting in the widespread development of Tarim Ediacaran-Middle Cambrian dolomite (Zhang et al., 2014). Sea water in aragonite-sea deposition was characterized by low Ca2+ content and high SO2- 4 content; salt brine after evaporation was rich in Mg2+, Na+, and K+, from which halite and epsomite (MgSO4) deposited after evaporation, followed by sylvite at last. Paleoclimate and paleo-ocean environment have a controlling effect on the formation and evolution of dolomite reservoirs. At the same time, most of the large-scale dolomite developed in the geological period is closely related to the evaporite. For example, quasi-contemporaneous dolomite appears in the evaporite platform, that is, the period when calcium carbonate sediments have just been deposited and are still in the original depositional environment. The replaced sediments include apatite or micrite magnesium-rich calcite in intertidal-supratidal and gypsum lakes. Evaporite is a soluble mineral that is easily corroded in a short period of time to form pores in humid hot/humid paleoclimates, which may further evolve into porous gypsum (gypsum) dolomite reservoirs with evaporite casting pores. Therefore, most of the Middle Cambrian in the Tarim Basin are the main producing layers of large oil and gas fields.

Geochemical of carbonate platform dolomite in the South China Sea: Take the Xisha region and Nansha region as examples.

1*

1. , , , , CHINA
E-mail: 814425521@qq.com

Keywords: the South China Sea,dolomite,geochemical,dolomitization model

Carbonate platform is one of the most important reservoir types, which contains a large number of biological sediments. The Cenozoic carbonate platform of the South China Sea were developed, and dolomite is common in the carbonate sequences of the Xisha region, and a large number of dolomitized carbonate sequences were developed in Mingji Reef of the Nansha Islands at a similar time of formation. Through the geochemical study of dolomite in well Xike 1, it is found that, the main gas compositions and the lon concentrations of the dolomite-hosted fluid inclusions, and the geochemical characteristics of the carbon and oxygen isotopic compositions of the dolomites indicate that the dolomitizing fluid is concentrated seawater derived from a surface environment. Geochemical studies of the dolomite in well ZK-1 revealed that the selective replacement dolomite is mainly developed at the depth of 180 ~ 289m of the core; In the case of depth exceeding 289m, more occluded replacement dolomite is more common. The pervasive crystallization of dolomite is caused by a combination of slightly evaporated seawater inflow and elevated temperatures, which is considered to occur in the relatively late diagenetic process at larger burial depth. Through the geochemical study of NK-1 core, it is found that the massive dolomite in the middle of Mingji reef is late deposition; their formation is related to the replacement of pre-existing calcite and cement in seawater. Much of the alteration of initial carbonates including dolomitization, probably occurred between about 15 °C and 28 °C and more than 200m below sea level. It is inferred that the fluid composition is related to a brine reflux mechanism. These results help to refine existing dolomitization model of tropical islands.

Genesis of dolomite in cold spring environment of south China Sea

1*

1. , , , , CHINA
E-mail: 976916385@qq.com

Keywords: dolomite,cold spring environment,diagenesis

The origin of dolomite has always been an important problem in the field of sedimentological carbonate rock research. Perfect and ordered dolomite crystals cannot be formed under the test conditions of normal temperature and pressure in the near-surface environment. Dolomite is commonly developed in modern and ancient cold spring environments, and dolomite precipitated in cold spring environments may provide new ideas and new ideas for studying the origin of dolomite in geological history. The cold spring system in the South China Sea develops a high content of dolomite, which is mainly produced in breccia-like, spherical, ellipsoid-like nodules and chimney-like structures with a microcrystalline structure. The carbon isotope values of cold spring dolomite vary greatly, indicating that the main sources of methane leakage from cold springs, dissolved inorganic carbon in seawater, organic matter oxidation, and residual CO2 from methane production, etc., and the changes in oxygen isotope values may be related to the formation of methane hydrate Decomposition, dehydration of clay minerals and deposition temperature, etc. By in-depth study of the relationship between the formation of protodolomite and very high magnesium calcite in the carbonate rocks of the South China Sea and the microbes, it is speculated that the extracellular polymers produced by sulfate-reducing bacteria provide chemically and structurally selectively from the environment. The template captures Mg2+ and Ca2+ in CO32-, and then combines with CO32- to form very high magnesium calcite and dolomite, and finally the very high magnesium calcite is converted into original dolomite. And in the process of dolomite formation, sulfide- and sulfate-reducing bacteria may simultaneously play a role in the precipitation of dolomite.

Classification and origin of microbial dolomite in Qigebulak Formation, Tarim Basin, NW China

Zhuang Ruan[1*]
1. School of Earth Sciences and Resources, China University of Geosciences (Beijing), Beijing, CHINA
E-mail: ruanz0103@cugb.edu.cn

Keywords: Tarim Basin, Qigbulak Fm, Microbial dolomites

A set of carbonate rocks dominated by dolomites were widely developed in the Tarim Basin during the Late Sinian, NW China. Among which, matted and mounds of microbial dolomites were found in the Qigbulak Fm of the Upper Sinian. However, the genesis and formation environment of these dolomites have not been clearly explained. In this study, geological observation, thin section identification and SEM are carried to pursue the the classification and genetic for the microbial dolomite of the middle and upper Qigbulak Fm. The results show that the stromatolites and clotted dolomites are the main types of microbiolites in Qigbulak Fm. The morphology of stromatolites shows mainly columnar, wavy, conical and horizontal stratified. The microtexture of rich microbial structure layer and sparry carbonate cement interlayer (MS/SP), rich organic matter and sparry carbonate cement interlayer(OR/SP), micritic carbonate minerals and sparry carbonate cement (MC/SP) interlayer and carbonate algal spherulite layer and siliceous cements interbed (OC/SiP) could be found in stromatolites. The morphology of clotted dolomites shows dome-shaped or blocky in macroscopically, which could be dived into micritic carbonate gobbet (MG), cavity texture gobbet (CG) and silk sheath texture gobbet (SG). It is considered that the formation of stromatolites is mainly controlled by hydrodynamic conditions and biological development degree. Micritic carbonate gobbet grow or develop in situ while the formation of cavity texture gobbet may be caused by several genies including bowl-shaped microorganisms, independent bacterial "body cavity" or microbial drilling.

Microbial dolomite: Sulfate-reducing bacteria promote dolomitization

[1*]

1. , , , , CHINA
E-mail: 2372297209@qq.com

Keywords: sulfate reducing bacteria, sulfate reduction reaction, dolomite precipitation

The microbial dolomite model is the most breakthrough dolomitization model proposed in the last 20 years. Sulfate-reducing bacteria promote dolomite precipitation was proposed relatively earlier and studied most carefully. The mechanism was first proposed by Vasconcelos and Mckenzie to precipitate dolomite by sulfate reducing bacteria in laboratory conditions, simulating the hypoxic reducing environment of lagoons. Cyanobacteria and sulfate-reducing bacteria in the modern Marine environment have a certain effect on carbonate precipitation. However, it is generally believed that bacterial sulfate reduction is one of the main factors leading to calcium carbonate precipitation in calcified microbial community. The expression of sulfate reduction reaction is summarized as: $CH_2O+SO_4^{2-}\rightarrow HCO^{3-}+HS^{-}+H_2O$. There are a lot of carbonate precipitation inhibition factors in seawater, which makes it difficult for carbonate to precipitate under the condition of supersaturation. This is mainly because Ca^{2+} and Mg^{2+} can easily form a mate bond with SO_4^{2-}, and sulfate-reducing bacteria consume sulfate ions through reduction reaction, increasing the concentration of Ca^{2+} and Mg^{2+} in seawater. At the same time, the formation of HCO^{3-} increases the alkalinity of the solution, affects the saturation index, and directly precipitates the dolomite. However, this model also has problems. A large number of experiments were carried out based on sulfate-reducing bacteria in the modern environment. However, it is not clear whether sulfate-reducing bacteria in geological history are significantly different from modern ones, and whether they have influenced modern dolomite deposition, which requires further research.

The organic substrate suited to facilitate low-temperature dolomite precipitation.

Chen Yan
School of Ocean Sciences China University Of Geosciences, Beijing ,100083

Recent studies have shown that microbial-derived organic matter plays a catalytic role in the precipitation of low-temperature dolomite (Bontognali, T. R. et al. 2010), and the presence of EPS can catalyze the low-temperature precipitation of magnesium dolomite under surface conditions. The pathway of this process was later considered to be the dehydration of Mg2 + promoted by carboxyl group, which acted as a nucleation site to overcome kinetic obstacles. Laboratory experiments showed that salinity also had a certain effect on the precipitation of low-temperature dolomite. In addition to increasing the number of nucleation EPS, salinity also increased the number of available Mg ions. With high salinity and transformation from cyanobacteria to chlorella or saline-alkali bacteria, the amount of EPS extracted and the proportion of carboxyl functional groups increased, which was the ligand for the formation of low temperature dolomite. Some results showed that salinity led to the transformation of microbial communities from oxygen-rich phototrophs to heterotrophic organisms, resulting in EPS conducive to dolomite nucleation (Diloreto et al., 2021). Fluctuations in the environment, especially changes in salinity, and changes in the heterotrophic advantage of microbial mats from oxygen to hypoxia create an organic matrix (EPS) that is particularly suitable for promoting the precipitation of low-temperature dolomite. Specifically, the increase in salinity led to a community dominated by anaerobic phototrophs, which degraded EPS produced by cyanobacteria. This leads to an increase in the concentration of carboxyl functional groups. As is known to all, carboxyl functional groups will promote the dehydration of magnesium and subsequent binding with carbonate minerals.

Formation mechanism of dolomite

Sun Jinghui[1], Zhang Jinming[2]
1.Beijing Geological Environment Monitoring Institute
2.Qingdao Jimo District Natural Resources Bureau

Dolomite has been an important research object of many geologists since it was first described by French historian Deodat de Dolomieu in 1791. As the main sedimentary carbonate rock, the formation mechanism of dolomite has always been one of the most complex, controversial and difficult problems in petrology. Since the 1950s, many experts and scholars have studied modern dolomite and ancient dolomite in the Bahamas, the Persian Gulf and some other areas. They have put forward a series of dolomite chemistry theories, and carried out many important theories and theories on its formation process and mechanism.

The existing studies are preliminarily introduced, including the generation theory of primary dolomite : primary precipitation, quasi-contemporaneous dolomitization, and reflux infiltration dolomitization. It is mainly in a certain hydrochemical conditions replacement precipitation dolomite precipitation way to achieve dolomitization. There are also some theories of secondary dolomite : mixed dolomitization and burial dolomitization ; it is mainly based on the existing calcite and replaces calcium ions in the form of metasomatism under specific water conditions. Although examples can be found to some extent about the previous theories, their harsh formation environment and conditions are not universal. There is still a lack of critical evidence for the specific formation process, and the debates on various theories are still ongoing. In recent years, with the help of microorganisms, some scholars can precipitate and form dolomite at room temperature, which provides a very meaningful direction and idea for the formation theory of dolomite.

Diatoms Diminish Dolomite

Huifang Xu[1*], Yihang Fang[1], Franklin W. C. Hobbs[1]
1. Department of Geoscience, University of Wisconsin-Madison, Madison, Wisconsin, UNITED STATES
E-mail: hfxu@geology.wisc.edu

Keywords: sedimentary dolomite, dissolved silica, the dolomite problem, diatom

There is a great abundance of sedimentary dolomite in the Proterozoic and Lower Paleozoic, but examples of primary dolomite are scarce in the Cenozoic. This discrepancy suggests a poorly understood, but dramatic shift in the geochemical system that inhibited dolomite formation. It has been demonstrated that the presence of 1-2 mM of aqueous $Si(OH)_4$ in high Mg:Ca ratio solutions at room temperature will promote disordered dolomite and even magnesite precipitation and inhibit aragonite formation. Molecular dynamics modeling calculations by show that dolomite growth is catalyzed through adsorption and desorption process of dissolved $Si(OH)_4$ on dolomite surface.

The appearance of diatoms in the Mesozoic greatly impacted the biogeochemical cycle of Si and resulted in the rapid decline in dissolved silica to the micro-molar concentrations observed in the modern surface ocean. To a first-order approximation, the dissolved silica in seawater is positivity correlated with dolomite abundance in marine sediments. This evidence suggests that the diversification of diatoms has greatly impacted the formation of sedimentary dolomite by efficiently removing dissolved silica from seawater. The depletion of dissolved silica in the modern ocean by the effective extraction from diatoms might be responsible for the decline in primary dolomite formation. This study provides a new model for abiotic sedimentary dolomite formation which is likely to be responsible for the significant amount of primary dolomite in the Earth history.

Abiotic driven primary dolomite precipitation in the Great Salt Lake, Utah, USA, catalyzed by dissolved silica

Yihang Fang[1*], Franklin Hobbs[1], Huifang Xu[1]
1. Geoscience, University of Wisconsin-Madison, Madison, Wisconsin, UNITED STATES
E-mail: fang9@wisc.edu

Keywords: Dolomite precipitation, hypersaline lake, dissolved silica, primary dolomite, XRD, TEM

Since the discovery of dolomite, numerous attempts have been made to understand its sedimentation and precipitation mechanism. It has been recognized that the dehydration energy barrier for surface Mg^{2+}-water complex impedes dolomite nucleation and growth. The relationship between microbial life and dolomite has been validated with laboratory synthesis that certain organic molecules, such as polysaccharides, exopolymeric substances, and hydrogen sulfide, could promote dolomite precipitation. However, some dolomite appeared to have an abiotic origin, and previous laboratory work shows that dissolved silica promotes disordered dolomite precipitation at room temperature. The modern occurrence of dolomite in the Great Salt Lake (GSL) has been studied since the early last century, with dolomite mainly dominating sediments in the South Arm sediments while the North Arm sediments are primarily aragonite. This heterogeneous distribution of sediments in GSL provides a perfect case study to understand abiotic dissolved silica-driven dolomite formation. Earlier studies proposed that dolomite precipitation in the GSL was possibly induced by microbial activity. However, this could not explain the lack of dolomite in microbial mats, especially on the North Arm, which is constituted by mostly aragonite with no dolomite. This work demonstrated that dissolved silica concentration and dolomite abundance are positively correlated, suggesting that dissolved silica likely controls dolomite formation in the GSL. Even though the North Arm has a much more concentrated Mg and Ca water from lack of freshwater input, dissolved silica levels in the South Arm (> 0.5 mM) are much higher than in the North Arm (< 0.2 mM). Dissolved silica is provided from streams feeding into the South Arm carries about ~0.2 mM, and is concentrated through evaporation. A high concentration of dissolved silica catalyzed the nucleation and growth of dolomite in the South Arm. However, a significant amount of silica was removed from the solution through adsorption on carbonate and authigenic clay mineral precipitation, resulting in silica-depleted lake water in the North. The dissolved silica catalyzed model explains many sedimentary environment settings of Phanerozoic marine dolomite associated with limestone. The new finding could also provide a new proxy for constructing climate changes in GSL area based on dolomite controlled by the abiotic process.

Characteristics and Genesis of Dolomite in the Lower Cambrian Xiaoerbulake Formation in the Western Margin of the Tarim Basin, China

Hui Zhou[1*]

1. Department of petroleum and natural gas geology, Research Institute of Petroleum Exploration and Development, Beijing, CHINA

E-mail: zhouhui03@petrochina.com.cn

Keywords: dolomitization, dolomite, in-situ geochemical test, Cambrian, Tarim Basin

The Lower Cambrian Xiaoerbulake Formation in the western Tarim Basin consist of shallow-water carbonates which have been pervasively dolomitized. Petrological and geochemical analyses were obtained in order to clarify the dolomite genesis and identify the dolomitization model by using the latest core data of Well XKD-1 in the western margin of the basin. The bulk rock geochemical data include strontium, carbon, and oxygen isotopes, and in-situ minor element and rare earth element measurements for different dolomite types by LA-ICP-MS. Four types of lithofacies were recognized in the Xiaoerbulake Formation based on different textures, which are laminated dolostone (LDS), thrombolite dolostone (TDS), bacteria-bonded dolostone (BDS), and grain dolostone (GDS). These lithofacies were interpreted to be deposited from intertidal to subtidal environment in an inner-ramp platform. Two types of dolomites were identified: matrix dolomite (MD) and cement dolomite (CD). MD is the primary type of laminated and bacteria-bonded dolostone, and CD developed mainly from grain dolostone and thrombolite dolostone. The δ13C and δ18O indicate that the grain dolostone and thrombolite dolostone have undergone more intensive diagenetic modification. On the contrary, the diagenetic modification of laminated and bacteria-bonded dolostone are relatively weak, which implies that the dolomitization of the latter two lithofacies occurs penecontemporaneous. The 87Sr/86Sr ratio indicates that the corresponding fluid for dolomitization was seawater or marine-derived fluids. The MD is formed in the penecontemporaneous near-surface stage via the penecontemporaneous dolomitization of seawater or hyper-saline seawater. The dolomitization of CD occurs in the burial environment, but the dolomitization fluid was of marine-source, indicating that the model of dolomitization was seepage reflux. Both types of dolomites are partially affected by hydrothermal activities.

The Role of Microorganisms in the Formation of Dolomite

1*

1. China Southwest Geotechnical Investigation & Design Institute Co.Ltd., China Southwest Geotechnical Investigation & Design Institute Co.Ltd., Chengdu, Sichuan, CHINA
E-mail: 761509265@qq.com

Keywords: Microorganisms, extracellular polymeric substance, Functional groups

Dolomite [CaMg (CO3) 2] is formed in different environments, such as lakes, shallow water, salt water recirculation zone, regional hydrothermal burial and high-salt brine-seawater mixing zone (Warren 2000). Some people mentioned : ' No rock is more concerned than dolomite ' (Van Tuyl 1916), because the controversy surrounding the origin of dolomite is still ongoing, known as the ' dolomite problem ' (Kaczmarek et al., 2017) ; mcKenzie and Vasconcelos 2009 ; warren 2000). The ' dolomite problem ', which emerged more than a century ago (Van Tuyl 1916), highlights two important aspects of its mysterious origins : 1) dolomite is abundant in rock records but rarely in modern settings ; 2) Dolomite cannot be precipitated in laboratory when near-surface low temperature environments of dolomite are found in simulated nature (Fairbridge 1957, Machel 2004).

The role of microorganisms in mineral formation includes changing their microenvironment by changing pH values and redox potentials, thereby altering solution chemistry to facilitate mineral formation (Benzerara et al. 2011). Different functional groups in microbial extracellular polymeric substances (EPS) have adsorption characteristics and metal binding ability. The affinity of these functional groups to metals depends on the pH value that affects their protonation and deprotonation states (Wang et al. 2012). In addition, some microbial active ion exchange mechanisms accelerate the formation of minerals by increasing mineral supersaturation in their adjacent microenvironment (Obst et al. 2009). Minerals generated during biomineralization are called biominerals (Weiner and Dove 2003), including a wide range of minerals, including silicates, iron oxide / sulfides and calcium carbonate (Gadd 2010). The role of microorganisms in carbonate formation was reported in different environmental environments (Eriksson et al., 2010). Zhu and Dittrich 2016). The ability of microbial communities to control carbonate precipitation stems from the effects of microbial metabolism on carbonate alkalinity and carbonate mineral saturation (Dupraz et al. 2009).

Geochemistry data and dolomitization as proxy of environment change during Tertiary

Fouad Al-Kaabi[1*]
1. Research and Development, Iraq Geological Survey, Baghdad, IRAQ
E-mail: fouadsaleem77@yahoo.com

Keywords: Depositional environments, Tertiary, Carbonate rocks, Dolomitization, Ca/Mg ratio, Iraq.

Change in depositional environments from marine to continental during Eocene to Pliocene has reflected by change in deposits from carbonate rocks to clastic sediments in Iraq. However, identifying different formations (Dammam, Jaddala, Ghar, Dibdibba, and Zahra), which are deposited in the southern Desert of Iraq seems to be difficult due to all of them contain the same type of rocks (carbonate rocks).

Geochemical data of sediment cores was successful employed to establish paleoenvironment, paleosalinity, and paleotemperature1. Thus, twenty-four cores, that contain Tertiary period, were collected from Al-Nasiriya project in the south of Iraq. The results show that the concentrations and ratios of some chemical elements are successful used to discriminate different depositional environments. The concentration average of SiO2, Al2O3, Fe2O3, TiO2, Na2O, K2O, P2O5, and Cl was increased from lower to upper part of the sequence of Tertiary, which indicates change in depositional environment from marine in Dammam and Jaddala formations to continental in Dibdibba Formation. Conversely, the concentration average of calcium, magnesium oxides and loss on ignition for these different formations show inverse patterns comparing with other oxides. Moreover, the ratio of Ca/Mg in carbonate rocks demonstrates that ratio is significant increased with change in these formations upward. The average of this ratio was 2.36 in carbonate rocks belong to Dammam Formation, 12.03 in carbonate rocks belong to Jaddala Formation, 18.84 for Ghar Formation, 17.47 for Dibdibba Formation.

The decreasing in MgO values and increasing in Ca/Mg ratio are agreed with change in age from older to younger for these formations. In addition, these changes in MgO and Ca/Mg indicate decreasing dolomitization from older to younger formations. Petrological study confirms that dolomitization in Dibdibba is the lowest compare with other formation, and it is the highest in Dammam Formation.

Therefore, geochemical data can be use accuracy to discriminate different lithologies, units, and formations although they are deposited in different or similar environments.

Microbial dolomite in Cambrian stromatolites in the of Tarim basin, northwest China

XueLian You[1*]
1. School of Ocean Sciences, China University of Geosciences(Beijing), Beijing, CHINA
E-mail: youxuelian@cugb.edu.cn

Keywords: Microbial mediated dolomite in Cambrian, the Tarim Basin, Cambrian seawater, reconstruction

The “Dolomite Problem” has always been one of the difficult and unsolved enigma in sedimentary, which has attracted the attention of Sedimentologists for over a century. This study focuse on microbial dolomites in Cambrian from the Tarim Basin in China, which is highlighted by both microbial tracers through time and/or as a proxy for microbial origin of dolomite and reconstruction of Cambrian seawater. On the basis of sedimentology, petrology, geochemistry and geomicrobiology, after the detailed field work, the results from high-resolution scanning electron microscopy, isotope geochemistry, trace elements, rare earth elements and PHREEQC are proven approach to the origin of microbial dolomite formation and paleo-environment parameters in Cambrian seawater.

Based on documented data, which are combined the microbial geochemistry conditions in bacterial culture experiments with the natural environmental conditions, microbial dolomite mechanisms are divided into two modes: the anaerobic and the aerobic modes, which is involved in sulfate-reducing bacteria, methanogenic Archaea and halophilic aerobic bacteria.The present is the key to the past. The particular morphological characteristics of microbially-mediated minerals and nanoglobule textures in initial nucleation stage preserved in the geological record may be one of the significant biomarkers.

Stromatolites and thrombolites are recognized as the two major components in the Middle and the Upper Cambrian. The microbial micro-facies combinations are indicated in peleaoenvironments for varying water depths and energy. Although the stromatolitic dolomites experienced burial, petrographic structures appear poorly affected by burial overprint, thus, may preserve potential textural, geochemical and isotopic signatures indicative of microbial tracers and past environmental conditions.

Extracellular polymeric substance (EPS) binds different elements, with preference to Si, Mg and Ca and it is composed of fibres arranged in a reticular pattern, would favor epitaxial crystallisation of dolomite on an organic substrate. The concurrence of suitable composition favoured the mineralized microbes and the dolomite nucleation on the substrate.

Additionally, poorly crystallized dolomite formed nanocrystal aggregates preserved in stromatolites that strongly resemble the morphology and size distribution observed in microbial culture experiments. And the mineralogy is confirmed in micro scale in situ by Confocal Raman Microscopy Atomic Force Microscopy. The spherical dolomite, the diameter of 50 ~ 100nm, composed of small spherical dolomite within or between the dolomite crystals and some times they gathered together dumbbell-shaped and chain dolomite sized 50nm ~ 170nm. The palaeo-temperature during dolomite precipitation are calculated based on the temperature dependent fractionation factor between dolomite and water in cuture experiments. The palaeo-temperature of the stromatolitic laminae matches any assumed seawater temperature very well, which is indicative of penecontemporaneous dolomite formation in microbial mats. The boron isotopes of microbial dolomite gives a “ best guess” paleo-pH in Cambrian seawater. The pH value is approximately between 8.1 to 8.6, which is a slight more alkaline than the pH value of modern seawater. Based on microscope observation, paleo-pH, biological communities in micrboal mat, the high concentration of calcium in Cambrian seawater and REE patterns, in this case the dolomites precipitated in microbial mats and biofilms are mediated by aerobic bacteria rather than sulfate reducing bacteria.

Characteristics and Genesis of Cambrian Mound shoal complex Reservoir In Tarim Basin, NW China

Zhang Jun long[1*], Zhang Yuan gao[1], Pan Wen Qing[1], Li Qiang[2]
1. Exploration Department, PetroChina Daqing Oilfield Company, DA QING, Hei Long Jiang, CHINA
2. Exploration and Development Research Institute, PetroChina Daqing Oilfield Company, DA QING, HEI LONG JIANG, CHINA
E-mail: zhangjl_0707@163.com

Keywords: Platform margin,Mound shoal complex, paleo-karst carbonate reservoir,Cambrian,Tarim basin

Cambrian platform margin mound shoal complex was one of the most important hydrocarbon exploration fields in Tarim Basin with the distribution area exceeding 20000 square kilometers, which has strong heterogeneous characteristics and greatly complex reservoir properties. Based on outcrop, cores, thin sections, CT scanning, physical properties datas and geochemical datas, dolomite reservoir characteristics and its genesis of Cambrian platform margin mound shoal complex of Tarim Basin was revealed. Two new understandings have been put forward.

Firstly, according to observation of hundreds of rock samples, Cambrian platform margin mound shoal complex is carbonate uplift composed of various types of microbial dolomite and granular dolomite, which reservoir spaces is dominated by fabric selective reservoir space including dissolved cavities, intragranular dissolved pores, intergranular dissolved pores and biological mold holes, and also develop some none-fabric selective reservoir spaces including structural fractures and intercrystalline dissolved pores. The reservoir porosity ranges from 2.0%-15.2%, and CT scanning shows pore connectivity ranges from 58.9% to 91.8%.

Secondly, Cambrian platform margin mound shoal complex developed karst reservoir, which mainly related to atmospheric fresh water dissolution and vertical distribution has cyclicity. A large number of bedding dissolution, selective dissolution, biological mold pores and bottom showing structures directly indicated that the mound shoal complex reservoir experienced meteoric water dissolution, in addition, geochemical analysis also provide more sufficient evidencesuch as the value of ^{87}Sr / ^{86}Sr ranges between 0.7095 and 0.7108, which is significantly higher than the global Cambrian seawater valuehigh strontium isotopic value and light oxygen isotopic composition, enrichment of Mn and Fe, V / (V + Ni) < 0.46, Sr / Ba < 1 etc. . Sea level fluctuation cycle characterized by the stable $\delta^{13}C$ shows that the karst reservoir of mound shoal complex generaly developed at lower sea level, and the reservoir physical properties are better in the sea-level decline cycle.

Frameworks and sedimentary models of microbial mounds and shoals in the second member of Dengying Formation, Sichuan basin

Jiaxin Ren[1*]
1. , , , , CHINA
E-mail: 1749375404@qq.com

Keywords: Sichuan Basin,Deng 2 Member,Microbial mound,Mound beach structure, Microfacies combination, Sedimentary model

Abstract: microbial mounds and beaches in the second member of Dengying Formation in Sichuan Basin are the focus of recent research and exploration, but the understanding of mound and beach structure and sedimentary model is not clear. Taking the typical outcrop profile of Dengying Formation as the research object, this paper dissects the structure of microbial mounds and beaches and establishes the sedimentary model of microbial mounds and beaches by means of profile measurement, thin section identification and UAV aerial photography modeling. The results show that: the main types of rock in the mound are laminated laminated dolomite, residual granular dolomite, breccia dolomite, crocus dolomite, foam dolomite, argillaceous dolomite and grape lace dolomite. Microbial mound can be divided into five microfacies: mound base, mound core, mound wing, mound flat and mound cover. The mound base is composed of laminated dolomite; The dune nuclei consist of dolomite, crocus dolomite and dolomite dolomite. The hill flank is composed of sandy gravel dolomite; The mound is composed of sandy dolomite and breccia dolomite; The dome is composed of laminated dolomite and micritic dolomite. There are four types of microbial mounds and shoals in Sichuan Basin, including Yangmu type, Gaojiashan type, Xianfeng type and Yangba type. Yangmu type microbial mounds and shoals are located in slope facies area, with a single mound and shoal thickness of 10-12m. The interior is dominated by 1-2 stages of mound core superposition development, and vertically is the microfacies combination of mound base, mound core and mound cover; Gaojiashan type microbial mounds and beaches are located in the facies area outside the platform margin and coexist with the front slope of the mound. The thickness of a single mound and beach is 18-22m. The internal mound and beach is superimposed and developed in 3-4 stages. Longitudinally, it is the microfacies combination of mound base, mound core, mound wing and mound flat; Pioneer microbial mounds and beaches are located in the inner belt facies area of the platform margin and coexist with the post mound lagoon. The thickness of a single mound and beach is 14-15m. The internal mound and beach is superimposed and developed in 2-3 stages. Vertically, it is the microfacies combination of mound base, mound core, mound wing and mound flat; Yangba type micro Hill Beach is located in the facies area within the platform and coexists with the platform. The overall performance is that the hill core and hill wing are alternately developed, and the thickness of a single Hill Beach is 11-13m. On this basis, the microbial mound and beach sedimentary model of denger member, Sichuan Basin is established.

Geological features of slip accumulation in the Lower Cambrian Mantui Formation of the North China Craton Luxi Massif

Yixin Zhang[1], li li[1*]
1. China University Of Petroleum, School of Geosciences, Qingdao, Shandong, CHINA
E-mail: lilywmwys@upc.edu.cn

Keywords: Mantou formation, Collapse accumulation,Carbonatite

The lower Cambrian Mantou formation can be seen in Quantou village, Linqu County, Shandong Province. As a whole, the Mantou formation is a sedimentary assemblage of platform margin facies, and collapse accumulation is found in Quantou village. The overall thickness is 2m thick limestone, the bottom is cataclastic limestone, the upper lithology is purplish red shale with thin limestone, and the scratch with attitude of 265° 51°can be seen on the section with strike of 220°. Under the microscope, two-stage cracks can be seen. The formation of dark mineral filled cracks is earlier than that of calcite filled cracks, symmetrical folds can be seen at the top of collapse accumulation, and the limestone is "pinched out" as a whole, indicating that there were denuded steep slopes in the region or locally in the Cambrian, The discovery and study of collapse accumulation in Mantou formation is conducive to further understand the Paleozoic paleogeomorphology, sedimentary environment and the formation and evolution of ancient buried hills in North China platform, so as to provide reference for the study of Paleozoic petroliferous basins and buried hills in North China platform and the exploration of oil and gas resources.

Carbonate deposition in fluvial systems influenced by hot springs

Lianchao Luo[1*], Enrico Capezzuoli[1], Orlando Vaselli[1], Huaguo Wen[2], Sándor Kele[3]
1. Department of Earth Sciences, University of Florence, Florenze, Tuscany, ITALY
2. Institute of Sedimentary Geology, Chengdu University of Technology, Chengdu, Sichuan, CHINA
3. Institute for Geological and Geochemical Research, Research Centre for Astronomy and Earth Sciences, Budapest, HUNGARY
E-mail: lianchao.luo@unifi.it

Keywords: fluvial carbonate, hot spring, sedimentology, fluvial erosion

Fluvial systems are often characterized by erosion or clastic deposition, but they can also form carbonates which are often termed 'fluvial tufas' (i.e. cold-water carbonates) or 'fluvial travertines' (i.e. hot-water carbonates). The lithofacies and facies association of the latter have been described and constructed based on fossil fluvial travertines, but studies about their modern counterparts are scant, limiting our understanding of fluvial travertines. Therefore, we here studied a modern fluvial travertine system at Bagni San Filippo (Italy) and compared it with reported fluvial travertines with the aim of disclosing processes affecting their deposition.

The depositional conditions of fluvial travertines were found to be very strict. Perhaps only rivers in mountainous terrain, which receive Ca^{2+}- and HCO_3^--rich waters from surrounding hot springs, can form fluvial travertine systems. This is mainly because travertine deposition depends on the flow path of hot spring water and without existing river beds regulating the spring water flow direction, travertine deposition would create other build-ups, like mounds, fissure ridges, and slopes.

Lithofacies compositions in fluvial travertine systems are diverse and complex. Carbonate facies, mixed clastic-carbonate facies, and clastic facies can be all observed and the specific lithofacies in different systems are controlled by the relative contribution of spring water to original river water: the higher contribution of spring water, the more abundant of carbonate facies.

Fluvial erosion may be common and unavoidable in fluvial travertine systems, since the fluvial travertine depositional areas are commonly mountainous areas and thus rainfall events can easily trigger flood events, eroding early formed travertine deposition and depositing clastic deposits. Such erosion is very notable in the studied Italian system and generated various erosional micro-landforms. The dominant erosion processes are abrasion and plucking, while dissolution and cavitation are also present.

Fluvial travertine systems can be divided slope-pool-waterfall subsystems and channel-pool-waterfall subsystems. Such subsystem differentiation is largely influenced by river bed geometry: wide and slightly inclined stream beds would yield widespread travertine slopes and associated slope-pool-waterfall subsystems and display high erosional resistance, while narrow stream beds would generate channels and associated channel-pool-waterfall subsystems and experience strong fluvial erosion.

Overall, this study shows that fluvial travertine deposition is controlled by topography, hot spring contribution, original river bed geometry, and fluvial erosion, and might aid in the interpretation of ancient fluvial travertine systems.

E-mail: yuan_xy@petrochina.com.cn

Keywords: Tectonic imversion, Carbonate plateform, Precaspian Basin, Carboniferous

The PreCaspian Basin is a super petroliferous cratonic basin developed on the Kazakhstan plate. Its eastern margin is adjacent to the Ural orogenic belt, and southeastern margin adjacent to the Tethys fold belt (Volozh et al.,2003; Jin Zhijun et al., 2007). Since the late Paleozoic, the southeastern margin of the PreCaspian Basin has experienced a geological history of stable cratonic platform deposition, evolution of Ural orogenic belt and closure of the Paleotethys Ocean, resulting in the present complex tectonic and sedimentary setting (Alexander, A.C,1999; Liang shuang et al., 2013).

In this paper, the tectonic evolution process of the Carboniferous system in the eastern margin of the PreCaspian Basin is reconstructed by the structural interpretation of the 2D and 3D seismic data and the combination of well-log and seismic data. Based on seismic facies analysis and layer flattening techniques, the favorable sedimentary-diagenetic facies zones such as platform reef, clastic beach and weathered karst zone were identified in comparison with the classical carbonate platform slope deposition models, and the tectonic and sedimentary model in the eastern margin of the PreCaspian Basin was established by structural and depositional reconstruction. The effects of Ural ocean closure and orogenesis on the eastern margin of the PreCaspian Basin is analyzed.

It is concluded that the eastern margin of the PreCaspian Basin underwent slope reversal, fold deformation, strike-slip transformation and differential uplift during the late Hercynian to Indosinian period, resulting in the hiatus, denudation. The hiatus of the Late Carboniferous were favorable to the formation of weathered karst reservoir facies. The tectonic inversion of platform margin carbonate ramp in late Permian was favorable to the formation of limestone shoal lithological reservoirs with updip occlusion. The large strike-slip fault zone is conducive to the formation of fault-fracture compound trap controlled by flower structure, which communicates with deep source rock. The tensional strike-slip fault zone developed in the southern uplift zone is conducive to the formation of fault solution and improves the deep reservoir conditions. Our study reveal the influences of Ural ocean closure and orogenesis on the sedimentation and tectonic deformation of the carbonate ramp of the carboniferous in the PreCaspian cratonic basin, and provide scientific references for the prediction of oil and gas exploration prospects in this area.

Keywords: Pre-salt, Santos Basin, Lacustrine carbonates, Diagenesis, Dolomitization

Aptian carbonate rocks of Santos Basin, in the Brazilian southeastern continental margin, show reservoir quality strongly controlled by the characteristics of the depositional environment and associated diagenetic alterations. This study presents a quantitative approach based on petrography, mineralogy, and geochemical data of the Barra Velha Formation to integrate spatial and stratigraphic distribution of sedimentological and diagenetic aspects and provide insights into the parameters controlling the genesis and distribution of the diagenetic phases of Pre-Salt carbonate reservoirs of Santos Basin.

The Barra Velha Formation consists of a heterogeneous mix of in-situ and reworked grains. The in-situ facies are composed of fascicular calcite (shrubs), spherulites, microcrystalline calcite, and clay minerals, whereas the reworked facies present different proportions of shrubs and spherulite fragments, siliciclastic/volcanoclastic grains, and variable clay content. The facies with higher Mg-clay content predominate in lower structural positions and regions with low relative relief. Higher proportions of spherulites occur in the transitional zones, and fascicular calcite occurs preferentially in the transitional and higher structural positions. Grainstones facies are observed in all depositional environments, but with variations in their composition (intraclasts, siliciclastic/volcanoclastic grain, and clay content). Stratigraphically, facies with higher Mg-clay content predominate in Units 3 (base) and 2 (intermediate), whereas Unit 1 (top) is marked by a greater proportion of grainstones and fascicular calcites. In Unit 1, fascicular calcite crusts tend to expand from the structural high, toward lower areas.

The main diagenetic products and their association with different facies, highlight the roles of depositional setting and primary constituents in the diagenetic processes. The tectonic and climatic context of the BVF favored Mg-clay precipitation that accumulated preferentially in lower structural portions of the basin. Mg-clays also show a preservation pattern strongly linked to the structural setting, with higher structural portions and fault zones more susceptible to their major diagenetic alterations. Dolomite is a major diagenetic phase in the studied samples, followed by silica. These diagenetic phases are largely associated with Mg-clay alteration and predominate in Unit 1. The dissolution of Mg-clays, as well as a major alteration of the carbonate phases, are concentrated in higher structural positions. Given the higher occurrence of faults in these areas and the presence of saddle dolomite, barite, celestine, and fluorite, which are typical products of hydrothermal alteration, part of the dissolution processes may be related to hydrothermal alteration. The depositional and diagenetic aspects indicate a close connection between the hydrochemical evolution of the lake waters and the origin and diagenesis of these deposits.

The depositional evolution and reservoir origin of Upper Cretaceous Cenomanian Mishrif Formation, SW U.A.E

Shun Xia[1], Jinmin Song[1*], Beiwei Luo[2], Congsheng Bian[2], Keran Li[1], Haigang Duan[2], Liji Li[1], Peiguang Yang[2], Qingchun Zhang[2], Xin Jin[1], Lingli Zhao[1], Yuxiang Feng[1]

E-mail: 270922757@qq.com

Keywords: Cenomanian Mishrif Formation, deposition evolution, bioclastic grain bank, reservoir origin, SW U.A.E.

The Upper Cretaceous Cenomanian Mishrif Formation carbonates are the most important hydrocarbon exploration targets in the Arabian Gulf, such as offshore U.A.E., Oman, and southeastern Iraq. The Mishrif Formation could be subdivided into three members, that is, Member Mishrif-1 (M-1), Mishrif-2 (M-2) and Mishrif-3 (M-3) form bottom up according to the lithology and well log data. Based on the seismic, well log data, core description and thin section analysis, it is a weakly-rimmed carbonate shelf in the age of M-1 and M-2, including open platform, platform margin and slope in sedimentary facies. but the depositional evolution and reservoir origin are still questions in SW U.A.E..

The Mishrif Formation reservoirs have undergone complex diagenesis. The diagenesis sequence is as follows: grainstone- micritization- seawater cementation- freshwater dissolution- freshwater cementation- compaction- the first stage of fracture- shallow burial cementation- the second stage of fracture- mid burial cementation- hydrocarbon injection- burial dissolution- latest calcite filling under CL analysis. The dissolution related to the freshwater in pene-contemporaneous stage and hydrocarbon injection in late Oligocene to mid Miocene is responsible for the reservoir formation and retention.

The diagenesis fluids are seawater modified by freshwater, according to major and trace elements, C-O isotope, Sr isotope and fluid inclusion analysis. The major elements of Na, K, Mn, Fe, Sr, Zr, Ti, and U-Th are 0-0.6ppm, 0.1-0.4ppm, 0-50ppm, 0-2ppm, 300-600ppm, 0.5-0.6ppm, 5-20ppm and 0.2-1.5ppm, respectively, in moldic grainstone and grainstone while 1-2ppm, 0.2-0.8ppm, 50-100ppm, 1-8ppm, 400-500ppm, 0.8-2ppm, 20 -40ppm and 1.6-4ppm in mudstone and wackestone. In contrast to the mudstone and wackestone, the moldic grainstone and grainstone are less in elements Na, K, Mn, Fe, Zr, Ti, and U-Th, which indicate the involvement of freshwater and seawater. The ΣREE value of moldic grainstone is 0.55-17.97ppm, and have relatively consistent distribution patterns of REEs with mudstone, with strong LREE enrichment, which means seawater influence in diagenesis fluids. Moreover, δ13C values range from 2.57‰ to 5.34‰, and δ18O values is from –5.33‰ to -8.81‰, within 18 samples. These carbon stable isotope values are positive and oxygen stable values are negative comparison with the C-O isotopic composition of Cretaceous seawater, with a range from 0‰ to 2.3‰ for δ13C and from −1.3‰ to −4.0‰ for δ18O (Veizer et al., 1999), showing the evaporated seawater modified by freshwater in the diagenesis system. The 87Sr/86Sr ratios for the Mishrif Formation range from 0.707279 to 0.707569 (average 0.707466), close to or slightly positive to the estimated 87Sr/86Sr ratio range (0.70725-0.7075) for Cretaceous seawater (Veizer et al.1999), suggesting the freshwater involvement in seawater. The homogenization temperatures of 19 fluid inclusion analysis are 55°C to 85°C, mostly in the range from 80°C to 85°C and the freezing temperatures are from -12°C to 0°C, with -6°C to -4°C in majority. And the salinity of the fluid inclusions is from 2% to 16%, with 3 samples less than 3%, indicating the freshwater influence. In a word, the Cenomanian Mishrif Formation reservoirs are the complicated products of skeletal grain bank, dissolution resulting from the pene-contemporaneous stage freshwater and hydrocarbon injection.

When is the Mixing-Zone, not the Mixing-Zone?

Peter Koenraad Swart[1*], Chaojin Lu[1]
1. Department of Marine Geosciences, University of Miami, Miami, Fl, UNITED STATES
E-mail: pswart@rsmas.miami.edu

Keywords: Diagenesis, Clumped Isotope,Mixing zone

The Allan and Matthews [1] model, widely used to interprete variations in the $\delta^{13}C$ and $\delta^{18}O$ values of diagenetically altered carbonates, predicts that the covariance between C and O isotopes seen in many young carbonate sequences reflects alteration in fluids that represent mixtures of freshwater (with isotopically negative $\delta^{13}C$ and $\delta^{18}O$ values) and marine waters (with relative more positive values). However recent reinterpretations of this zone of covariance, based on the known changes of sea level and the position of the zone of covariance relative to this change, suggests that the region in which the $\delta^{13}C$ and $\delta^{18}O$ values are strongly correlated actually occurs within the freshwater phreatic zone[2], rather than the mixing zone. In order to distinguish the driving force of diagenesis, from the potential product of diagenesis, we suggest that such trends be termed the zones of covariance, rather than mixing zone trends. If the interpretion of Swart and Oehlert [2] is true, then all the alteration and precpitation of low-Mg calcite, is taking place in meteoric waters, with a greater amount in upper portion of the zone and a decreasing proportion lower in the zone of covariance. It follows therefore that the $\delta^{18}O$ values of the fluids forming the calcite cement will be the same throughout the zone of covariance. This concept can be tested through the use of clumped isotopes, a technique that independently measures the temperature of formation, and can in conjunction with the conventional measurement of $\delta^{18}O$ values, be used to determine the $\delta^{18}O$ of the fluids. In order to test this notion we analyzed the Δ_{47}, $\delta^{13}C$ and $\delta^{18}O$ values and the mineralogy of carbonates throughout several cores in which the $\delta^{13}C$ and $\delta^{18}O$ values of bulk carbonates show clearly defined trends from isotopically negative to more positive values. These results will be discussed in this presentation.

Keywords: The Gulf, epeiric sea, carbonate grain, facies distribution

The Gulf is well known for its actualistic sabkha and carbonate depositional environments, but it is also one of the fastest developing regions globally. A shallow-water ramp characterises the southern coastal Gulf with widespread carbonate deposition typified by a series of lagoonal to open marine facies. Previous work compared this setting, specifically the lagoons of Abu Dhabi, with the coastal portions of ancient epeiric seas. To the present day, however, the details of the complex spatial facies distribution and their related sediment particles in the Abu Dhabi lagoons are only in part understood. Here, we present the outcome of a study aiming to provide quantitative data on unconsolidated carbonate sediment components and their spatial and environmental distribution in this region. Data on sediment size, sorting and component analysis of 105 samples are presented. Sediment particles were analysed under a binocular microscope and grouped as bioclasts, lithic clasts, ooids, peloids, micritic sediment and non-carbonate particles. Grain size analysis shows a limited relationship with water depth but a distinct correlation with energy. Sediment samples, collected along a seaward (relatively high energy) to landward (low energy) transect display decreasing grain size. Sorting is typically related to the grain type and depositional setting. Ooid shoals are dominated by very well-sorted and very coarse to coarse ooid sands. Ebb delta lobes, ebb channels and shoreface settings are mainly characterized by well to moderately well-sorted and coarse to medium sized lithic clasts. Mixed bars and relatively deep-water outer lagoon settings are characterised by bioclasts and lithic clasts. Samples collected from mixed bars, affected by current, are typically moderately sorted medium arenitic bioclasts. The sediments from portions of the outer lagoon are rich in lithic clasts and higher concentrations of micrite are present in embayments. Under decreasing hydrodynamic levels, particularly in the middle and inner lagoon, sediments are dominated by poorly sorted medium to fine grade arenites. The abundance of finer-grained micrite increases towards mangrove swamps and islands, reflecting ‘protected waters’ with low energy conditions. Due to higher hydrodynamic levels in the dredged channel systems, sediments of the middle lagoon are moderately well sorted arenitic lithic clasts and peloids. Dredged channels, and other areas with the significant anthropogenic activity of the inner lagoon record a distinct increase of clastic material.

Keywords: Endorheic Lakes, Basin and Range, Microbialites, Lahontan, Great Salt Lake/Lake Bonneville

The Basin and Range hosted several continental lacustrine systems that accommodated extensive microbial carbonate deposits: the Lahontan on the western side (since 48 kyr cal BP) and the Bonneville (from 30 to 11.5 kyr cal BP) and Great Salt Lake (since 11.5 kyr cal BP) on the eastern side. While the eastern domain of the Basin and Range shows a transition from freshwater to hypersaline conditions, the western domain does not show any significant change from the originally freshwater conditions. Mapping and characterization of microbial deposits in both domains allows for a comparison between the different lakes and their specific spatial distribution. The morphology, size and distribution of the carbonate deposits is mainly affected by environmental changes (i.e., seasonal to long-term water level fluctuations, particular geomorphological heritage, fault-induced processes, groundwater seepage, substrates) and have the potential to provide further insights into the reconstruction of paleoenvironments and paleoclimatic changes through time. Although all the lakes show a paleoshoreline distribution of some microbial-rich structures (crusts, hemispheroid, and part of domes) related to climatic-induced lake level variations, the presence of columns and complex domes in the western Basin and Range seems related to groundwater influxes. In the west, the Winnemucca and the Pyramid Lakes, with extensive springs on the flexural margin and along faults generate bigger structures than the ones observed in the eastern Basin and Range lakes. The presence of large size of thinolites, domes, and columns in the western side of Basin and Range appears to respond to local hydrological, fault-related processes and groundwater flows. This contrast in the distribution, composition, and size of the microbial deposits between both sides of the Basin and Range suggests changes in chemistry, physiography and meteoric/groundwater influxes. Furthermore, this work provides a novel model for the formation of abiotic carbonates in lacustrine settings and identifies the role of microbialites to store carbon.

On the formation of reefal microbialites

Joern Peckmann[1*]
1. Institute for Geology, Center for Earth System Research and Sustainability, Universität Hamburg, Hamburg, GERMANY
E-mail: joern.peckmann@uni-hamburg.de

Keywords: No

Precambrian reefs were sustained by microbial primary production, forming stromatolitic and thrombolitic lithologies. During the Phanerozoic, microbial activity persisted in reef ecosystems, yet microbial carbonate became an accessory component of most reef bodies. Exceptions are bioherms and reefs that formed during periods of major environmental perturbation like the earliest Triassic, the time after the end-Permian extinction event, when microbial mats regained a key role in shaping reef ecosystems. However, in spite of an overall Phanerozoic decline of the abundance of microbial carbonate in reefs, in concert with large, transient fluctuations, microorganisms have always been an integral component of reef communities and have contributed to carbonate production. The two main factors held responsible for the abundance of microbial carbonate in reefs are the carbonate saturation state of seawater and the diversification of metazoan. Here, I will look into the mechanisms of how microorganisms, in particular members of the bacterial domain, contribute to the production of carbonate in reef ecosystems. Although cyanobacteria are expected to contribute to carbonate production – through photosynthetic carbon dioxide removal and the interaction of solutes with extracellular polymeric substances – the great majority of geochemical evidence suggest that sulfate-reducing bacteria are the key players of microbial carbonate production in reefs. One factor that may explain such heterotrophy-driven carbonate production is the circumstance that the majority of microbial carbonate has formed within crypts of the reef framework.

E-mail: jreitne@gwdg.de

Keywords: Early Archean, carbonate, REE, Sr isotopic composition

Early Archean carbonates from the Pilbara Craton (Western Australia) occur in a variety of facies, including ca. 3.5–3.4 Ga pillow-basalt interspace carbonates (North Star Basalt, Mt. Ada Basalt, Apex Basalt, Euro Basalt), ca. 3.5 Ga hydrothermally formed bedded chert-carbonates (Dresser Formation), and ca. 3.4 Ga dolomitic stromatolites (Strelley Pool Formation). The carbonates exhibit variable mineralogies, ranging from calcite, through dolomite, to Fe/Mn-rich dolomite (ankerite/kutnahorite). Previous work suggests that the Pilbara carbonates were formed via the following pathways: 1. Abiotic precipitation (interstitial carbonates between pillow basalts); 2. Organomineralization (fine-grained sedimentary carbonates in the Dresser and Strelley Pool Formations as well as carbonate crystals in bedded cherts of the Dresser Formation); 3. Microbially mediated mineralization (stromatolites in the Strelley Pool Formation). Abiotically precipitated carbonates within pillow basalts appear particularly interesting as these records provide valuable insights into environmental conditions and oceanic crust alteration processes on the early Earth. Primary acicular crystal-fans consisting of Mn-rich calcite likely precipitated abiotically from seawater with increased alkalinity as indicated by $\delta^{13}C_{VPDB}$-values (ca. 0±1‰), $^{87}Sr/^{86}Sr$ ratios (0.701795–0.704657), and characteristic REE+Y signatures (LREE-depletions, positive La and Eu anomalies, superchondritic Y/Ho ratios). Their relatively high contents of Mn , Mg and Fe can plausibly be explained by the hydrothermal alteration of the associated basalts, which is well in line with other geochemical characteristics such as relative MREE-enrichments, positive Eu anomalies, and elevated $^{87}Sr/^{86}Sr$ ratios. It seems plausible that the formation of these carbonates was directly linked to intense pumping of seawater through the oceanic crust, and that this process was a significant sink for CO_2 during Archean times. This brief review highlights the meaning of abiotically precipitated carbonates for reconstructing environments, hydrothermal alteration processes, and geochemical cycles on the early Earth.

E-mail: jreitne@gwdg.de

Keywords: organic matter, organomineralization, mineralization, laminae, solution saturation

Widespread ooids throughout most of Earth's history have attracted much attention for a long time, especially in the last 50 years. Nevertheless, their formation mechanisms in terms of abiotic or biotic influences remain disputed. Possibly, not just one way of forming ooids exists. The role of organic matter (OM) in forming ooids is investigated herein, differentiating extracellular polymeric substances (EPS) and degraded OM (independent of the living organisms which it derives from) (Suarez-Gonzalez & Reitner 2021). Triassic and modern ooids have been studied, from the Germanic Basin and Great Salt Lake, respectively, because both are extremely comparable, suggesting similar formation processes (Reitner et al. 1997; Pei 2022). By applying analytical petrography and imaging technique, four types of ooids in both places are distinguished based on cortex. Type A is dominated by radial cortex with indistinct growth lines while type B is dominated by tangential cortex with distinct growth lines. Type C is a mixture of both radial cortex and tangential cortex. Type D is an alternation of radial cortex and tangential cortex. Besides, some compound ooids containing several cores are observed. Radial cortex of the ooids grew into the above Triassic stromatolites, confirming that some ooids could form associated with microbial mats or even within them. Our results suggest that the dynamic balance of EPS and degraded OM shapes the ooid types described. When degraded OM controls mineralization (i.e. organomineralization), radial cortex forms, probably because OM has a relatively weak inhibition of precipitation and there is an increased calcium carbonate saturation. The tangential cortex has closer association with EPS (with stronger inhibition of carbonate precipitation), than the degraded OM involved with radial cortex. The process of exactly how OM interacts with Ca^{2+} to form radial or tangential cortex is so far not fully understood. In the near future, OM, including different varieties of amino acids (proteic material) and polysaccharides should be extracted and characterized to carry out experiments.

Experimental study on bio-induced hydromagnesite mineralization in Bangor Lake, Tibet

Pengcheng Zhang[1], Huaide Cheng[1*]
1. Key Laboratory of Salt Lake Geology and Environment, Qinghai Institute of Salt Lakes , Chinese Academy of Sciences, Xining, Qinghai Province, CHINA
E-mail: chenghuaide@isl.ac.cn

Keywords: Hydromagnesite,Bangor Co,Biogenic

Bangor Co is an inland salt lake in the northern Qinghai-Tibet Plateau with reserves of more than 50 million tons of carbonate (mainly hydromagnesite), and microalgae are widely developed in the lake. At present, there are two main understandings on the formation of natural hydromagnesite: evaporative depositional origin and biological origin. Combined with previous research on the preparation of hydromagnesite in the laboratory, it is found that it is difficult to form huge carbonate reserves under the natural conditions of high altitude in Bangor Co. Therefore, it is speculated that the formation of Bangor's Carbonate may be related to the microalgae in the lake. Based on the above speculations, this study investigated the relationship between the life activities of microalgae and the genesis of Bangor Co hydromagnesite by conducting indoor hydromagnesite crystallization experiments and comparative experiments with or without microalgae natural crystallization. The study found that it is difficult to form hydromagnesite under natural evaporation conditions; Bangor Co microalgae are closely related to the formation of large carbonate reserves in lakes, and microalgae can significantly increase the pH of water (up to 10.564) through photosynthesis , while inducing crystallization and precipitation of carbonate minerals at the nodes of the microalgal network. Therefore, this study confirms that the life activities of Bangor Co microalgae are closely related to the formation of carbonates in the lake.

E-mail: aoehlert@rsmas.miami.edu

Keywords: fish, carbonate, microbiome, isotopes, geochemistry

Carbonate precipitates formed in the intestines of marine fish comprise a significant component of the sedimentary budget of tropical, shallow marine environments. These biologically-mediated precipitates, called ichthyocarbonates, are formed in the intestines of marine fish as a result of their strategy to maintain internal salt and water balance. However, despite the early recognition of co-occurring microbial communities, the role of microbes in the formation of ichthyocarbonates remains unclear. Motivated by this uncertainty, we investigated the impacts of fish- and microbe-based contributions to the formation of ichthyocarbonate. In this study, we conducted tank collection of ichthyocarbonate excreted by the Gulf toadfish (Opsanus beta). Geochemical analysis of ichthyocarbonates from the Gulf toadfish revealed that they are composed of up to 7.5% organic carbon. The average $\delta^{13}C_{org}$ value of the embedded organic matter in ichthyocarbonates was -19.3‰ V-PDB, approximately 1‰ higher than co-occurring fecal pellets. CN ratios of the organic matter preserved within ichthyocarbonate ranging from 6.48 to 9.94, consistent with published ranges for both marine bacteria and fish fecal pellets, demonstrating the need for alternative geochemical approaches to quantify contributions from fish and the intestinal microbiome. Petrographic analysis revealed that ichthyocarbonates are composed of micritic carbonate with evidence of microbial cells occurring throughout the micrite, suggesting that ichthyocarbonates originally formed in intimate association with organic matter and microbial cells. Results of initial 16S rRNA gene sequencing indicate that ichthyocarbonates are associated with a diverse assemblage of microbes employing various metabolic pathways, dominated by Vibronaceae, including *Thaumasiovibrio, Photobacterium,* and *Vibrio spp*. In addition, *Desulfovibrio*, a known sulfate reducing microbe implicated in the precipitation of carbonate in other microbial systems was identified. Thus, our initial data from Gulf toadfish ichthyocarbonates suggest that microbial communities are not solely colonizing the exterior of ichthyocarbonates prior to excretion and may play a role in their formation. In concert, these integrative approaches provide new insight into the complex biogeochemistry of ichthyocarbonate formation and highlight the need for further study of the interplay between fish and microbial community influences on the sedimentary record in shallow marine settings through geological time.

E-mail: miles.frazer@chevron.com

Keywords: Carbonates, Ooids, Factory, Photosynthesis, Ocean Chemistry

Spatial and temporal changes in sediment factory outputs are one of the primary drivers of facies variability within shallow-water carbonate systems. In concert with sediment transport and deposition, fluctuations in sediment production also plays a key role in determining levels of accommodation filling across carbonate platforms. Despite this, relatively few studies focus on quantifying carbonate sediment production; this study addresses this paucity of data by providing quantitative insights into the dynamics of ooid production within the Joulter Cays grainstone factory on northern Great Bahama Bank.

Four submarine-environment monitoring stations (SEMS) were anchored within an active tidal channel for 8 days in April 2019. This array recorded pH, conductivity, water depth and dissolved oxygen levels along a 3.26 km flow path between the open ocean and stabilized sand flat regions of the sand body. Local weather conditions (barometric pressure, temperature, light levels) were monitored from a nearby island. Ocean water samples were drawn from each SEMS site on a near-hourly basis, over the course of a single daytime floodtide. These samples were filtered, analyzed for pH, and titrated for alkalinity within 24 hours. The results were used to calculate the full carbonate system chemistry using the CO2sys ocean chemistry code. Surficial sediments were collected at each SEMS site along a transect perpendicular to the tidal channel axis. A sonar sounding survey was also conducted for the tidal channel to calibrate a high-resolution bathymetry map generated from SPOT satellite imagery.

Results estimate a maximum calcium carbonate precipitation rate of c.7.5 mg CaCO3 per liter of seawater during the observed flood tide and identify two distinct mechanisms that together, maximize ooid formation within the sand body: (1) CaCO3 precipitation from low-residence, high alkalinity waters, delivered from the open ocean and (2) photosynthetically-induced precipitation from long-residence time, tidally recycled, low alkalinity waters. Sediments collected at the outboard SEMS site contain the largest (350-400 µm), most polished, and most spherical ooids with the least evidence of microbial boring, suggesting that here is where growth is most active. Inboard sediments show mean grain sizes below 100 µm and are dominated by peloids and skeletal fragments which may form ooid nuclei.

Results highlight some important complexities associated with where, how and why sediment production occurs within carbonate environments. These complexities are a key driver of facies variability within carbonate platforms, shelves, and reservoirs.

Petrography and biotic/abiotic precipitation of freshwater- spring carbonates in modern caves: example from India

Sanghita Dasgupta[1*], Pooja Bachani[1]
1. Earth Sciences , Indian Institute of Technology Bombay , Mumbai , Maharashtra , INDIA
E-mail: sangu.dg@gmail.com

Keywords: spring carbonate, modern cave, petrography, biocalcification, bacteria, algae

This study investigates the different biotic and/or abiotic mechanisms of precipitation of calcium carbonates in modern spring/tufa system, northeast India. Spring related carbonates hold valuable repositories of information on different mechanisms of biocalcification. A first-time expedition to Mahakal caves near Jayanti, West Bengal, India has been carried out to document and study the stalactite samples. Different stalactites were observed of all forms and shapes. Sample J-2 was collected in an in-situ environmental condition at Dark Zone with Constant Temperature (DZCT), resembling cylindrical shape, converging downward. Sample J-5 was collected at entrance zone (EZ), having irregular shape. Cylindrical, elongated, rod-like stalactites were observed hanging from the cave ceiling. Well preserved architectural structures having alternating laminae/band of mixed calcite and/or aragonite were observed. Petrographical study under microscope reveals evidence in support of neomorphic processes through different mineralogical fabrics and morphologies, along with variations in laminae thickness. Calcified rock sample J-4 was collected from the waterfall cascade along the cave wall. Precipitation of minerals from water dripping is facilitated by different biotic activities. Water sample was also collected to decipher geomicrobiological aspect especially, the diversity of bacteria and algae. Macro-algae, micro-algae and diatoms were observed as well as bacteria were also isolated from stalactite sample to carry out calcite induced experiments in laboratory. The microscopic observation showed Cladophora spp. (macro-algae) filamentous and branched-in nature. Lyngbya (cyanobacteria) and Chlorella spp. (green micro-algae) were also identified. Diatom mainly Navicula spp. was observed during microscopic examination of the same sample. The bacterial sample were isolated after bringing spring water to lab on nutrient agar media. Both gram positive and gram-negative species were present. Morphological features of bacteria such as shape, size surface, color, opacity, elevation and margin were noted after isolating on nutrient agar media. In this research, we have mainly focused on diversity of algae and bacteria and their role in biocalcification.

Sedimentary facies evolution and gas reservoir development model of carbonate platform reef-shoal deposits: a case study of the Changxing Formation and the Feixianguan Formation in the Kaijiang Liangping Trough, eastern Sichuan Basin, China

OUMAR IBRAHIMA KANE[1*]
1. GEOSCIENCE, YANGTZE UNIVERSITY, WUHAN, HUBEI, CHINA
E-mail: oumarkane92@hotmail.fr

Keywords: Reef-shoal, Gas reservoir, Changxing Formation, Feixianguan Formation, Sichuan Basin

Large and medium-size gas fields have been discovered in the platform margin reef-shoal deposits around the Kaijiang-Liangping Trough. In the study area, the Upper Permian Changxing Formation with eight gas reservoirs and the Lower Triassic Feixianguan Formation with fourteen gas reservoirs have declared proven reserves of 477.6×108 m3 and 2084.66×108 m3, respectively. Although the reef-shoal gas resrvoirs of the Kaijiang-Liangping Trough have a great potential, the distribution and prediction of favorable gas reservoir areas is still facing many challenges. Furthermore, the main controlling factors of reef-shoal gas reservoir differences in both sides of the trough lack detailed study. Therefore, it is of great significance to conduct research on reef-shoal sedimentary facies evolution, reservoir distribution, and main controlling factors of gas reservoirs on both sides of the trough. Based on the high-frequency sequence stratigraphic division, the observation of field outcrop profiles, cores, and microscopic thin sections, as well as the interpretation of 3D seismic sections, the sedimentary microfacies evolution and gas reservoir model, as well as a prediction map of favorable reservoir areas were established. In accordance with the interfaces of lithological and facies transition, exposure of unconformity, and electric mutation the Changxing Formation and the Feixianguan Formation were both divided into two third-order sequences and further subdivided into five fourth-order sequences. The studies conducted on the sedimentary facies types and characteristics revealed that the Changxing Formation is dominated by marginal carbonate deposits which are composed of various types of platform including fault-controlled steep slopes, sedimentary steep slopes, and relatively gentle slopes. The determination of the distribution of reef and shoal deposits on both sides of the trough showed that: (1) SQ1 and SQ2 both developed reef and shoal deposits on the West and East sides of the trough with the reef main development occurring in SQ1; (2) the reef bodies on the western side of the trough are of large scale compared to those of the eastern side which are smaller, more uniform, and better connected; (3) the reefs on the west side of the trough mainly accumulate vertically and the platform margin belt on the east side of the trough tends to regress into the platform. The results of this study show that, tectonic paleogeomorphology controls the stage and scale of reef-bank development, and sea-level fluctuations control the superimposed pattern of reef-bank deposits. Furthermore, primitive structural paleogeomorphology and sedimentary background determine the material basis of reef-shoal facies reservoirs, and early exposure dissolution and dolomitization play an important constructive diagenesis effect on reservoir development. The gas reservoirs on the east side of the trough are mainly controlled by reservoir thickness, porosity and permeability, and reservoir heterogeneity. This research clearly investigates the type and characteristics of reef-shoal gas reservoirs around the Kaijiang-Liangping Trough to contribute in the process of high-efficiency and precise development of gas fields in the eastern Sichuan region.

Keywords: western Sichuan Basin, middle Permian, Qixia Formation, dolomite, characteristics, genetic mechanism

Recently, oil and gas breakthroughs have been made in the middle Permian Qixia Formation dolomite reservoir in Western Sichuan Basin. However, they are highly inhomogeneous and the dolomitization mechanism is not clear, which makes it difficult to predict the distribution of high-quality dolomite reservoir. In this study, the lithological and geochemical characteristics of different dolomite types in Qixia Formation in Western Sichuan were comprehensively analyzed. Combined with sedimentary facies and thermal events of Emeishan Large Igneous Province, the action periods and genetic mechanism of different dolomite types were systematically summarized. The results show that the dolomite of Qixia Formation in Western Sichuan is mainly porphyritic dolomite or stratified, and the dolomite is mainly fine grain, followed by medium coarse grain, micrite and saddle dolomite cements. Micrite dolomite is mainly developed at the bottom of the Qixia Formation, mostly stratiform or laminar, porphyritic as well. It is mainly subhedral-anhedral crystal, often accompanied by strawberry pyrite. Some micritic dolomite are sphaerolitic, dumbbell morphology, cauliflower morphology. The δ13CV-PDB values are negative, and δ18OV-PDB values are in the range of normal seawater. These characteristics suggest that micrite dolomite may be produced by microbial-mediated process. Fine crystalline dolomites are developed in both the first and second member of Qixia Formation, generally porphyritic or stratiform, which are mainly euhedral to subhedral crystals with mist-centered bright-edge structure and brown-dark red inside to bright red outside under cathode luminescence. Fine crystalline dolomites have obvious residual grain structure, indicating that the original lithology is grainstone. The δ18OV-PDB values, δ13CV-PDB values and 87Sr/86Sr values of fine crystal dolomites indicate that the dolomitization fluid is seawater, which may be formed by reflux seepage dolomitization with medium salinity during shallow burial period, and often developed in beach reservoirs with good porosity and permeability. The middle-coarse crystalline dolomites mainly develop in the second member of Qixia Formation, which is porphyritic or stratiform, mainly anhedral nonplanar crystals, and mainly dark inside to bright outside under cathodoluminescence. The δ18OV-PDB values are slightly lower than the normal sea water range, indicating that it has been modified by later fluids. The 87Sr/86Sr values of some middle-coarse crystalline dolomites are higher than seawater of the same period, and they are porphyritic or zebra-like, often accompanied by saddle dolomites in vugs. These characteristics indicate that they are directly influenced by thermal fluids of deep clastic rocks. The 87Sr/86Sr values of middle-coarse crystalline dolomite, which are still in the seawater range without saddle-shaped dolomite, may be derived from recrystallization or thermal adjustment of fine crystalline dolomite. In general, the dolomites of Qixia Formation in Western Sichuan Basin have successively undergone syngenetic microbial-mediated dolomitization, shallow burial reflux seepage dolomitization, and late thermal fluid modification, among which shallow burial reflux seepage dolomitization is the main genetic mechanism.

Research on sedimentary compensation and diagenetic transformation mechanism of lacustrine carbonate rocks in gentle slope platform

Qiang Tong[1], Jixin Huang[1*]
1. Inter American Institute, Research Institute of Petroleum Exploration and Development, Beijing, CHINA
E-mail: huangjixin@petrochina.com.cn

Keywords: Santos Basin, lacustrine carbonate rocks reservoir, carbonate platform,sedimentary compensation mechanism,diagenetic transformation mechanism

The deep-water pre-salt lacustrine carbonate rocks reservoir of Brazil is neither of these margin origin nor has the characteristics of lacustrine basins in China, instead, it is formed into a lake by plate tension and rift, featuring deep water and mesa with gentle slope. Due to the existence of multi-stage lake flooding and unconformity, rapid change of sequence boundary, basement tectonic activity, frequent lake transgression and other factors, the paleogeomorphic changes are significant, which leads to a drastically differential sedimentary compensation mechanism in carbonate plateform. Besides, the development of sequence transformation and the spatial-tempral pattern of paleogeography lead to the intensification of diagenetic transformation under the control of sedimentary model, resulting in technical bottlenecks such as complicated reservoir controls genesis and unclear relationship between reservoir and oil deposit. However, there has been no in-depth study on its sedimentary compensation and diagenetic transformation mechanism. Based on the relationship between the base-level change and the accommodation space of the lake basin, this paper will clarify the sedimentary compensation mechanism and the change process of the paleogeomorphology, and describe the distribution of paleogeography in the sequence transformation mode, and then establish the sedimentary model of the huge thick lacustrine carbonate rock. Furthermore, it is necessary to analyze the complex sedimentary diagenesis of lacustrine carbonate rocks by integrating the main controlling factors of reservoir development, and jointly analyze the diagenetic transformation mechanism of forming hige-quality reservoirs. This study will not only have theoretical significance for the understanding of sedimentary compensation mode and diagenetic transformation mechanism of lacustrine carbonate rock reservoir in mesa with gentle slope, but also make an important contribution to the deep-water oil exploration and development in Brazil's santos basin, helping PetroChina to realize its equity production of 100 million tons of petroleum overseas.

Analysis of the Contribution of Different Strike-Slip Fault Zones on Petroleum Charging Episodes in the Shunbei area, The Tarim Basin, NW China

Wei Wu[1], Honghan Chen[1*]
1. School of Earth Resources, China University of Geosciences (Wuhan), Wuhan, Hubei, CHINA
E-mail: hhchen@cug.edu.cn

Keywords: Shunbei area, Strike-slip fault zone, Hydrocarbon charge, Oil inclusion, Contribution, Geochemistry

In recent years, newly discovered ultra-deep fault-karst reservoirs in the Shunbei area of the Tarim Basin have greatly increased the prospectivity of the basin and become a hotspot for further hydrocarbon exploration. However, the formation mechanism of these Ordovician carbonate reservoirs and hydrocarbon charge history appears to be complex and is still the focus of a number of studies. This investigation focused on determining the origin of the reservoir oil based on quantitative gas chromatogram-mass spectrometry (GC-MS) measurements and stable carbon isotope ($\delta^{13}C$) counts. The reservoir oil samples were taken from the Ordovician Yijianfang Formation $O_2yj$and Yingshan Formation$O_{1\text{-}2}y$ in the Shunbei No. 1, No. 5 and No. 7 strike-slip fault zones. It is thought that the Ordovician reservoir oils are derived from source rocks within the Cambrian Yuertusi Formation which were deposited in a highly reducing marine environment. The generated hydrocarbons subsequently migrated upward along faults to the Ordovician reservoir. The reservoir diagenetic sequences were established by observation of thin sections under transmitted light, reflected light and cathode luminescence. The hydrocarbon charge history in the Shunbei area was reconstructed and associated with a series of diagenetic events using fluid inclusion microthermometric measurements, and microscopic fluorescence spectrum parameter analysis, combined with one-dimensional basin modeling. The results show that the Shunbei site has experienced three hydrocarbon charging episodes in total, the first charging episode occurred in the late Caledonian (437.2—405.8 Ma), the second charging episode occurred in the late Hercynian (291.6–236.8 Ma) and the third charging episode occurred in the late Himalayan (23.6–0.3 Ma). Locally, the Shunbei No. 1 and No. 5 fault zones experienced three hydrocarbon charging episodes, whereas the Shunbei No. 7 fault zone reservoir shows no evidence for the last hydrocarbon charge episode. Finally, the relationship between measured QF-535 factors and the API gravity of crude oil was used to predict the API gravity of oil in inclusions. This allowed quantification of the level of contribution of each of the petroleum charging episodes to the No.1, No.5, and No.7 fault zone reservoirs. The results shows that hydrocarbons in the No. 1 fault zone reservoir are mainly derived from the third petroleum charging episode, the No. 5 fault zone reservoir is dominated by the second and third petroleum charging episodes, and the No. 7 fault zone reservoir was charged predominantly by the first petroleum charging episode. Overall, the contribution of early hydrocarbon charging episodes gradually increases from west to east in the Shunbei area. This increase was driven by different tectonic events through geological history and the subsequent evolution of paleo-structural patterns. This study reveals the history and looks at differences in the reservoir hydrocarbon accumulations in different fault zones of the Shunbei area. This information with have a significant impact on marine carbonate reservoir evaluation in strike-slip fault zones in China.

Stylolites quantitative characterization and effects on reservoir quality in the ultra-deep limestone reservoirs: A case study of the Lower Triassic Feixianguan Formation, northeastern Sichuan Basin

Ling Zhou[1], Guangwei Wang[1*], Fang Hao[1]
1. Shandong Provincial Key Laboratory of Deep Oil and Gas, China University of Petroleum (East China), Qingdao, Shandong, CHINA
E-mail: wanggw@upc.edu.cn

Keywords: ultra-deep limestone reservoir, stylolite, pressure solution, reservoir quality, Feixianguan Formation, northeastern Sichuan Basin

Pressure solution, a common and important diagenetic process in carbonates (Koehn et al., 2008; Morad et al., 2018), involves physical reduction of the volume in rocks and chemical dissolution-precipitation process in pores, and thus leads to the significant heterogeneity of reservoirs (Ehrenberg, 2004; Paganoni et al., 2016). This study was based on the ultra-deep Feixianguan limestones (approximately 7000 m) of the Lower Triassic (northeastern Sichuan Basin, China) because of the various limestones and abundance of stylolites. Quantitative characterization of the morphology, distribution, and residual seam composition of stylolites in the Feixianguan limestones were performed to evaluate the intensity of pressure solution. Moreover, the impacts of pressure solution on the evolution of porosity and permeability were revealed via integrating quantitative statistics from cores and thin sections with geochemical data.

The following four types of stylolites were observed in the Feixianguan limestones according to pure geometry, known as wave-like, rectangular, sharp-peak, and seismogram types. From matrix supported limestone to grain supported limestone, the type of stylolites gradually change from wave-like to rectangular, sharp-peak and seismogram types, accompanied by increased surface roughness and amplitudes, and significantly decreased residual seam thicknesses. The stylolite density tend to decrease from the lower to upper part of the sedimentary cycle. In addition, two quantitative analysis methods of studying the intensity of pressure solution were carried out according to the clay mineral content respectively for relatively clean grainstones, and for mudstone, wackestones and packstones.

Calculations prove that the average intensity of pressure solution in mudstones (235.78 mm/m) is significantly larger than that in grainstones (90.42 mm/m), confirming that grainstones are more resistant to pressure solution and more porous. The obvious difference in pressure solution intensity leads to the strong heterogeneity in limestone quality. The values of Al + K + Ti, Zr/Al, and alumina content are negatively correlated with porosity and positively correlated with stylolite density, implying that clay minerals could facilitate the pressure solution. The relatively intensive cementation in proximity to stylolite and the negative correlation between the porosity and intensity of pressure solution indicate that pressure solution has a destructive effect on the pores during stylolite formation. Moreover, pressure solution caused a decrease in the porosity of limestone by approximately 11.31%. However, some calcite cements, abundant pores, and accumulated bitumen within stylolites indicate that the stylolites can act as predominant pathways for fluid migration, which can improve the reservoir permeability by at least an order of magnitude. Concludingly, we highlight quantitatively differences in pressure solution intensity on a millimeter scale.

Keywords: Diagenetic parasequence, Diagenetic fluid, Microbial reservoir, Dengying Formation, Ediacaran, Sichuan Basin

The central part of the Sichuan Basin in South China shows an excellent exploration potential in the dolomitized microbial reservoirs of the Dengying Formation in late Ediacaran. However, the influence of diagenesis on the formation of high-quality reservoirs is unclear. This study aims to establish the parasequence of the diagenesis in microbial reservoirs and decipher its control on the quality of microbialite-dominated reservoirs. The microbialite of the Dengying Formation consists of stromatolites and thrombolites, which firstly underwent meteoric alteration in the early diagenetic stage. The fabric-selective pores in the reservoir, which are generated by the decline of sea level, reflect freshwater dissolution. Subsequently, the microbialites experienced fibrous and bladed dolomite cementation and dolomitization. Laminated and clotted sedimentary fabrics are well-preserved in dolomite with less than 100μm in crystal sizes. The $\delta^{13}C$ (2.3 ± 1.1‰), $\delta^{18}O$ (-3.8 ± 1.2‰), $^{87}Sr/^{86}Sr$ (0.708717 ~ 0.709322) values, Mn (145.2 ± 45.3 ppm), and Fe (971.0 ± 330.0 ppm) concentrations in the microbial dolomite were similar to the geochemical compositions of Ediacaran seawater, indicating the marine origin of the dolomitizing fluid. The fibrous and bladed dolomite cement filled in the pores with dark-dull red cathodoluminescence has $\delta^{13}C$ (2.1 ± 1.0 ‰), $\delta^{18}O$ (-3.8 ± 2.0‰), $^{87}Sr/^{86}Sr$ (0.709181) values, Mn (187.5 ± 57.6 ppm) concentrations close to the matrix, which means the diagenetic fluid is originated from the coeval seawater. The medium-coarse crystalline granular dolomite cement filled later than the fibrous cement. Its composition of $\delta^{13}C$ (1.7 ± 0.8‰) and $\delta^{18}O$ (-8.2 ± 1.7‰) values indicate the diagenetic fluid derived from marine, and is affected by the recrystallization caused by the temperature rise after burial. Finally, the saddle dolomite cement filled in the fractures and veins, cross-cutting the host rock and early cement. The $\delta^{13}C$ (1.1 ± 1.3‰) value of saddle dolomite is similar to the matrix and early cement, while the $\delta^{18}O$ value is significantly lighter (-10.9 ± 1.0‰). The high Mn (751.4 ± 570.0 ppm), Fe (3872.5 ± 3347.9 ppm) concentrations, homogenization temperature (194 ± 26 ℃) derived from the fluid inclusion within the saddle dolomite, and concomitant silicification suggest its formation of Fe-rich high-temperature burial fluid. For the microbialite-dominated reservoir of the Dengying Formation, first, its initial porosity (34.07 ± 8.80%) is high. Second, porosity and permeability characteristics show dissolution-specific behaviors, suggesting a key factor of meteoric diagenesis in enhancing the reservoir. Third, the early dolomitization helps to resist compaction and pressure dissolution. Fourth, although the cementation of marine-derived fluids occupies the most pore space (28.15 ± 7.89%), hydrothermal fluids slightly influence the quality of the reservoir. Therefore, after multiple fluid diagenetic evolutions, the porosity of the microbialite reservoir in the Dengying Formation is concentrated in 3 ~ 5% with high porosity (6 ~ 10%) locally developed, which demonstrates the exploration potential of the Precambrian deep-buried dolostone reservoir.

E-mail: guning.syky@sinopec.com

Keywords: Ordos Basin, Majiagou Formation,gypsum-molded pore,intercrystalline pore,fracture

In the Ordovician, sea level changed frequently under arid climate in Fuxian area in the southeastern Ordos Basin, and the Caledonian movement made the basin undergo 130 million years of weathering and erosion. Three types of reservoirs were identified in the Ordovician Majiagou carbonate rocks in Fuxian area, including gypsum-molded pore-dissolution pore, dolomite intercrystalline pore and fracturedeveloping under distinctive sedimentary environments and experiencing special ways and degrees of karstification.

Gypsum-molded pores and dissolution pores were mainly developed above water-retaining layers and were affected by vertical karstification. As regression occurred and Sabkha dolomitization proceeded, gypsiferous dolomitic flat facies were deposited in the supratidal environment in the period of Ma 5 1st-4th. During the supergenes stage, karst water leached downwards, dissolving the soluble anhydrite nodules in the strata to develop gypsum-molded pores and dissolution poresand the associated pressure release resulted in network fractures communicating pores in the matrix dolomites. On the other hand, filling also played an important role on the effectiveness of gypsum-molded pores. Being the most important reservoirs in Fuxian area, favorable gypsum-molded pore reservoirs mainly distributed on the ancient burial hills and platforms with relatively high ancient landforms where filling were weak.

Dolomite intercrystalline pores were mainly controlled by lateral bedding karstification. During transgressive period in Ma 55thMa 5 7th, Ma 5 9th,thick layers of powder-fine grained dolomites were deposited in the ancient subtidal shoals by seepage reflux dolomitization, with middle size grains and numerous intercrystalline pores. The karst water flowed along the laminar with the tectonic setting of Ordovician high in the west and low in the east , so that the intercrystalline pores were further dissolved and enlarged. In the drainage areas of pressurized water flow, the dolomite intercrystalline pore-dissolution pore reservoirs are locally contiguous, where dissolution is strong.

During the supergenes stage, anhydrite nodules or layered anhydrites swelled and dissolved in karst water, causing the surrounding tight carbonate strata broken until collapsed, resulting in the development of fractures. Fractures were widely spread in the strata of the Ma 5 and Ma 6 members in Fuxian area. The fractures in the thick-layered micrite limestone of the Ma 6 member deposited during the largest transgressive period of the Ordovician and the thick-layered dolomite of the Ma55th sub-member during the largest transgressive period of the Ma 5 are the most typical. Filling in the supergenous and burial periods controlled the effectiveness of fractured reservoirs, which distributed locally.

E-mail: liuyf1103@foxmail.com

Keywords: Qixia Formation, Maokou Formation, slope-break belt, platform margin, dolomite

The middle Permian is rich in oil and gas resources in Sichuan Basin, especially dolomite reservoirs. However, the differences in understanding of the sedimentary pattern evolution and dolomite genesis in the Middle Permian lead to unclear understanding of the development law of large-scale reservoirs and restrict exploration deployment. In view of the above problems, based on drilling, logging, seismic and geochemical data, this study proposed the understanding of penecontemporaneous dolomite, sedimentary evolution pattern of multistage slope break and control reservoir model of multistage slope break in Qixia-Maokou Formation. The results are as follows: (1) It is clear that the dolomite of Qixia-Maokou Formation is crystalline, the protolith structure is grainstone, and the dolomitization fluid comes from seawater rather than hydrothermal. The viewpoint of facies-controlled dolomite is put forward. (2) The distribution of high-energy bioclastic shoals was controlled by the multistage slope break paleogeographic pattern, which was formed by the “S” paleo-uplift of central-western Sichuan and tectonic extension, in Qixia-Maokou Formation. (3) A new control storage model of dolomite reservoir is proposed. The "one edge and one slope break" sedimentary pattern of Qixia Formation and the distal steep break zone of Maokou Formation controlled the distribution of dolomite reservoir. The research is guiding significance to the oil and gas exploration of Middle Permian in the future.

Factors Influencing Stylolite Formation in the Cambrian Longwangmiao Formation, Sichuan Basin, SW China

Weiqiang Yang[1], Huayao Zou[1*]
1. College of Geosciences, China University of Petroleum (Beijing), Beijing, CHINA
E-mail: huayaozou@cup.edu.cn

Keywords: Pressure solution, Stylolite, Quantitative analysis, Sichuan Basin, Longwangmiao Formation

With the deep and ultra-deep exploration of carbonate rocks, more and more evidence has been obtained that shows that the pore reduction effects of compaction, pressure-solution, and cementation are crucial factors for the preservation of carbonate reservoirs porosity (Croizé et al., 2010; Moore et al., 2013). However, most studies of the stylolite in the Longwangmiao Formation were inclined to lack quantitative analysis relating the stylolite distribution parameters and the mineral composition, lithofacies, and rock textural characteristics. To better understand the controls on the formation and distribution of stylolites, the Longwangmiao Formation is selected as an example to examine this hypothesis. Based on the lithofacies, textural constituents, stylolite types, and X-ray diffraction (XRD) data obtained from thin sections, cores, and outcrops, and the results revealed the following that. Dolomite (79.6%), calcite (11.4%), and terrigenous clastic (5.6%) are the main mineral components in the Longwangmiao Formation, Sichuan Basin. The rocks with dolomite content of more than 80%, calcite content less than 30%, and terrigenous clastic less than 1% have low stylolite density and amplitude. Based on the multiple techniques, four types lithofacies of carbonate were recognized, including the grainstone (dolo-grainstone, grainstone), packstone (dolo-packstone, packstone), wackestone (dolo-wackestone, wackestone), and mudstone (dolo-mudstone, mudstone). Moreover, the density and amplitude of stylolites in dolo-grainstone, dolo-packstone, dolo-wackestone, and dolo-mudstone increase in order within the one well. Significantly, the stylolite density and amplitude in the dolo-grainstones are lower when those with grain contents of 50%–70% and cement contents of 25%–30%, which have high average porosity and permeability and are facilitate the formation of high-quality reservoirs. Vertically, the stylolite density and amplitude tend to decrease from the lower to the upper part of the sedimentary cycle, which indicates that the degree of chemical compaction in the lower part of the fourth-order sequences is strong. This study confirms that dolo-grainstone with a high dolomite content (>90%), a grain content of 50%–70%, a cement content of 25%, has a strong pressure solution resistance, which facilitates the conservation of pores.

Distribution and characteristics of microbial carbonate reservoirs in the 4-3 submember of the Middle Triassic Leikoupo Formation, Western Sichuan Basin, China

Minglei Yang[1], Huayao Zou[1*]
1. College of Geosciences, China University of Petroleum, Beijing, Beijing, CHINA
E-mail: huayaozou@cup.edu.cn

Keywords: Distribution of microbialites, microbial carbonate reservoir, the Triassic Leikoupo formation, Western Sichuan Basin

Microbial carbonate reservoirs are the main petroleum exploration targets in the third submember of the fourth member of the Leikoupo Formation in the western Sichuan Basin. To improve understanding of the origin of microbial carbonate reservoirs, detailed facies description and reservoir characterization were performed based on sedimentological and petrophysical analysis from cores and outcrops. Compared with modern analogs, the microbialites depositional model is established, and the controlling effect of microbialites on the reservoir is evaluated. Nine facies types can be grouped into five facies associations in the Lei4-3 submember, corresponding to two cycles, portraying an epeiric marine carbonate platform in the western Sichuan Basin. Cycle 1 is dominated by tidal flat environment. Laminated microbial dolomudstone mainly in the southern area of the western Sichuan Basin, representing the intertidal to supratidal settings in the proximal platform, a low gradient area with weak hydrodynamics protected by Longmenshan subaqueous paleohigh. In the central area of the western Sichuan Basin, wavy to domal stromatolitic dolowackestone and thrombolitic dolomudstone are common in the intertidal to subtidal environments, where the substrate gradient is steep, and the seawater circulation is also relatively restricted by the subaqueous paleohigh. Many intraclast dolopack-grainstone on behalf of the shoal or tidal channel environments in the northern area of the western Sichuan Basin, indicating the site is frequently disturbed by tides and waves with better seawater circulation, which may be less limited by the subaqueous paleohigh. Cycle 2 with large preserved thickness only in the central area of the western Sichuan Basin due to varied denudation caused by Indosinian orogeny. With the rise of sea-level, the western Sichuan Basin is less limited by the subaqueous paleohigh. Cycle 2 is mainly a semi-restricted subtidal environment without microbialites. The regional distribution of microbialites in the cycle 1 is controlled by the variation of regional topographic gradients and the tidal and wave energy affected by the seawater circulation. High-frequency relative sea-level fluctuations lead to frequent exposure of tidal flat with meteoric alternation, resulting in the formation of solution enlarged pores from microbial framework pores in microbialites and vugs from interparticle pores in intraclast dolopack-grainstone. The early dolomitization formed the intercrystalline porosity in microbialites or intraclasts dolopack-grainstone and made dolomite more resistant to compaction during burial. The abundant fractures provide channels for the migration of fluid and hydrocarbon, especially in the central area near the Pengzhou hidden fault.

Tectono-sedimentary evolution of the carbonate platform in central Tarim Basin during the early Cambrian: New insights from stratigraphic forward modeling

Weijing Liu[1], Keyu Liu[1*], Kuanhong Yu[1], Jianliang Liu[1], Yaxin Shang[1]
1. School of Geosciences, China University of Petroleum(East China), Qingdao, Shandong, CHINA
E-mail: liukeyu@upc.edu.cn

Keywords: Carbonate Platform, Tarim Basin, Early Cambrian, Stratigraphic Forward Modeling

The Lower Cambrian carbonate platform sequences in the central Tarim Basin play an important role in controlling the development of hydrocarbon source rocks and reservoirs, as well as the formation and distribution of oil and gas. A large number of studies have been conducted on its formation and evolution, but most of them are based on qualitative analysis and paid little attention to the influence of differential deposition of the carbonate platform sequences.

Based on previous research findings and supplementary analysis of key seismic sections, outcrops, well logs, core, and cuttings, we have investigated the Early Cambrian paleoenvironment in the central Tarim Basin. By using the Earth System Science approach, we studied the Lower Cambrian carbonate platform sequences through stratigraphic forward modeling (SFM) by taking into consideration of key geological factors such as the initial paleo-topography, tectonic movement, high-frequency sea-level changes, carbonate growth/denudation, and clastic sediment input. The 3D stratigraphic forward model was calibrated and validated using a variety of geological data.

Through uncertainty analysis of different geological factors and variables, and combined with previous research findings, we have systematically analyzed the tectono-sedimentary evolution process responsible for the development of the carbonate platform margin facies in both time and depth domains and evaluated the contribution of key factors on the evolution of platform margin facies quantitatively, and finally clarified the formation mechanisms and evolution model of the platform margin facies in central Tarim Basin.

The study showed that the initial paleogeomorphology and tectonic subsidence jointly controlled the fluctuation of relative sea level, which determined the migration direction and internal structure of the carbonate platform margin. The differential stratigraphic architecture and stacking patterns of the carbonate sequences were primarily caused by the exposure duration and the slope angles of the platform margin collectively.

The evolution of diagenetic fluids in Shunbei area, Tarim Basin: Constraints from isotopic geochemistry and U-Pb dating of calcite

Keywords: Tarim Basin, Shunbei area, U-Pb dating of calcite, fluid-rock interaction, Mid-Caledonian orogeny

Faults are generally considered as the main conduits for the focusing and migration of fluids. This study focuses on the strike-slip faults in the Shunbei area, Tarim Basin, where calcite, autogenic quartz and minor saddle dolomite cements co-occur within the different fault zones. Calcites, as the exclusively vein- and/or fracture-cement in the northern fault zone, have large overlaps in isotopic composition with that of host limestone, indicating that the diagenetic fluids mainly inherited their composition from remnant pore fluids or were buffered by formation water through intense fluid-rock interaction. In addition, the presence of mono-phase fluid inclusion also implies that they were formed in a shallow burial environment with relatively lower temperature. However, the calcite cements in the southern fault zone may have precipitated from more intense water-rock interaction at elevated temperature in view of the relatively lower δ18O values. This inference was also testified by the pervasively occurrence of replacive and fracture-filling quartz, which probably resulted from episodic influxes of hot silica basinal brines from the depth. U-Pb dating of two calcite cements yield isochron ages of 456.38 ± 5.50 Ma and 445.20 ± 14.30 Ma, respectively, definitely falling within the Late Ordovician, thereby attesting to a causal link to the Mid-Caledonian orogeny. At that time, the Katak uplift experienced extensive tectonic overthrusting due to the final closure of North Kunlun Ocean, resulting in a series of nearly NE-trending secondary faults. Afterwards, high-temperature silica-rich fluids had been expelled from depth and driven to migrate upwards into the fractured limestones, resulting in intense dissolution mainly along the fault/fracture networks with subsequent precipitation of quartz and calcite cements. This study provides a useful analogue to understand the diagenetic processes associated with faulting, fluid source and pathway in the compressional setting.

Reservoir features and development model of globigerina limestone, southern east Java basin

Taotao Yang[1*], Lin Li[1], Dong Li[1]
1. Offshore Research Center, PetroChina Hangzhou Research Institute of Geology, Hangzhou, Zhejiang, CHINA
E-mail: yangtt_hz@petrochina.com.cn

Keywords: East Java basin, Globigerina limestone, Reservoir features, Development model

Globigerina is a class of plankton-like foraminifera, which can form reservoirs by accumulation after death. High quality reservoirs can be formed through secondary modifications, and a group of such reservoirs have been discovered globally. In the southern part of east Java basin, the globigerina limestone reservoir is distributed along the relatively high paleography of the shelf margin. The lithology is mainly grainstone and wackstone. The content of bioclasts is high and there are many species, while the influence of terrestrial material was weak. The reservoir has excellent physical properties, with average porosity of 43% and permeability of 120mD. It is the main target of oil and gas exploration and development. According to the analysis and paleontological data, distribution of globigerina limestone reservoirs in southern east Java basin was mainly controlled by four factors: Firstly, the relative height of paleography controls the reservoir quality and scale, the higher paleography the better quality but the thickness decreased, and lower paleography the worse quality but thickness increased. Secondly, the offshore current carried out secondary transformation such as agitation and transportation for the accumulated foraminifera, which accumulated more in the higher paleography and carried away most of the marl. Thirdly, the upwelling current carried the deep foraminifera to the shallow part, and interacted with the offshore current at the margin of the shelf. The uniform deceleration led to the weakening of the carrying capacity. The carrying capacity were further weakened because of the influence high paleography, and it is resulted that the continuous enrichment of foraminifera in the high part of the high paleography at the margin of the shelf. Finally, the lower cutting erosion of the later developed channel affects the local reservoir distribution. The physical properties of globigerina limestone reservoir are controlled by six major factors: grain size, globigerina content, burial compaction, diagenesis, marl matrix content and pore throat radius. According to controlling factors mentioned above, the development and distribution model of the upper Pilocene globigerina limestone reservoir is established in the south of east Java basin, which provides a basis for geological deepening evaluation, exploration and development potential analysis of this type of reservoir.

E-mail: pangxq@cup.edu.cn

Keywords: Carbonate source rock, mass balance approach, present-day low TOC, genesis mechanism, platform of Tarim Basin

The continually discovered large volumes of marine hydrocarbons have indicated a huge exploration potential within the carbonates of Ordovician in the Tarim Basin (northwest China); however, the carbonate source rocks of the Middle–Upper Ordovician (O2+3) are at high mature stage. These rocks presently contain a low amount of total organic carbon (TOCpd ≤ 0.5%). In this study, the source rocks that have expelled hydrocarbons are identified by mass balance approach. The characteristics and genesis mechanism of hydrocarbon expulsion from low-TOCpd (present-day TOC) source rocks are studied, which is significant for the marine oil exploration in the basin. Results showed that an O2+3 source rock with low TOCpd having expelled hydrocarbons was of type I and had a very narrow oil window. With high maturity, nearly 80% of the generated hydrocarbons were expelled, and the original TOCo (original TOC) values were over 1%. The oil and source rock extracts were relatively lean in gammacerane and C28 steranes, with the distribution of regular steranes having a V-shaped trend, suggesting a possible genetic relation between the source rocks with low TOCpd and the marine oils in the Tabei area. The genesis mechanism for the low-TOCpd carbonate source rocks is as follows. The main hydrocarbon parent materials were hydrogen-rich planktonic algae or acritarchs, distributed in the subsiding platform-slope facies). Organic matter was preserved under reducing conditions, and source rocks were formed with a good kerogen type and moderate hydrocarbon generation potential. Thus, hydrocarbon expulsion could have occurred, resulting in TOCpd ≤ 0.5%.

Characteristics and Reservoir Responses of the Ordovician Hydrothermalism in the Tarim Basin

Jian Wang[1*], Yingchang Cao[1]
1. School of Geosciences, China University of Petroleum (East China), Qingdao, Shandong, CHINA
E-mail: wangjian8601@upc.edu.cn

Keywords: hydrothermalism, Ordovician, carbonate rock, reservoir responses, Tarim Basin

The alteration of reservoir by hydrothermal fluid is a key issue in the field of Geology. In this paper, the Ordovician carbonate reservoirs in the Tabei-Tazhong area of the Tarim Basin are studied. Based on core observation, thin section analysis and related geological data, through the methods of cathodoluminescence, fluid inclusion analysis, isotope and rare earth element analysis and numerical simulation, the basic characteristics of the Ordovician reservoirs, hydrothermalism characteristics and reservoir responses to different hydrothermal fluids in the Tabei-Tazhong area are systematically studied. A model of carbonate reservoirs altered by hydrothermalism is established.

The Ordovician carbonate reservoir in the study area is composed of micrite limestone, granular limestone, algal bound limestone, dolomite and silicified siliceous rock. The main diagenesis types are cementation, compaction, pressure solution, recrystallization, dolomitization, silicification, fracture, dissolution and filling. The main types of reservoir space are dissolution pores, dissolution caves, fractures and karst caves. In petrology, hydrothermalism in the study area is characterized by thermal fading, thermal cracking and magmatic intrusion. In diagenesis, hydrothermalism is characterized by dissolution and fracture, and the filling of hydrothermal minerals such as saddle dolomite, fluorite and quartz.

The results show that, in the study area, there are mainly two kinds of hydrothermal fluids in the Ordovician carbonate strata: Mg-rich stratigraphic hydrothermal fluid and F&Si-rich magmatic hydrothermal fluid. The minerals formed by Mg-rich stratigraphic hydrothermal fluid are characterized by medium to high homogenization temperatures and salinities of inclusions, medium to negative carbon and oxygen isotope values, positive anomalies of δEu and negative anomalies of δCe. The main active period of Mg-rich stratigraphic hydrothermal fluid is from the late Caledonian to the Early Hercynian. The minerals formed by F&Si-rich magmatic hydrothermal fluid are characterized by high homogenization temperatures and salinities of inclusions, more negative carbon and oxygen isotope values, obvious positive anomalies of δEu and negative anomalies of δCe. The activity of F&Si-rich magmatic hydrothermal fluid is controlled by the tectonic movement in the late Hercynian and the magmatic volcanic activity in the early Permian.

Geological data and the results of numerical simulation show that, the diagenetic response of Mg-rich stratigraphic hydrothermal fluid in the late Caledonian to the Early Hercynian is mainly manifested as dissolution, hydrothermal dolomitization and filling, which has both constructive and destructive effects on the reservoir space, but overall, it was constructive process. The diagenetic response of F&Si-rich magmatic hydrothermal fluid in the late Hercynian mainly characterized by fracturing, dissolution, metasomatism and filling. The fluid has an obvious destructive effect on the reservoir space, but with certain constructive effect. Tectonic movement and magmatic activity provide heat and power source for hydrothermal fluid activities, and the fault system provides channel space. The carbonate hydrothermal altered reservoir is constrained by fault system, and the calcite precipitation filling zone formed in the upper part of the hydrothermal altered reservoirs also played a certain sealing role.

Relationship between stylolite morphology and the sealing potential of stylolite-bearing carbonate cap rocks in the deep-burial carbonates in the Tarim Basin, China

Jun Wu[1*], Tailiang Fan[1]
1. School of Energy Resources, China University of Geosciences (Beijing), Beijing, CHINA
E-mail: zgdzdxbjwj@126.com

Keywords: Carbonate cap rocks, Stylolite types, Pore structure, Sealing effectiveness, Tarim Basin.

The sealing effectiveness of cap rocks bearing different types of stylolites is analyzed using a combination of petrographic, petrophysical, pore structure and sealing capacity characterization techniques. This study is based on examples of carbonate cap rocks that seal ultradeep hydrocarbon reservoirs of the Tarim Basin (China). Samples from both drill cores and their outcrop analogues are investigated to quantify how morphology does influence the sealing capacity of different types of stylolite-bearing rocks. The study cap rocks consist of mudstone, wackestone to packstone, grainstone and dolomitic limestone. Four types of stylolites are identified: rectangular layer, seismogram pinning, suture & sharp peak and simple-wave like types. The difference in the sealing capacity of carbonate cap rocks is attributed to their pore structure connection and the types of stylolites they develop. Samples bearing simple-wave like stylolites have the best sealing capacity, followed those with rectangular layer and suture & sharp peak types, whereas carbonates hosting seismogram pinning type have the lowest sealing capacity. The impact of stylolite segments on the rock sealing properties, however, differ from one segment to another. Rectangular layer type stylolites can be divided into three distinct segments (with good, moderate and poor sealing, respectively). Both the seismogram pining and suture & sharp peak stylolite types are divided in two parts, with the former one having moderate and poor sealing and the latter exhibiting good and moderate sealing. The simple wave-like type has a good sealing capacity all along the pressure-solution seam. The most effective sealing barriers for vertical fluid flow form when (1) calcite and siliceous cements are pervasively distributed in the vicinity of stylolites, forming highly cemented zones with lower porosity and permeability than their surrounding host rocks; (2) stylolites are enriched in insoluble residues; (3) rare microfractures and dissolution vugs are found along the stylolites. This work provides useful examples for the prediction of the sealing potential of stylolite-bearing carbonate rocks according to stylolite morphology in other geological settings.

Impact of diagenesis on the pore evolution and sealing capacity of carbonate cap rocks in the Tarim Basin, China

Jun Wu[1*], Tailiang Fan[1]
1. School of Energy Resources, China University of Geosciences (Beijing), Beijing, CHINA
E-mail: zgdzdxbjwj@126.com

Keywords: Carbonate cap rock, Diagenesis, Pore structure evolution, Sealing capacity classification, Tarim Basin.

Analyzing the pore structure and sealing efficiency of carbonate cap rocks is essential to assess their ability to retain hydrocarbons in reservoirs and minimize leaking risks. In this contribution, the impact of diagenesis on the cap rock's sealing capacity is studied in terms of their pore structure by analyzing rock samples from Ordovician carbonate reservoirs (Tarim Basin). Four lithology types are recognized, including highly compacted peloidal packstone-grainstone, highly cemented intraclastic-ooidal-bioclastic grainstone, peloidal dolomitic limestone, and incipiently dolomitized peloidal packstone-grainstone. The pore types of cap rocks comprise microfractures, intercrystalline, and intergranular pores, and dissolution vugs. The pore structure of these cap rocks was heterogeneously modified by six diagenetic processes, including calcite cementation, dissolution, mechanical and chemical compaction, dolomitization, and calcitization (dedolomitization). Three situations affect the rock's sealing capacity: (1) grainstone cap rocks present high sealing capacity in cases where compaction preceded cementation; (2) residual microfractures connecting adjacent pores result in low sealing capacity; (3) increasing grain size in grainstones results in a larger proportion of intergranular pores being cemented. Four classes of cap rocks have been defined according to the lithology, pore structures, diagenetic alterations, and sealing performance. Class I cap rocks present the best sealing capacity because they underwent intense mechanical compaction, abundant chemical compaction and calcite cementation, which contributed to the heterogeneous pore structures with poor pore connectivity. A four-stage conceptual model of pore evolution of cap rocks is presented to reveal how the diagenetic evolution of cap rocks determines the heterogeneity of their sealing capacity in carbonate reservoirs.

E-mail: zhangzhenghong@zhenhuaoil.com

Keywords: Carbonate ramp, Upper Cretaceous, Sequnece stratigraphic, Reservoir prediction

The Turonian-Lower Campanian Khasib, Tanuma, Sa'adi Formation, three major carbonate reservoir units in central Iraq, contain estimated cumulative reserves of around 9 billion *brl*. Difficultly in predicting the presence of best reservoir units is mainly due to the complex paleogeography.

Sea level change analysis, trace fossils, microfossil communities and microfacies identification indicate that Upper Cretaceous carbonate are deposited in ramp setting, with depositional facies ranging from basin to inner ramp. Basin facies and outer ramp facies consists of argillaceous and marly limestone containing planktonic foraminifera (*Globotruncana sp., Oligosteginids sp.*) and calcispheres. Mid ramp facies is recognized by highly bioturbated (*Thalassinoides-Rhizocorallium*), commonly clay-rich wackestone-packstone. Inner ramp facies is characterized by shoal bioclastic grainstone-packstones intercalated with lagoonal gray-green mudstone.

A sequence stratigraphic framework has been constructed based on cuttings and core samples and wireline logs responses (gamma-ray, INPEFA, density and sonic) from 9 wells. The Khasib, Tanuma, Sa'adi Formations represent a complete 3rd-order sedimentary cycle respectively. Facies can be grouped into transgressive and regressive(T-R) cycles reflecting deepening and shallowing conditions across the carbonate ramp. Lower units of regressive cycles are dominated by outer ramp facies, which grade up to mid ramp proximal facies and then to shoal facies, the sequences capped by basin facies or lagoon. Eustatic changes were the primary control on this sequence development, the growth faults activities also affected the Turonian-Lower Campanian carbonate dispositions.

Petrographic analysis reveals the porosity increasing beneath sequence boundaries due to karstification and meteoric dissolution. The HST (mid ramp proximal) reveals the best reservoir characteristics (thickness, porosity, and hydrocarbon saturation) in central Iraq. The paleogeomorphology map of the three formations studies integrated the well correlation and logging facies analysis showed the distribution of the best reservoir units in the Turonian-Lower Campanian. These units constitute the primary targets for exploration in central Iraq. Such reservoir predicational method may have similar beneficial application to carbonate reservoirs elsewhere in the world.

Keywords: Sichuan Basin,Ediacaran Dengying Formation,Sequence stratigraphic framework,Reservoir distribution,Sedimentary Palaeo-geomorphology,Favorable exploration zones

In order to study the sequence stratigraphy of the ancient rimmed platform, we take the third and fourth member of Sinian(Ediacaran) Dengying Formation (shortened as Deng 3 and Deng 4 member) in Gaomo area, Sichuan Basin as an example. A comprehensive study is carried out on sequence stratigraphy, sedimentary evolution, reservoir distribution and prediction of favorable reservoir zones through comprehensive analysis of cores, thin sections, logging and seismic data, combined with previous research results. The research results asfollows: (1) Based on the identification of sequence interface, the Deng 3 and Deng 4 member can be divided into SQ3 and SQ4 sequences, which are well-developed in the area and have good isochronicity and traceability. The thickness of SQ3 and SQ4 is obviously different, and the west side of SQ3 is thicker than the east side, while the northwest side of SQ4 is thicker than the southeast side. (2) The sedimentary environment from SQ3 to SQ4 has experienced the evolution from mixed tidal flat to rimmed carbonate platform, and the platform rimmed system on the west side is characterized by the development of platform margin microbial mounds and shoals assemblages. The intra-platform area in the east is a restricted platform facies composed of a variety of dolomite, and there are local micro-geomorphic highlands of different scales, and there are scattered intra-platform mounds and shoals. (3) It is pointed out that the Deng 4 member reservoirs in the study area show obvious phase-controlled characteristics, and are controlled by the third-order sequence and high-frequency upward-shallowing cycles. It is mainly distributed in the high-stand systems tract of the third-order sequence and the upper part of high-frequency upward shallow cycle. On the plane, the reservoirs in the platform margin belt are more developed than those in the intra-platform belt, and the Gaoshiti platform margin belt is more developed than the Moxi platform margin belt. (4) Three types of reservoir favorable zones of Deng 4 Member have been finely described by 3D seismic, among which the mound and shoal facies area developed in the landform highland in the intra-platform can be used as a favorable zone for subsequent exploration. The research results will provide a new idea and reference for well deployment of Deng 4 member in Gaomo area.

New insights on the geometry and kinematics of the Shunbei 5 strike-slip fault in the central Tarim Basin, China

Qingqing Sun[1*], Tailiang Fan[1]
1. School of Energy Resources, China University of Geosciences (Beijing), Beijing, CHINA
E-mail: zgdzdxbjsqq@163.com

Keywords: Strike-slip faults, The Central Tarim Basin, Geometric characteristics, Kinematic evolution, Reservoir formations

Integrated geological-geophysical methods have been used to depict the geometric characteristics and kinematic evolution of the Shunbei 5 (SB5) and adjacent Shunbei1 (SB1) strike-slip faults in the central Tarim Basin, China. Geometric evidence for strike-slip faulting includes the occurrence of positive and negative flower structures in stepover zones, oblique secondary splay faults, en echelon folds, and adjacent secondary faults. The multi-humped along-strike and along-dip displacement variations of the SB5 fault provide insights into the initial segmentation, interaction and polycyclic growth of the fault zones both in plan and section views: The SB5 fault initiated as an apparent “X-type” conjugate pure shear fault system in the north and a simple shear fault system in the south respectively. At depth (mainly in Cambrian to Middle Ordovician rocks), the northern and southern parts of the SB5 fault exhibit a typical dextral strike-slip architecture consisting of multiple fault segments connected via transpressional push-up or transtensional pull-apart stepovers or bends. The southern part has a linear, narrow sinistral ridge system. At shallower depths (in Upper Ordovician to Middle Devonian rocks), the lower subvertical faults propagated upwards as en echelon normal faults in the north, and as a two-phase, partitioned system consisting of boundary grabens and en echelon normal faults that dissected the early-formed border grabens in the south. With progressive deformation, the northern and southern parts of the SB5 fault reactivated and transferred into one large, sinistral fault in Upper Devonian to Permian rocks. Four major tectonic phases matching the kinematic evolutions of regional fault systems and uplifts in the study region, have also been recognized in the Middle Ordovician to Cretaceous. The pull-apart stepover and single fault zones developed in Middle Ordovician rocks are favorable fracture-related reservoirs.

Depositional model and distribution characteristics of Cambrian source rocks in Bachu Maigaiti area, Tarim Basin

Xiaoyu Wu[1], Hua Wang[1*], Si Chen[1]
1. resource academy, China University of Geoscience (Wuhan), Wuhan, Hubei Province, CHINA
E-mail: wanghua@cug.edu.cn

Keywords: Tarim Basin,Yuertus Formation,Source rock, depositional model, Spatial distribution

Tarim Basin is the largest petroliferous basin in China ,which is rich in oil and gas resources. This study aims to explore development model and the distribution characteristics of source rocks by using core observation, thin section identification, combined with seismic, drilling, surrounding outcrops and organic geochemical analysis.The results show that From the old to the new, The Cambrian strata in Bachu Maigaiti area develop lower Yuertus Formation (1y), Shorbluk Formation (1x) and Wusonger Formation (1w) ; Middle Shayirik Formation (2s) and Awatag Formation (2a); Lower Qiulitage Formation of upper series (3xq). Cambrian source rocks in Tarim Basin are mainly divided into argillaceous source rocks and carbonate source rocks. Their source rock depositional models are mainly divided into two types: shelf slope facies source rock depositional model related to upwelling current paleomarine deposition and carbonate platform facies source rock depositional model related to intra platform depression lagoon facies deposition. Cambrian argillaceous source rocks are widely distributed in this area. They are developed in the shelf slope sedimentary facies belt in the southwest of Tarim depression and Maigaiti Slope, with a thickness of about 800 ~ 1200m, and gradually thinning to 100 ~ 200m eastward. The quality of carbonate source rocks of Yuertus Formation is the best, and the Yuertus Formation is a set of tidal flat deposits, which is a high-quality source rock with a total organic carbon content (TOC) of 9.67% and an average of 5.1%.Ro is between 2.03% - 4.5%, which is in the stage of high over mature evolution and has great hydrocarbon generation potential.The generally higher than 30m thickness, the good continuity ,widely distribution, the large buried depth (main body is between 4800-5500m) of the source rocks. ensure good sealing conditions of the gas reservoir. The argillaceous source rocks of Yuertus Formation are widely distributed, with high abundance and good types of organic matter; The microbial mound reservoir in the platform is formed in the carbonate rocks of Shorbluk Formation; The Middle Cambrian strata form a set of gypsum mudstone caprocks, which constitute a good source reservoir cap rock combination and have great resource potential.

Characteristics and Genesis of Middle Permian Dolomite Reservoir in Sichuan Basin

Duan Jin bao[1], Li Bi song[1], Jin Min dong[1*], Xu Zu xin[1], Jiang Zhi li[1], Cao Huan yu[1]
1. Oil and Gas Exploration Management Department, Exploration Company of SINOPEC, Chengdu, Sichuan, CHINA
E-mail: 931377531@qq.com

Keywords: Dolomite Reservoir,Freshwater Dissolution,Upward Fluid,Dolomitization,Middle Permian,Sichuan Basin

Carbonate platform deposits are widely developed in the Middle Permian in Sichuan Basin, and the early exploration is mainly concentrated in the karst fracture cave limestone reservoir of Maokou Formation around Luzhou paleo-uplift, with high production from individual Wells but small reservoir sizes. Recently, dolomite reservoirs have been drilled in the Qixia Formation of northwest, southwest and middle Sichuan, and the Maokou Formation of north and southeast Sichuan, showing good exploration prospects. However, the development characteristics and genesis of reservoirs are quite different, and the research is relatively weak, which restricts the evaluation and deployment of oil and gas exploration. In this study, based on a large number of drilling cores, imaging logs, outcrops, by means of thin section identification, geochemical testing and analysis, the characteristics and genesis of Middle Permian dolomite reservoir are systematically analyzed. Middle Permian dolomite reservoirs can be divided into two types. The first type is controlled by sedimentary facies, and the reservoir development of this type is related to atmospheric freshwater dissolution and penecontemporaneous marine fluid dolomitization, with the plane distribution mainly controlled by the platform margin of western Sichuan Basin and the uplifted-subsidenced paleogeographic pattern of central Sichuan Basin. The reservoir rock is mainly residual particle fine-crystalline dolomite and the reservoir space is mainly intergranular pore-intergranular dissolved pore, while the reservoir is characterized by wide distribution and good physical properties. The other type is mainly related to the upward fluid modification. The magnesium-rich hydrothermal fluid enters into the bioclastic limestone of Maokou Formation though the basement fault, then causing the stratiform-like dolomitization. This fluid modification, on one hand, physically breaks the bedrock to form fractures and holes, on the other hand , results in chemical corrosion, which both improve the reservoir storage and permeability properties. The plane distribution of such reservoirs is mainly controlled by the basement fault, with the reservoir rock of mainly dark gray fine-medium crystalline dolomite and reservoir space of mainly matrix dolomite intergranular pores and semi-filling dissolved caves.

Hydrothermal dolomite (HTD) bodies have been recognized as potentially good hydrocarbon reservoirs and are regarded to be a hot area for hydrocarbon exploration in the future. Although various examples of hydrothermal dolomitization have been documented worldwide, the most challenging point is the timing and the burial depth of dolomitization, which can only be inferred from indirect evidence regarding the regional context and the burial history, bringing uncertainty and limitation to the dolomitization process interpretation. In the eastern Sichuan Basin, thick successions of Maokou formation limestone were alternated by fracture-bound dolomitization, showing typical hydraulic structures and saddle dolomite cementation. Here we investigated these hydrothermal dolomite bodies and recognized two types of matrix dolomites together with three types of cement dolomites based on petrographic observation. In-situ LA-ICP-MS U-Pb ages gave a confidence interval from 251±11 Ma to 264±10 Ma, indicating an early-stage dolomitizing event that may correspond to the activities of the Emeishan mantle plume and its related thermal effects. The high homogenization temperature combined with high $^{87}Sr/^{86}Sr$ ratios and depleted $\delta^{18}O$ in all types of dolomites suggests that the dolomitizing fluid may be derived from deep crustal brines that mixed with down-flowing seawater at very shallow depths. Those syn-depositional fault system, which may relate to the activities of deep major faults, was most likely to provide dominant pathways for fluid migration and mixing.

Diagenesis and pore evolution of the Paleogene Shahejie Formation Mixed Siliciclastic-Carbonate Rocks reservoirs in Bozhong sag

Yawen Du[1], Jianping Yang[1*], Xiyu Qu[1]
1. School of Geosciences in China University of Petroleum(East China), China University of Petroleum(East China), Qingdao, China, Shandong Province, CHINA
E-mail: yangjp3028@sina.com

Keywords: Bozhong Sag,Paleogene,Shahejie Formation,mixed siliciclastic-carbonate rock,diagenesis,Pore evolution

The Paleogene Shahejie Formation in Bozhong Sag is an important field of oil and gas exploration in China, and the high quality reservoir of mixed siliciclastic-carbonate rock is developed in the first and second member of Paleogene Shahejie Formation. In order to study the influence of diagenesis on reservoir development and reservoir pore evolution in mixed siliciclastic-carbonate rock, to explore the relationship between diagenesis and pore evolution model, through core observation, casting thin section, scanning electron microscope and other technical means, the reservoir characteristics of mixed siliciclastic-carbonate rock in five wells of QHD29-2E-4, QHD29-2E-5, QHD36-3-2, BZ13-1 and BZ2-1-3 in Bozhong Sag were studied. The main results are as follows:1Mixed siliciclastic-carbonate rock reservoirs dominated by terrigenous clastics, mixed siliciclastic-carbonate rock reservoirs dominated by bioclastics and mixed siliciclastic-carbonate rock reservoirs dominated by chemical carbonates are developed in the Paleogene, the reservoir space is mainly dissolved pores, intergranular pores and a small amount of biological cavity pores, among them, the types of biological cavity pores are mainly spiral cavity pores and mesomorphic cavity pores, and porous reservoirs are developed. 2Compaction has little effect on reservoir during the whole diagenetic evolution, the cementation is the main reservoir destruction, and the dissolution is the main role of reservoir construction, at the same time, the micrite crust in syngenetic stage, the leaching of atmospheric fresh water in syngenetic stage and the quasi-synchronous dolomitization are also three important reservoir constructive effects.3The diagenetic evolution process of the mixed rock reservoir in the study area was quantitatively calculated by ' porosity inversion ',the initial porosity of the mixed siliciclastic-carbonate rock is 54.2 %, During the syngenetic period, the cementation reduced the porosity by 23.68 %, and the primary dissolution increased the porosity by 17.47 %. In early diagenetic stage, compaction reduced pore by 6.7 %. During the middle diagenetic stage, the cementation porosity decreased by 17.43 %, the acid dissolution porosity increased by 4.02 %, and the present porosity was 31.2 %. Clear dissolution and cementation are the main factors affecting reservoir physical properties.

Tectono-depositional differentiation of Sinian in Sichuan Basin and its controls on reservoir formation

LI SHUANG JIAN[1*], He Zhi Liang[1], Li Ying Qiang[1], Yang Tian Bo[1], Wu Chong Yang[1]
1. Petroleum Exploration, Petroleum Exploration and Production Research Institute, SINOPEC, Beijing, CHINA
E-mail: hawkingli@163.com

Keywords: Tectono-depositional differentiation, reservoir, dolomite, Sinian, Sichuan Basin ,

To understand the sedimentary filling and tectono-depositional differentiating principles in marine craton basins and rebuild the tectono-depositional evolution processes at key tectonic periodsare of great geological significance for characterizing the distribution patterns and formation mechanism of large-scale reservoirs. In this paper, we described the sedimentary filling features and geochemical records, together with the latest exploration progresses, and then summarized the tectono-evolution processes of Sinian intra-craton paleo-rifts in Sichuan Basin and analyzed the geodynamical mechanism according to regional tectonic settings. Based on the reestablishment of Sinianpaleogeography, the diagenetic types and environment were first concluded according to petrography and in-situ geochemical analysis,and the microbial mineralization experiments were then conducted, as such the controlling factors for the formation of large-scale reservoirs were determined. Our studies show that, the tectono-depositional differentiation of Sinian cratons in Sichuan Basin is controlled by the subduction and retreating extension of the peripheral plates since NanhuaPeriod and characterized by the inherited development and intermittent activities. The continuous sedimentary records of deep-water environment for the Dengying Formation in rift trough were discovered in northwestern Sichuan Basin, confirming that the Mianyang-Changning paleo-rift was an inherited negative geomorphological tectonic unit.The rare earth element patternsfrom the layered siliceous dolomite indicate that the Dengying Formation developed along the edge of the rift trough wascontrolled by hydrothermal activities. And the deposits ofthe Doushantuo Formation along the rift trough were thicker, suggestingthatsubsidence occurred at an early stagewith microbial rocks developing along the platform margins andthe basin has a background of periodicalsubsidence. The evidence of onlap and exposure dissolution of stratainside rift trough, confirming that there used to be multi-stage erosion in the Dengying Formation. The formation and distribution of large-scale reservoirs of Sinian is controlled by high-energy facies belt together with early dolomitization and early dissolution. The microbial induction experiments showed that dolomitization at the quasi-contemporaneous periodcould be promoted by specific paleo-ocean, paleoclimate and paleontological conditions,and the organic acids produced by the microbial degradation were beneficial to the early dissolution of carbonate minerals.The frequent exposure and dissolution of microbial rocks in the platform margin zone contributed to the development and distribution of high-quality reservoirs in the Dengying Formation, which was also the basis for the development of lithologic traps in the platform margin zone.

Keywords: Characteristics, Main control factors, Dolomite Reservoir , Xiaoerblak Formation, Lower Cambrian, Tarim Basin

Lower Cambrian pre–salt ultra–deep formation (>6500m) is an important exploration field in Tarim basin, NW China, but the features and genesis of reservoir are still unclear. This study took Aksu area (NW Tarim basin) as an example, the lower Cambrian outcropped more than 28km, based on 7 outcrops, more than 800 thin sections and multi-parameter geochemical data, it was found that: (1) The reservoir is mainly developed in Xiaoerblak Fm., and the lithology is mainly microbial dolomite; The thickness of Xiaoerblak Fm. is between 158m and 178m, form the bottom up, it can be divided into four members, Member X1 mainly developed laminated microbial dolomite (LMD) with gentle ripple-like structure and bright–dark pattern; Member X2 mainly developed massive thrombolite dolomite (MTD); Member X3 mainly developed foamy microbial dolomite (FMD), grain dolomite (GD) with microbial bind structure and oncolite domolite (OD); Member X4 mainly developed laminated microbial dolomite with Tepee (LMDT), laminated stromatolite dolomite (LSD), micritic dolomite (MD) and argillaceous dolomite (AD); (2) Vugs, framework pores, fenestral pores, intergranular dissolved pores are the main reservoir spaces; The porosity has high lithofacies selectivity, FMD has the highest average porosity (5.7%), MTD and OD are secondly (4.1%~4.3%), GD and LSD are thirdly (2.2%~2.4%); Generally speaking, the microbial reservoir has the characteristics of middle–high porosity and middle–low permeability, and the average thickness is about 41.3m. (3) Low dolomite order degree(0.45~0.77), relatively low Fe, Mn and high Na content, δ18O(-6‰~-8‰, PDB) and 87Sr/86Sr (0.7090~0.7095) have the characteristics of Cambrian seawater, deficit of light REE and enrichment of heavy one indicate that the dolomitization of microbialite were took place in early diagenetic stage and the main dolomitization fluid is relevant to coeval seawater. (4) Pores were formed in synsedimentary or penecontemporaneous period based on laser U-Pb radiometric dating data (Age of microbial dolomite is 515±30Ma and calcite cement in the pores is 495±12Ma); According the negative excursion points in δ13C curve are correspond with the high porosity zones, it can be clearly prove that there exist disconnected surface of sedimentary, microbialites were dissolved by fresh water in penecontemporaneous period. Cambrian pre–salt ultra–deep microbial reservoir was mainly controlled by lithofacies and high–frequency sequence and early dolomitization. By establishing the reservoir geological model of study area, it shows that microbial mounds in inner to middle ramp around the ancient uplift are the favorable facies zone.

Reservoir rock classification based on fusion clustering analysis: A case study of M Group in H oilfield, Iraq

Guanghui Duan[1], Meiyan Fu[1*], Can Ling[1], Haoxiang Lan[1], Pei Chen[1], Xinyi Han[1]
1. College of energy, Chengdu University of Technology, Chengdu, Sichuan, CHINA
E-mail: fumeiyan08@cdut.cn

Keywords: H oilfield,M formation,fusion clustering,carbonate rock classification, reservoir type

The carbonate reservoir of formation M in H oilfield of Iraq has strong vertical heterogeneity and complex pore structure. Accurate understanding of the reservoir rock type severely restricts the development and deployment of waterflood in the later stage of the reservoir. Based on the data of core, thin section, logging and petrophysics, a clustering classification method combining petrophysics and geological origin of formation M in H oilfield is established, and five reservoir rock types are divided: mudstone, wackdetone, low-energy granular limestone, mixed granular limestone I and mixed granular limestone II, high-energy granular limestone I and high-energy granular limestone II. The physical properties from good to bad are: high-energy granular limestone I, high-energy granular limestone II, mixed granular limestone I, mixed granular limestone II, low-energy granular limestone, wackdetone and mudstone. The results show that the mixed granular limestone I, the high-energy granular limestone I, and the high-energy granular limestone II have a large oil production index per meter and a long stable production time. The high-energy granular limestone I is an abnormally high-permeability layer, and it is the rock type that should be evaluated during the water flooding process. The classification method of reservoir rock types established in this paper provides a new geological basis for geological modeling, reserve evaluation and waterflooding development plan design.

Reservoir characteristics and formation model of the Mao-1 Member of Middle Permian in eastern Sichuan Basin

jianping fan[1], jinmin song[1*], shugen liu[2]
1. College of energy, Chengdu University of Technology, Chengdu, Sichuan Province, CHINA
2. Xihua University, Xihua University, Chengdu, Sichuan Province, CHINA
E-mail: songjinmin@sohu.com

Keywords: eastern Sichuan Basin, Makou Formation, reservoir characteristics, pore structure, controlling factor, reservoir development model

The Permian is an important period for the transformation of the Phanerozoic global pattern and the Pangea supercontinent began to break up and the Paleo-Tethys Ocean expanded further. The global paleoclimate experienced a transition from cold to warm in Permian and the climate was still cold in the early to middle Permian. Recently, great exploration discoveries have been made in unconventional argillaceous limestone of Mao-1 Member in Middle Permian of borehole JS1 and YH1 in Eastern Sichuan Basin. Based on field outcrop, core description, thin section identification, petrophysical analysis, X-ray diffraction, nuclear magnetic resonance, Ar-ion polishing scanning electron microscope, TOC test and CT scanning, as well as well logging data interpretation, the reservoir characteristics and controlling factors of Mao-1 Member argillaceous limestone have been discussed in this paper. The mudstone, micritic bioclastic limestone, bioclastic micritic limestone and argillaceous bioclalstic micritic limestone dominate in Mao-1 Member with intergranular pores (fractures), organic pores, dissolved pores (fractures), fractures and talc shrinkage pores (fractures) in reservoir spaces. The Mao-1 Member reservoir in eastern Sichuan Basin is low porosity and low permeability. The pores of mudstone are mostly less than 0.1μm in size with unimodal style, 0.69% in average porosity, lower movable fluid saturation and connectivity. As for the micritic bioclastic limestone reservoirs, the pores are dominated by small to medium pores in size of 0.1μm to 0.5μm, with bimodal style, 0.79% in average porosity and grade II connectivity. The bioclastic micritic limestone and argillaceous bioclastic micritic limestone are higher quality reservoirs with medium to larger pores in size of 0.5μm to 1μm, bimodal style, larger movable fluid saturation, grade III connectivity and 1.97%, 2.70% in average porosity respectively. The Mao-1 Member reservoirs in eastern Sichuan Basin is controlled by sedimentary microfacies, organic matters abundance and diagenesis processes. The outer ramp bioclastic micritic limestone microfacies and argillaceous bioclastic micritic limestone microfacies are the most favorable reservoirs with more pores and clay minerals. The pores are close related to the clay mineral. On one hand, the pores are protected through inhibiting calcite precipitation resulting from the organic matter adsorbed by clay minerals. On the other hand, the newly formed micropores and organic pores by clay mineral transformation, which consist of the most part of the reservoir spaces. Besides, the pores related to dissolution and dolomitization occupy another part of reservoir spaces, which would further improve the reservoir quality. Finally, the reservoir development model of Mao-1 Member in eastern Sichuan Basin is established. During sedimentary period, the bioclastic micritic limestone and argillaceous bioclastic micritic limestone have been selectively dissolved by meteoric freshwater, forming dissolution pores and channels for fluid modification. During the medium to deep burial phase, sepiolite underwent diagenetic transformation, forming a large number of clay micropores and organic matter pores. At the same time, the released Mg^{2+}-enriched diagenetic fluid result in dolomitization, so as to improve the reservoir quality. In the deep burial period, the acid fluid further modified the reservoir, to form pressure solution fractures which would further improve the reservoir quality.

Compound karst development in carbonate-evaporite basin: models and application to reservoirs of the Ordovician Majiagou Formation in Ordos Basin, China

Tao Zhang[1*], Xiaohui Jin[1], Juntao Zhang[1], NIng Gu[1]
1. oil and gas exploration department, Petroleum Exploration and Production Research Institute, SINOPEC, Beijing, CHINA
E-mail: zhangtao1973.syky@Sinopec.com

Keywords: Carbonate-evaporite basin, Compound karst, reservoirs, Majiagou Formation, Ordos Basin

Abstract: Three carbonate and evaporite sedimentary cycles are well developed in the Ordovician Majiagou Formation. Members 1, 3 and 5 of the Ordovician Majiagou Formation are composed of gypseous dolomite and anhydrite-salt rocks. Members 2, 4 and 6 are mainly carbonate rocks. Reservoirs with prominent characteristic of sandwich-like structure are extensively distributed in basin marginal areas, which is an important field of gas exploration in Ordos Basin. Based on the comprehensive analysis of formation correlation, sedimentary principle analysis and sequence stratigraphic interpretation in evaporite-carbonate successions from wells, cores and field profiles, the following understanding of the genetic model of compound karst and the controlling factors of reservoir development are got as follows1) Thick evaporites must correlate to unconformities in their surrounds, there is an asynchronous time between carbonate in the basin margin and evaporates in basin center. 2) Sequences begin with the evaporites, precipitated as lowstand basin-centre halite fills in complete drawdown basin, and carbonate sediments mainly deposited on shallow-water platforms apron the basin during transgressive and highstand systems tracts; 3) Early dissolution occurred in basin margin, and the edges of a thick evaporite succession where flushing by meteoric water and characterized by layers of thin dissolution breccias when the evaporite dissolves completely, especially in the thin layers of carbonate interbedded with sulphate rocks; 4) It is clear that the stratiform gypsum-dissolved breccia layers are mainly distributed in the outer area of evaporite, the shoal dolomite beds below breccia layer are favorable reservoir segments, and the gypsum-moldic pores were developed outside; 5) The lateral erosion or sedimentary discontinuities are the main factors for the interlayer dissolution, and the multi-stage sedimentary discontinuities control the development range of reservoirs. These models are applied to the Ordovician Majiagou Formation in Ordos Basin, and sequence and parasequence boundaries are identified. Together with regional uncomformity (between Ordovician and carboniferous), shoal facies and fault-reated corrosions, the reservoirs model with features of superimposed compound karst zones are proposed and play significant role in predicting the distribution of favorable reservoir area.

Controlling effect of Cretaceous shoal facies types on reservoir development in Iraq---- Take KH2 Member of Khasib Formation in A Oilfield as an example

zhonghui cai[1*]
1. petroleum geology, Chengdu University of Technology, Chengdu, Sichuan, CHINA
E-mail: 1218577750@qq.com

Keywords: Shoal facies type, Cretaceous, Reservoir development mechanism, Khasib member, Iraq

The cretaceous limestone reservior in Iraq A oilfield has complex pore structure and strong longitudinal heterogeneity, and the unclear controlling factors of reservior development seriuosly restrict the oilfield development and recovery efficiency.Based on the data of core, thin section and logging response, the sedimentary subfacies of the KH2 member is divided into intra-platform shoal and grey flat, which are mainly composed of psammitic shoal, bioclastic shoal, algal-clastic shoal and inter-shoal. On the basis of Dunham classification, the KH2 member can be divided into seven lithofacies according to the main particle types, including planktonic foraminifera wackstone, laminar bioclastic wackstone, intraclast bioclastic packstone, patchy green-algal packstone, bioclastic intraclast packstone and intraclast grainstone. The pores of carbonate resevoir are mainly moldic pore, intrafossil pore, intergranular pore and dissolved pore. Based on the differences of sedimentary microfacies, lithology, pore type, physical characteristics and pore structure, it is clear that the type of shoal facies is the main controlling factor of reservoir development. Psammitic shoal and algal-clastic shoal have the best physical properties and have the characteristics of stable transverse distriction. This study reveals the controlling factors of thick shoal limestone reservior and makes it clear that the key factor for the development of such reservior is the fine description and evaluation of sedimentary microfacies and lithofacies.

Genesis and Classification of Breccia in Cretaceous limestone Reservoir of H Oilfield in Iraq

1*

1. , , , , CHINA
E-mail: 764600583@qq.com

Keywords: Iraq,Cretaceous,H oilfield,Carbonate breccia,genetic classification

Breccia rocks with different production and characteristics develop in the Cretaceous reservoirs in Iraq, but they have not attracted enough attention in previous studies.In order to clarify the sedimentary process and diagenesis contained in the breccia, this study classified the breccia according to their origin.Using the drilling core, thin section and logging data in the study area, this study thought Iraq H oilfield Cretaceous carbonate breccia in formation can be divided into two categories: sedimentary origin breccia, for early weak consolidation carbonate geological effect, such as short-term high-energy water transformation, formed in the slope and bottom scour breccia, collapsed breccia and storm breccia, etc; non-sedimentary breccia, mainly karst breccia from unintegrated surface, whose development is related to the unintegrated surface in the top area of Mishrif group.The sea-level drop caused large exposure, forming karst breccia of grey-green mudstone mixed with white carbonate breccia.The sedimentary breccia reflects the slope-ancient uplift area, indicating the development of grain shoal and rudist organic reefs in its adjacent area.Karst breccia indicates the geomorphic units with more obvious topographic fluctuations, such as the residual mound edges in karst slopes and karst depressions.The results support the origin of breccia in carbonate reservoir under similar geological background.

Origin of the deep buried dolostone reservoir of the Lower-Middle Cambrian, Tarim Basin, NW China

Bo Liu[1*]
1. School of Earth and Space Sciences, Peking University, Beijing, CHINA
E-mail: bobliu@pku.edu.cn

Keywords: Origin, Deep Buried, Dolostone Reservoir, Cambrian, Tarim Basin

The origin of the porous dolostone in the deep buried environment arouses the interests of geoscientists and attracts the attention of explorationists. Recent global oil and gas exploration is advancing to deep and ultra-deep ancient marine carbonate rocks, one of such targets is the deep buried Cambrian dolostone reservoir in the Tarim Basin. It is obvious that the deep buried old strata had experienced the processes of sedimentation and diageneses. Sedimentation created the primary pores and the diageneses reworked the pores by enlarging or filing the pore space. For deep buried carbonate reservoir, the diagenetic evolution sounds playing the key role to establish the final reservoir. Based on the microfacies analyses, petrographic research and geochemical analyses of the dolostone reservoir samples from the Cambrian outcrop and well core, we ascribe the origin of the reservoir to the preservation of original pore spaces in the process of burying.

The Lower-Middle Cambrian can be divided into five third-order sequences (SQI-SQV), in which 17 microfacies (MF) types were recognized and further grouped into 7 microfacies associations. SQI-SQIII were mainly ramp deposits which changed vertically from muddy ramp to carbonate ramp and then to mixed ramp, while SQ IV-SQV were weakly rimmed carbonate platform deposits. The reservoir is mainly composed of microbial dolostone (MF9) and grain dolostone (MF10c, MF13). The reservoir quality of grain dolostone is better than that of microbial dolostone. The pore space of grain dolostone reservoir is intergranular pores and intercrystal pores, while the microbial dolostone reservoir is dominated by microbial framework pores, vugs or caverns and fractures.

The grain or microbial dolostones developed as shoals and microbial mounds in the high energy environment had abundant intergranular primary pores, which also deposited as a positive landscape and then be easy affected by the early diagenesis, such as penecontemporaneous meteoric dissolution. When these deposits with high primary and early secondary porosity were buried, the preservation of porosity was attributed to early massive dolomitization and rapid sealing effect of the overlaying thick evaporites. One reason is that the relatively closed buried system can keep pore fluid overpressure and reduced the pressure solution and cementation of the pores. The other diagenetic changes such as deep faulting and related thermal fluids affection might have strong influences on the reservoir quality and distribution, but generally these changes took place in deep environment could only attribute a little or local reconstruction of reservoir space by considering the limited fluids flux and its dissolution ability.

Keywords: Microbialites, Numerical Simulation, Dengying Formation, Sichuan Basin

As one of the oldest and deepest carbonate gas-bearing strata in China, Dengying Formation reemerged as the exploration target after the breakthrough of GS1 well in Central Sichuan Basin [1]. Previous studies indicated that reservoirs of Dengying Formation mainly dominated by microbial dolomites, including stromatolitic dolomitess, thrombolitic dolomites and straticulate dolomites [2, 3]. Researches of microbial dolomites characteristics in Second Member of Dengying Formation (Z2dn2) has been carried out via cores, slices, logging and seismic interpretation [4, 5]. However on account of large burial depth and strong heterogeneity, it's hard to accurately predict the spatial and temporal distribution of microbial-dominated reservoirs in Z2dn2. Based on documents investigation, 10 wells cores description, slices observation and samples experiments, we acquired the necessary parameters like simulation duration, palaeotopography, eustatic sea-level change, tectonic subsidence, temperature, salinity, subaerial erosion and microbialites growth fuzzy sets. After multiple parameters calibration during simulation process, we carried out the 3D sedimentary forward modelling of microbialites developments in Z2dn2 using Sedsim software. By comparing simulation results with actual geological data including seismic sections, depositional facies and individual well thicknesses, we confirmed the model validation. Our simulation results indicated that six types of sedimentary facies are developed in Z2dn2, including supratidal facies, intertidal facies, shallow-subtidal facies, deep-subtidal facies, slope and basin facies. Microbial-dominated reservoirs mainly developed in shallow-subtidal facies and abundant high-quality dolomite calcolistolith also occurred in slope and basin facies.

Keywords: Waveform indication inversion,Seismic facies,sedimentary facies,Thin reservoir prediction,shuangyushi structure

The dolomite reservoir of the Middle Permian Qixia Formation in shuangyushi structure in the northwest of Sichuan Basin has deep burial depth, thin thickness and strong heterogeneity. Under the condition of low resolution seismic data, the reservoir signal is not easy to identify and the reservoir prediction is difficult. Based on high-resolution seismic data processing, well seismic combination, starting from forward simulation and combined with real drilling profile, this study defines the waveform characteristics corresponding to different reservoir development modes. The research shows that the reservoir of Qixia Formation in the area has two response modes of "weak peak" and "complex wave". Through waveform clustering technology and referring to the drilled lithofacies information, a seismic facies plan is formed to finely depict the plane distribution of the reservoir; On this basis, high-resolution seismic waveform indication inversion under facies control constraints is carried out to clarify the distribution range of dolomite reservoir. The actual drilling results confirm that the coincidence rate of reservoir prediction is high, which provides a reference for the prediction of ultra deep and thin reservoirs in this area.

Keywords: Carbonate reservoir, Formation pressure, Maximum and minimum principal stress, Stress difference, Upper Member of Yingshan Formation, Tarim Basin

Since carbonate strata is brittle and prone to fracture, the tectonic movement is of great significance to the formation and distribution of carbonate reservoirs, especially the surface stress field is closely related to the reservoir distribution. However, it is still unclear how the surface stress field controls the distribution of carbonate reservoirs. In order to clarify the specific control effect of surface stress field on deep carbonate reservoir, this paper takes the Upper Member of Yingshan Formation in well S66 of Tahe Oilfield in Tarim Basin as an example, and makes full use of geophysical data to carry out comprehensive research in combined with drilling and reservoir engineering as well as other information. Firstly, the overlying strata pressure, formation pressure, maximum and minimum principal stress and stress difference in a single well were calculated. Then the distribution law of surface stress and stress difference in space were determined. In addition, through the comprehensive analysis of the correlation between the parameters such as porosity, reservoir thickness and fracture thickness. Finally, the distribution of surface stress field parameters, and the control effect of current surface stress field on reservoir distribution were determined. The surface stress interpretation data show that the overlying formation pressure of the Upper Member of Yingshan Formation is high in TK629H in the east, S66 in the middle and TK671 in the west, ranging from 129.95 to 130.95 MPa, and is low from TK682 to TK677 well area in the south with a value between 123.2 and 124.56 MPa. The formation pressure is between 57.8 and 61.81 MPa, with an average of 58.2 MPa, and the formation pressure coefficient is between 1.07 and 1.14, with an mean of 1.10, implying a normal pressure system. The maximum horizontal principal stress varies from 151.8 to 160.4 MPa, with a mean of 155 MPa, the minimum horizontal principal stress is between 91.6 and 97.2 MPa, with an average of 95.2 MPa, and the stress difference between maximum and minimum ranges from 58.1 to 63.2MPa, with an average of 59.5 MPa. Study on the relationship between surface stress field and reservoir parameter distribution shows that the high reservoir thickness value area is mainly distributed in the relatively low formation pressure, low maximum horizontal principal stress, high minimum horizontal principal stress and low stress difference value area. The high value area of reservoir porosity distribution is mainly distributed in the high value area of pressure coefficient and minimum principal stress, the low value area of maximum principal stress and stress difference. The high value area of fracture thickness is mainly developed in the low to middle value area of formation pressure coefficient, maximum horizontal principal stress and stress difference, as well as the relative low value area of minimum horizontal principal stress.

E-mail: wiliam.freitas@pucrs.br

Keywords: image analysis, micro-CT, porosity, pre-salt reservoirs, carbonates

Pre-salt deposits respond for more than 70% of hydrocarbon production of Brazil, and are currently the subject of several petrological, sedimentological and stratigraphic studies. These complex deposits present important reservoir heterogeneities, and their evaluation by different methods is necessary for a better understanding of their petrophysical properties. This study seeks to compare different porosity assessment tools in core samples, thin sections, and digital photomicrographs. Porosity quantification was performed using three methods: (i) image acquisition and processing using a Bruker SkyScan 1173 µ-CT; (ii) thin section point-counting; and (iii) porosity analysis on photomosaics using ZEISS ZEN 3.1 and Bruker CTAn 1.13 image analysis software. The selected samples represent different facies of a cored interval in one well of the Pre-Salt section of Santos Basin, and show different porosity characteristics, owing to different depositional and diagenetic aspects. Samples comprise shrubstones, mudstones, shrubs-spherulstones, and reworked intraclastic facies. The results indicated that the calculated porosity values vary according to the applied method and the resolution of the analysis. µ-CT scanning was performed at a resolution of 10 µm to 7 µm, which yielded higher porosity values. While point-counting petrography resulted in a measurement of 23% of porosity for a sample from a reworked deposit, values between 4% and 5% were obtained through the analysis of a photomosaic from the same thin section. Preliminary quantitative petrography analysis resulted in significantly high porosity values when compared to semi-automated porosity calculation on a photomosaic, which resulted in values close to those obtained through microtomography image processing of a sample. On the other hand, petrography helped to recognize the types and distribution of pores in each facies, allowing the refinement of the regions of interest (ROI) for porosity calculation through image analysis. In addition, detailed petrography was used to understand the possible causes of the discrepancies between the techniques. For example, the microporosity in calcite aggregates and intraclasts present in these lithologies, which is observed in petrography, is not properly assessed by the other techniques, as the micropores sizes are usually below the resolution of the methods. Additionally, it must be noted that the samples cut for thin section preparation and for µCT must be representative of the layer, considering the rapid vertical variation of Pre-Salt deposits. The work in progress aims to gather data for a statistical analysis of the patterns of discrepancy among the results coming from the different methods, as well as to discuss their geological significance, concerning the porosity characteristics observed in petrography and core analysis of the Pre-Salt reservoirs.

3. Petroleum Exploration and Development, PetroChina Research Institution, Beijing, CHINA

E-mail: wanggw@cup.edu.cn

Keywords: Longgang area,Changxing-Feixianguan Formation,Carbonate reservoir,Image logs facies,Sedimentary microfacies

The Changxing-Feixianguan Formation in the Longgang area of the Sichuan Basin is rich in oil and gas resources. However, the development of reservoir evaluation has been severely restricted by the complex sedimentary types, variable lithology and lithofacies, and strong reservoir heterogeneity. Thus, it is great significant to study the logging identification of lithology and sedimentary microfacies in this area .In this study, the carbonate reservoir of the Changxing-Feixianguan Formation in the Longgang area is taken as an example. Based on the cores, thin sections, conventional logs, image logs, experiment and production data, the classification scheme for image logs facies and sedimentary microfacies has been established firstly with the guidance of classic carbonate deposition models. Then, the comprehensive identification chart of sedimentary microfacies has been established by using the method of "conventional + image + core + geological model ", and the vertical continuous identification of sedimentary microfacies of each single well has been achieved. Finally, the relationship between high-quality reservoirs and sedimentary microfacies has been clarified by combining the test data and comprehensive logging interpretation. The results indicated that the sedimentary facies types of Changxing-Feixianguan in Longgang area are mainly platform margin facies, open platform facies, restricted platform facies and slope facies. According to the characteristics, they can be further subdivided into ten subfacies including platform margin beach, platform margin reef-complex, beach interact sea , intra-platform beach, intra-platform reef, open sea, platform flat, restricted lagoon, restricted tidal flat, upper slope and more than twenty microfacies. Meanwhile, the image logs facies of typical sedimentary microfacies in the study area are mainly divided into five categories: layered pattern, linear pattern, strip pattern, spot pattern and massive pattern, which can be further divided into nine sub-categories: laminar pattern, thin-layered pattern, strip pattern, irregular line pattern, single line pattern, bright massive pattern, dark massive pattern, honeycomb dark spots pattern, and blocky dark spots pattern. In addition, the results of oil testing and statistical analysis of comprehensive logging interpretation further prove that microfacies such as high-energy bioclastic beache and dolomitized oolitic beache are favorable sedimentary microfacies for the development of high-quality reservoirs. The research results provide basis for the fine evaluation of reservoirs in the Changxing-Feixianguan Formation.

Defining the age of ultra-deep carbonate diagenetic minerals and their fluid sources based on in-situ U-Pb isotope dating, in-situ isotope and rare earth element analysis techniques: A case study of the Cambrian subsalt dolomite reservoir in the Tazhong uplift, Tarim Basin

Chaozheng Li[1*], Jianzhong Li[1], Xiaowan Tao[1]
1. Institute of Petroleum and Natural Gas Geology , Research Institute of Petroleum Exploration and Development, Beijing, CHINA
E-mail: lcz_cup@163.com

Keywords: Cambrian subsalt dolomite, U-Pb isotope dating, Rare earth element, Thermal fluid, Permian magmatic activity

The formation and distribution of diagenetic minerals in reservoirs and the sources of diagenetic fluids are of great significance for analyzing reservoir formation and evolution, limiting hydrocarbon and other geological fluid charging events, and analyzing their related geological processes.

The Lower Cambrian Xiaoerbulak Formation in wells ZH1 and ZH2 in the Tazhong uplift in the Tarim Basin was taken as an example. Based on rock thin section observation, cathodoluminescence analysis, scanning electron microscope observation and energy spectrum analysis, combined with the analysis of the homogenization temperature of inclusions, the mineral type, occurrence and relative diagenetic sequence were clarified. And the ages of carbonate diagenetic minerals and sources of diagenetic fluids were determined by using the methods of laser in-situ U-Pb isotope dating, in-situ carbon and oxygen isotopes, strontium isotopes and rare earth elements (REEs).

The results show that the dolomite reservoirs of the Xiaoerbulake Formation in the Tazhong area mainly develop silty-fine-crystalline dolomite, saddle-shaped dolomite, granular calcite and quartz minerals. The silty-fine-crystalline dolomite is mainly distributed at the edge of the pores and is a relatively early dolomitization product. The cathodoluminescence is similar to that of host rocks. The diagenetic fluid is normal seawater pore fluid. The saddle-shaped dolomite is divided into two stages, with a U-Pb age of 453±7Ma and 435±29Ma. The REE distribution pattern is similar to that of host rock. Therefore, it is a buried dolomitization product and the diagenetic fluid is normal seawater in pores. The U-Pb isotopic dating indicates that the calcite filled with dissolved pores was formed in the Middle Permian (263±9Ma). The analysis of carbon and oxygen isotopes, strontium isotopes and REEs shows that the values of $\delta^{13}C$, $\delta^{18}O$, $^{87}Sr/^{86}Sr$ of calcite cement from ZH1 is close to those of host rocks. The REE distribution pattern is characterized by light REE enrichment and positive δCe anomaly and the total content of rare earth elements (∑REE) is slightly higher than that of host rocks, which reflects that calcite inherits the characteristics of REE in host rocks. This further indicates that the calcite diagenetic fluid is derived from a mixture of diagenetic fluids and hydrocarbon-generating fluids.

Compared with well ZH1, the calcite from well ZH2 has more negative carbon and oxygen isotope values. That is, the average value of $\delta^{13}C$ is -4.3‰ and the average value of $\delta^{18}O$ is -11.0‰. Moreover, some calcites have bright red cathodoluminescence, and the luminescence intensity is higher than that of the host rocks. REE analysis shows that there is a relatively obvious δEu positive anomaly. In addition, the calcite can be symbiotic with quartz in pores and fractures, and the homogenization temperature of primary inclusions is higher than the maximum burial temperature of contemporaneous strata. These indicates that this type of calcite cement is mainly the result of the combined interaction of diagenetic fluid and thermal fluid, and the thermal fluid is probably related to the Tarim Permian magmatic activity.

E-mail: jiaocl.syky@sinopec.com

Keywords: Dolomite reservoir,sedimentary facies,Control factors,Xiaoerbulak formation,Tarim Basin

The Cambrian Xiaolbulak Formation in the central and western Tarim Basin is composed of dolomitic limestone, dolomite, microbiolite, limestone interspersed with a small amount of argillaceous limestone and gypsum dolomite. It is dominated by carbonate gentle slope and carbonate confined platform faciesIn the northeast the water deepened to shelf - basin facies, and thirteen microfacies could be identified. Tidal flat facies dolomite and bioherm beach facies dolomite reservoirs are developed in Xiaolbulak Formation. The atmospheric water dissolution and dolomitization in supergene period are the key to formation and development of reservoir. Fracturing and burial (hydrothermal) dissolution improve the reservoir. Tidal flat facies dolomite reservoirs are developed in the restricted environment of middle and inner gentle slope, tight limestone deposits are formed in the middle and outer gentle slope semi-restricted environment, and better dolomite reservoirs are formed in the late platform margin zone. The dolomite reservoir of Xiaoerbulak Formation in northeastern Tahe platform margin and central-western Tazhong area are favorable exploration targets for subsalt deep strata.

Differences and pattern of karst reservoirs in the Majiagou Formation in the northern Ordos Basin

juntao zhang[1*]
1. petroleum exploration and production research institute, sinopec, Beijing, CHINA
E-mail: zhangjt.syky@sinopec.com

Keywords: evaporated salt minerals, carbonate rock; karst model, reservoir, Majiagou Formation, Ordos Basin

Karst reservoirs are generally developed in the Majiagou Formation in the northern Ordos Basin, but are obviously different from the classic karst model. Through petrological and geochemical analysis, three types of reservoirs with genetic connection and affected by gypsum-bearing strata are identified, and the karst model of evaporated rock in Majiagou Fm. is established. The results show that gypsum mold pore reservoir is formed by the Sabkha dolomitization and rich in evaporated minerals, the sedimentary environment is gypsum-bearing dolomite flat. Dissolved pore-intercrystalline (vug) pore dolomite reservoir is formed by the brine-reflux dolomitization, which fluid comes from the overlying gypsum bearing strata and is mainly developed in shoal facies. Limestone-fractured-cavity reservoir is mainly developed in limestone formations, the original sedimentary environment is limestone flat, and the formation of cracks in (dolomitic) limestone is related to the dissolution and deformation of the underlying gypsum-bearing rock. In terms of spatial distribution in the study area, all three types of reservoirs are distributed in the central and eastern regions, the dissolved pore-intercrystalline (vug) pore dolomite reservoirs developed in the western, and the limestone-fractured-cavity reservoirs in the northern. The same reservoir type also exhibits different rock and geochemical characteristics in different paleo-geomorphic units. The higher parts are mostly characterized by seepage areas. The reservoirs are well preserved, a small amount of filling, and less atmospheric precipitation geochemical characteristics. The lower part shows the characteristics of stagnant water area, with serious reservoir damage, a large amount of calcite filling, and more atmospheric precipitation transformation characteristics.

Sequence Stratigraphic Framework of Leikoupo Formation of Middle Triassic in Western Sichuan and Hydrocarbon Generation and Reservoir Effect of Tidal Flat Lagoon Carbonate Rocks

Lingfang Zhou[1*]

1. Wuxi Research Institute of Petroleum Geology, Sinopec Petroleum Exploration and Production Research Institution, Wuxi, Jiangsu Province, CHINA
E-mail: jzzlf309@21cn.com

Keywords: Leikoupo Formation, sequence stratigraphic framework, microbial rocks, tidal flat lagoon, hydrocarbon generation and reservoir formation

During the Middle Triassic period, the West Sichuan depression was a closed evaporating tidal flat lagoon sedimentary environment. Ten shallowing-upward sedimentary cycles, which were composed of carbonate evaporates, were identified and subdivided into four third-order sequences based on detailed observation of five outcrop sections and four drillcores. At that time, microbialites mainly composed of columnar stromatolites and clotted agglomerates were extensively present in the second and fourth members of Leikoupo Foramtion. Columnar and wavy stromatolites generally occurred in the lower part of the intertidal-supratidal zone, whereas clotted limestones and oncolites mainly distributed in the lower part of intertidal-subtidal zone during the sea-level cycle of declination. The number and thickness of these microbial rocks are gradually decreasing (thin) from west to east and columnar stromatolites accordingly transform into wavy stromatolites to mound. These microbialites generally exhibit variable reservoir heterogeneity. The high-quality microbialite reservoirs, which consist of stromatolite and clotted limestone, mainly occurred in the rising semi-cycle. In addition, the salt rocks formed in the evaporating tidal flat and lagoon have well hydrocarbon generation potential during the regression period. Therefore, tidal flat and lagoon are favorable sedimentary environments for the foramtion of source rocks.

Distribution Characteristics and Sedimentary Model of Gypsum-bearing Evaporite of the Middle Cambrian Gaotai Formation in the eastern Sichuan Basin

Jixuan Wang[1], Zhongui Hu[1*]
1. School of Geosciences, Yangtze University, , , CHINA
E-mail: hzg1978@yangtzeu.deu.cn

Keywords: Gypsum-bearing evaporite, Eastern Sichuan Basin; Gaotai Formation, Normal lagoon, Mixed deposition lagoon, Depositional model

ABSTRACT Gypsum-bearing evaporite is a globally important oil and gas cap-rock. Sealing of oil and gas reservoirs by gypsum-bearing evaporite is of great importance for oil and gas storage, particularly for natural gas. During the Middle Cambrian, the Gaotaii Formation, gypsum-bearing evaporite was deposited in the eastern Sichuan Basin, which is a key caprock for deep oil and gas resources. Yet little research exists on the gypsum-bearing evaporite of the Gaotai Formation. Based on a field survey, the latest well, lithology, logging and comprehensive analysis of previous data, the lithological division, and genetic type analysis of the gypsum-bearing evaporite, a platform sedimentary model was established. Two sets of gypsum-bearing evaporate associations are developed longitudinally in the Middle Cambrian Gaotai Formation in the eastern Sichuan Basin. The sedimentary environment is divided into normal lagoon and mixed deposition lagoon environments and is influenced by the provenance supply. As sea-level decreased, a “bull’s eye ring banding” pattern of sedimentary units formed in the normal lagoon. When the sea-level rose, thinly interbedded gypsum-bearing evaporite was deposited in both type of lagoons. Overall, gypsum-bearing evaporite has a "broad circular ring" distribution in the northeast direction, indicating that the dry and hot paleoclimate, continuous sea level decrease, incoming materials, and shoal barrier provided favorable conditions for the development of the gypsum-bearing evaporite in the Middle Cambrian Gaotai Formation in the eastern Sichuan Basin. The Jianshen 1 well-Wuxi gypsum-bearing evaporite block and the Taihe 1 well-Shizhu outcrop gypsum-bearing evaporite block were the two primary gypsum-bearing evaporite deposition areas at that time. Increased paleo-temperatures led to the formation of the thinner Gaotai Formation evaporite caprocks overlying the hydrocarbon-bearing reservoirs in the Longwangmiao Formation.

Sedimentary Characteristics and Developmental Models of the Cambrian Dolostone-evaporite Paragenesis System in the Sichuan Basin

zhonggui hu[1*], Jixuan Wang[1]
1. School of Geosciences, Yangtze University, Wuhan, Hubei, CHINA
E-mail: hzg1978@yangtzeu.edu.cn

Keywords: dolostone, evaporite, paragenesis system, sedimentary characteristics, developmental models

Abstract: The Cambrian strata of Sichuan Basin, China, present many dolomite-evaporite paragenesis systems (DEPS), which contain oil and gas resources with industrial exploitation. However, despite their wide distribution, the formation models and influencing factors of DEPS remain poorly understood. Regarding an abundance of literature from China, this study comprehensively summarises the sedimentary characteristics, combination patterns of rocks, and formation models of DEPS. The research significance, research questions, and future research directions of DEPS are also clarified. Firstly, the distribution of DEPS is clarified based on published studies: DEPS are widely distributed in Longwangmiao Formation, Gaotai Formation, and Xixiangchi Formation of the eastern and southern Sichuan Basin. Evaporite and dolostone combination patterns in DEPS include the following modes: interbedding of dolostone and evaporite, evaporite overlying thick dolostone, thick dolostone mixed with thin evaporite, and thick evaporite mixed with thin dolostone. Secondly, five types of evaporites and five types of dolostones have been identified. Thirdly, the spatiotemporal distribution, influencing factors, and developmental models are summarised. Studies on DEPS provide new insight into the origin of dolomite. Such research also provides theoretical guidance for the exploration of oil and gas resources in DEPS.

Understanding depositional evolution of ancient carbonate systems using 3D stratigraphic forward modelling: A case study in Puguang area (Late Permian, northeast Sichuan Basin, China)

Yuan Huang[1*], Taizhong Duan[1], Yanfeng Liu[1], Wenbiao Zhang[1], Meng Li[1], Qiqi Ma[1]
1. Overseas Project Technical Support Center/Geo-Modeling Department, SINOPEC Petroleum Exploration and Production Research Institute, Beijing, CHINA
E-mail: huangyuan.syky@sinopec.com

Keywords: Puguang area, Late Permian, deep burial carbonates, depositional evolution, stratigraphic forward modelling

Predicting temporal and spatial features of deep burial ancient carbonate depositional systems is challenging, which is limited by the lack of well data, poor seismic quality and unclear sedimentological mechanisms. The formation of carbonate depositional systems is a dynamic evolution process controlled by the interactions between various factors which determine the carbonate system types, geometries and facies distribution. To better understand the evolution history and the interactions between controlling factors of ancient carbonate systems, a quantitative analysis of the Late Permian carbonate depositional systems in Puguang area (northeastern Sichuan basin, China) is performed using iRDS-CarbSIMS, a 3D process-based stratigraphic forward and inverse modelling software able to simulate the sedimentary facies and internal architecture. Qualitative research on depositional characteristics within sequence stratigraphic frame is a precondition for stratigraphic forward modelling. Based on seismic interpretation, cores and well log data analysis, the transition from a carbonate ramp to a high-relief, reef-rimmed platform during the Late Permian Changxing period were investigated. Five main categories of parameters used for modelling were deduced from the geological qualitative research and analogue with modern deposition, including initial topography, sea level curves, subsidence, carbonate production and sediment transport. Modelling results reconstruct the evolution process of the Late Permian carbonate depositional systems in Puguang area, revealing sedimentary facies distribution in areas with sparse wells. Sensitivity analyses of the parameters provide insights into the interactions between controlling factors of carbonate platform growth, as well as the effect of regional controls on differential evolution. The integrated sedimentological approach combining qualitative research and numerical modelling is useful for mining information of geological data to the utmost in deep burial carbonate successions. Stratigraphic numerical models can promote the understanding of mechanisms of depositional evolution, improving the accuracy of sedimentary facies prediction of deep burial carbonate reservoirs.

Reformation of the hydrothermal fluid activities to the Lower Paleozoic carbonate reservoir in Dongying Depression

Zhang Xue mei[1], Li Qing[1*]
1. College of Geosciences, China University of Petroleum(Beijing), Beijing, CHINA
E-mail: liqing@cup.edu.cn

Keywords: Dongying Depression, The Lower Paleozoic strata, Carbonate reservoir, Hydrothermal fluid, Reservoir property

Abstract: The carbonate reservoir of the Lower Paleozoic in Dongying Depression is controlled by multiple types and stages of hydrothermal fluids after experiencing multiple stages of tectonic activity and volcanic activity after depositionwhich leads to the enhancement of reservoir heterogeneity, and seriously restricts the further exploration and development of the study area. Taking the lower Paleozoic marine carbonate reservoirs in the Dongying Depression as the research object, through the mineralogy and electron probe analysis technology, identified the types of fillings in the fractures (holes) in this study area, and combining geochemical data and pore evolution characteristics, the hydrothermal fluid properties, and the hydrothermal fluid's influence on the reservoir property is explored. The results show that: (1) Thermal fading of the carbonate rocks, hydrothermal fluid activities induced fractures, and hydrothermal minerals are widely developed (such as saddle dolomite, ferroan dolomite, celestite, anhydrite). The fluid inclusions of the fillings have a higher temperature than the maximum burial temperature, and positive Eu anomaly, $\delta^{18}O$ values negative anomaly. These characteristics also indicted that hydrothermal processes exist extensively in this study area; (2) The hydrothermal fluids mainly included the Mg-rich, Ca-rich and Sr-rich hydrothermal fluids in the Yanshan movement period, which precipitated the ferroan dolomites, saddle dolomites, granular ferroan calcites and celestite, respectively. Under the influence of terrigenous clastic materials, the ferroan dolomites and granular ferroan calcites exhibit high $^{87}Sr/^{86}Sr$ values and extremely positive Eu anomalies, respectively. The hydrothermal fluid dissolves the gypsum and salt layers in Sha-3 Sha-4 formation to form S-rich hydrothermal fluid in the Himalayan movement period, dissolves carbonate formation to obtain Ca^{2+}, and precipitates anhydrite in fractures; (3) Reservoir reformation by hydrothermal action controlled by lithology, fault, and fluid properties. The hydrothermal fluids mostly intruded along the dolomite and grain limestone with better original physical properties and formed more dissolution pores; Faults communicate with hydrothermal fluids, and the closer the formation is to faults, the more dissolution pores are developed, and the carbonate reservoirs have the better physical properties; The columnar and meso-crystalline fillings formed by the Mg-rich and Sr-rich hydrothermal fluids can effectively retain the early residual pores and play a constructive role in reservoir properties. The patchy anhydrite formed by S-rich hydrothermal fluids has serious damage to reservoir properties.

Sedimentary model of subsalt lacustrine carbonate reservoir in the Santos Basin

jingjing liu[1*], Jun Li[1], Yongqiang Guo[1]
1. Overseas Exploration and New Project Evaluation, Petroleum Exploration & Production Research InstituteSINOPEC, beijing, CHINA
E-mail: liujj.syky@sinopec.com

Keywords: Santos Basin, Subsalt, Lacustrine carbonate reservoir, Sedimentary model

The exploration practice indicates that the reservoir sedimentary characteristics are the key factors affecting the oil and gas production of the subsalt lacustrine carbonate rocks in the Santos Basin. The high-quality reservoirs are mainly microbial reefs and shoal carbonate rocks deposited on the ancient uplift. Based on drilling, seismic and gravity data, this paper redefined the subsalt structural unit of the Santos basin and carried out the series research about the core facies-logging facies-seismic facies-sedimentary facies. Then combined with the structural evolution characteristics and the paleogeography during rift period, the sedimentary facies distribution of subsalt depression period was determined, and the sedimentary models for the high-quality carbonate reservoir was established.

Based on the structural analysis of seismic data and gravity data, the subsalt structural layer of the Santos Basin can be divided into five first-order structural units. Seaward, there are the nearshore depression belt, the Oceanic hinge belt, the offshore depression belt, the outer uplift belt and the pelagic structural belt. The outer uplift belt is a unique geological unit for the Santos basin. During the breakup of the South Atlantic, the mid-ocean ridge underwent a transition to the West African side, and the outer uplift belt was developed from the abandoned mid-ocean ridge resulting from the transition. The outer uplift belt can be further divided into three secondary tectonic units, including the western uplift zone, the central uplift zone and the eastern uplift zone. It is very conducive to the development of microbial reefs.

Carbonate platform, depression and semi-deep lacustrine to deep lacustrine subfacies are developed in the strata of the subsalt depression period in the Santos Basin. The carbonate platform subfacies can be further subdivided into four microfaciesincluding the microbial reefs, the shoals (internal debris shoal, medium crust shoal and spherical microbial shoal) and intraplatform depression microfacies. Sedimentary facies studies indicate that multiple carbonate platforms with different sizes were developed during the depression period in the subsalt core area of Santos Basin. There developed a giant carbonate platform in the outer uplift belt, and a series of small-scale platforms were developed in the west and southeast of the outer uplift belt, the offshore depression belt and the pelagic tectonic belt. They were divided by depression facies and deep lake - semi-deep lake facies. According to the characteristics of tectonic evolution and paleogeography during the rift period, four types of high-quality reservoir sedimentary models for high-quality subsalt lacustrine carbonate rocks in the Santos Basin have been established, including the large gentle slope sedimentary model, the isolated platform sedimentary model, the inner highland sedimentary model and the steep slope sedimentary model. The reservoir of the first three sedimentary models has obtained good oil and gas discovery, such as Lula field, Iara field and Carcara field.

Sedimentary facies and reservoir controlling factors of Carboniferous carbonate rocks in the eastern margin,Pre-caspian Basin

Xueke Wang[1*], Zhen Wang[1]
1. Central Asia and Russia, Riped, Beijing, CHINA
E-mail: wangxueke01@petrochina.com.cn

Keywords: Carbonate rock,Carboniferous, Sedimentary facies, Main control factors of reservoir, Pre-caspian basin

Carboniferous in the eastern margin of Caspian Basin can be divided into Dune Stage, Weixian Stage and KT-II reservoir group, MKT mudstone section and KT-I reservoir group from bottom to top, among which the subsalt KT-II and KT-I carbonate reservoir groups are the exploration emphases. Using thin section, logging and seismic data, sedimentary facies and reservoir controlling factors of KT-II and KT-I reservoirs are studied.The following results are obtained: Through the study of lithofacies, logging facies and seismic facies, carbonate platform sedimentary system can be established in the eastern margin of the basin.Four sedimentary facies are developed, which are limited platform, open platform, platform edge and platform front slope. Open platform intra-platform shoal subfacies and platform edge reef beach are where high-quality reservoirs develop. The reservoirs in the eastern margin of the basin are mainly develop bioclastic shoal limestone and algal (bonded) limestone, oolitic limestone and a small amount of algal lattice limestone. The reservoirs mainly develop intergranular dissolution pores, intragranular erosion pores, and dissolution expansion pores. The distribution characteristics of reservoirs are controlled by the distribution of "intra-platform shoal & unconformity surface dissolution". Reservoirs develop in multiple layers vertically in the middle and upper part of the high-frequency cycle, and the horizontal discontinuity is widely distributed. The reservoirs have experienced four diagenetic sequences: cementation and dissolution in the (quasi) syngenetic period → shallow compaction and cementation filling in the early diagenetic period → unloading fracture caused by tectonic uplift in the supergene diagenetic period, and ancient supergene karst and fresh water filling cementation → re-burial compaction, pressure dissolution and burial cementation in the middle-late diagenetic period. The main controlling factors of reservoir development are quasi-contemporaneous dissolution of favorable intra-platform shoal subfacies and dissolution of unconformity surface. High-energy platform beach facies deposition is the foundation of reservoir development, with the best physical properties and the largest thickness. The dissolution of atmospheric fresh water in the syngenetic period is the key to reservoir development,which makes the dissolution porosity larger. Unconformity surface corrosion further improves the reservoir quality, and the reservoir with dissolved pores develops.

Through the study of sedimentary facies and reservoir controlling factors, this paper clarifies the sedimentary system in the eastern margin of the basin and the factors controlling the distribution of reservoirs, which provides a basis for finding high-quality reservoirs and then conducting exploration and deployment.

Keywords: microbial carbonate rocks, diagenesis, pore types and porosity evolution, Leikoupo Formation of Middle Triassic

Reconstruction of the past diagenetic conditions and porosity evolution in microbial carbonate rocks is often under constrained. The microbial dolomite reservoir of Leikoupo Formation of Middle Triassic in Western Sichuan, as one of the exploration targets with a buried depth of more than 5000 m, provided an excellent example to demonstrate how the lithofacies and diagenesis (Early diagenesis especially) affect the reservoir quality. In this study, we investigate the diagenetic fluid, cementation and their relationship with pore evolution and preservation, based on the detailed petrographic observation and some technical methods, such as casting thin-section, cathodoluminescence (CL), scanning energy spectroscopy (SEM-EDS), fluid inclusion microthermometry, carbon and oxygen isotope analysis for micro-drill sampling, carbonate clumped isotopes (47 thermometer), U-Pb dating of calcite and dolomite, FIB-SEM and so on. The results show that there are three early diagenetic subsystems: open, closed and semi-open (transition), which respectively correspond to humid, arid-climate and interaction between bacteria & microbial and carbonate micrite at synchronously sedimentary in the shallow buried periods. De-dolomitization are supposed to take place either in the early or the burial diagenesis stage, associated with the meteoric water influx in subaerial exposure near the upward-shallowing high-frequency sequence boundary or the infiltration along the fault-controlled fractures. However, the large-scale dolomitization and de-dolomitization occurred in Carnian226.5 ± 9.68 Maand Norian 211.5 ± 1.5 Mastage of Late Triassic, with temperatures of 43℃ and 50.2℃, respectively. Four phases of dolomitization & dolomite recrystallization and four phases of calcites cementation have been identified, showing that the δ18Owater (VPDB) of parent fluids varies between -9.70‰ and -0.83‰ for dolomite, and between -12.94‰ and -1.16‰ for calcites, while the $\delta^{18}O_{water}$ of parent rocks varies from -4.60‰ to -0.94‰ for microbial dolomite and -6.68‰ to -1.68‰ for microbial limestone, respectively. The $\delta^{18}O_{water}$ decrease gradually in response to the increasing of crystallization degrees in the progressive burial or meteoric water influx. Statistics reveal that the main pore types of microbial carbonate rocks are vugs and solution-enlarged fracture (43.69%), framework pore (32.28%) and micro-pore. The good preservation of micro-pores in deep burial is due to the small throat radius and special pore fluid, which inhibits the occurrence of large-scale cementation. In summary, the upward-shallowing meter-scale sedimentary cycle for microbial rock in the shallow subtidal to supratidal zone, combined with the early open to semi-open diagenetic system contribute to the development and preservation of the pores, however, the superposition and transformation of the buried diagenesis lead to the overall reduction of porosity.

Keywords: Ultra-deep buried, Middle Triassic Leikoupo Formation, Marine carbonate, Petroleum system, Western Sichuan depression

Ultra-deep buried (>5000 m) marine carbonate reservoirs gradually become important exploration targets in recently years. Marine carbonates are among the most crucial hydrocarbon reservoirs that hold up to 60% of the world's oil and gas reserves and many giant carbonate reservoirs are likely to have a production lifetime more than 50 years, most of the larger oil or gas fields occurring in the Middle East, North America, Europe, Latin America and Mexico, Africa, and Asia etc. deposition region. This research focuses on understanding characterization of ultra-deep buried Middle Triassic Leikoupo carbonate petroleum system in the western Sichuan depression, China. Combined with previous studies about source rock characteristics and the hydrocarbon generation processes, the analysis results of seventy three source rocks organic geochemistry, four gas compositions and five C–H–He–Ne–Ar isotopes suggest that reservoir is charged with compound gases from four source rock units including the Permian Longtan, Middle Triassic Leikoupo, Late Triassic Maantang, and Xiaotangzi formations. One hundred and eight samples were collected from 50-m fresh outcrops and 100 m cores from scientific exploration drilling wells YS1, PZ1, XQS1, CK1, XCS1 and TS1, and analyzed for petrography and petrophysics. Thin-section and scanning electron microscope (SEM) observations, porosity and permeability measured by helium, mercury injection capillary pressure (MICP), combined with wire-line logging (5,500–6,900 m) indicate reservoir lithologies including algal argillaceous limestones, dolograinstones, crystalline dolostones, limestones, and thrombolite dolomites. Reservoir properties exhibit extremely heterogeneity induced due to combination of constructive (i.e., epigenic paleo-karstification, burial dissolution, structural movements, pressure-solution [stylolites], and dolomitization) and destructive diagenesis (i.e., physical/chemical compaction, calcite cementation, infilling [e.g., pyritization, celestite, and silicification], recrystallization, and replacement). An unconformity-related epigenetic karstification zone occurs in the upper fourth member of Leikoupo Formation (T_2l^{4a}), with developed solution holes/pores leading to high porosity (1.8–14.2%) and permeability (0.2–7.7 mD). Further below the unconformity (T_2l^{1-4b}), reservoirs become more homogeneous and tighter, characterized by solution pores, intracrystalline pores, fractures, and stylolites, with helium porosity (0.6–4.1%) and permeability (0.003–125.2 mD). Regional seals consist of the Late Triassic Xujiahe Formation ~300 m shales, mudstones and further enhanced by the Jurassic to Quaternary ~5,000 m continental overburden rocks. Effective traps are dominated by the combination of structural-lithological typing. The hydrocarbon associated aqueous fluid inclusions reveal homogenization temperatures of 98–140 ^{o}C and 140–171 ^{o}C, suggests twice hydrocarbon charging

occurred between 220–170 Ma and 130–90 Ma, respectively. One-dimensional basin evolution models with seismic profile have determined hydrocarbon vertical migration and entrapment mainly via faulting-fractures networks and lateral migration through unconformity plane which were driven by buoyancy, fluid flow abnormal pressure and formation overpressure during the Indosinian and Yanshanian orogenies, and then experienced additional transformations during the Himalayan orogengy. These multidisciplinary approaches on the ultra-deep buried Middle Triassic Leikoupo marine carbonate petroleum system (!) have scientific significance and practical applications for potential hydrocarbon resources exploration in deep or ultra-deep basins in China and elsewhere worldwide. We believed that there are significantly hydrocarbon resources still to be discovered in future.

Characteristic and controlling factors of fractured-porous carbonate reservoir: a case study of X oilfield, Lower Carboniferous, Eastern margin Pre-Caspian Basin

Demin Zhang[1*]
1. Technical Support Center of Overseas Projects, Sinopec Petroleum Exploration and Production Research Institute, Beijing, CHINA
E-mail: zhangdm.syky@sinopec.com

Keywords: Fractured-porous reservoir, pore structure, fracture type, Characteristic, Pre-Caspian Basin

Fractured-porous reservoir is one of a complex type of carbonate reservoir. In order to analyze the characteristics, main control factors and distribution of this kind of reservoirs, this paper takes KT-II of middle and lower Carboniferous in X oilfield in the eastern margin of Pre-Caspian basin as an example. Based on the data of core, thin section, scanning electron microscope (SEM), FMI logging and seismic, etc., the research work of sedimentary microfacies, reservoir space, physical property, pore structure, fracture type and its main controlling factors and distribution are carried out. The study shows that the target strata in the study area are open platform subfacies, including high-energy shoal, low-energy shoal and inter-shoal sea microfacies. The reservoir space is mainly composed of intragranular pores, intergranular pores and moldic pores with fabric selective. The fracture porosity is low and the reservoir performance is poor. The porosity and permeability vary in a wide range, and are low to medium porosity and low to extra-low permeability on the whole, in which the physical property of the microfacies of high-energy shoal is relatively good and is characterize by large pores and coarse throat, the physical property of the microfacies of low-energy shoal is relatively poor and is characterize by small pores and fine throat, and the reservoir property of the inter-beach sea is the worst. Fractures are mainly high-angle fractures, and the fracture density of inter-beach sea facies is higher than that of the other two faices. In terms of genesis, the fractures include the associated fracture system of fault and the associated fracture system of anticline. The direction of the associated fracture of fault changes with the change of fault. The associated fracture system of anticline structure is mainly distributed in the high part of the structure, and is dominated by reticular fractures. The development and distribution of reservoir are controlled by sedimentary facies and fracture.

Sedimentary Characteristics and Distribution of Granular Beach in Tongzi - Honghuayuan Formation of Ordovician in Middle - Upper Yangtze Region

LI ZHOU[1*]

1. School of Geoscience and Technology, Southwest Petroleum University, Chengdu, Sichaun, CHINA
E-mail: ZHOU1204LI@163.com

Keywords: Central-Upper Yangtze,Granular beach,Sedimentary characteristics,Distribution law,Ordovician

Based on the data of drilling, logging, core and thin section, the sedimentary characteristics, distribution law and main controlling factors of grain beaches of Tongzi Formation and Honghuayuan Formation of Ordovician in the middle-upper Yangtze region were comprehensively analyzed. The rock types of granular beach in the study area are mainly granular limestone and granular dolomite. The particle types are mainly sand debris, followed by oolitic, raw debris and gravel. Granular beach mainly developed upward shallow, coarse grain size sedimentary sequence, vertical development of restricted lagoon - platform beach - platform, tidal flat - tidal flat - tidal flat, restricted lagoon - tidal flat - restricted lagoon three sedimentary facies sequence ; the continuity of granular beach is good in the horizontal direction, and the distribution of ancient land and uplift is zonal in the plane. After further analysis, it is considered that the relative change of sea level and the level of sedimentary energy control the development scale of granular beach, and the structural conditions determine the continuity and the difference of plane distribution of granular beach.

Main controlling factors and evolution model of Changxing Formation reservoir in Zhongjiang-Moxi area

JinHao Bai[1*], Hong Liu[1]
1. School of Earth and Science and Technology, Southwest Petroleum University, Chengdu, Sichuan Province, CHINA
E-mail: baijinritian@icloud.com

Keywords: Changxing Formation,The main controlling factors of the reservoir,Reservoir evolution model,Sedimentary facies,Paleomorphology

The Upper Permian Changxing Formation in the Sichuan Basin has always been the focus of exploration. At present, the exploration research of this formation focuses on the platform margin area in northeastern Sichuan, and there are few studies on the origin of reservoirs in the vast intra-platform area. Therefore, taking the Changxing Formation in the Zhongjiang-Moxi area as an example, the petrology, physical properties and distribution characteristics of the reservoir were studied by using various data such as core observation, thin section identification, physical property analysis and well logging. The reservoir space is dominated by intragranular dissolved pores and residual intergranular pores, and no strong epigenetic karstification has been observed. There are mainly two types of reservoir models—thin and inter-reservoir models and large sets of thick reservoir models. Reservoir stacking styles and development degrees vary greatly in different models. The study believes that the intra-platform beach reservoirs in the Zhongjiang-Moxi area are typical facies-controlled reservoirs, and the degree of reservoir development is mainly controlled by contemporaneous-paracontemporaneous karstification, in which the multi-level cyclic changes of sea level determine Reservoir thickness, superimposition style, and micro-paleo-geomorphic differences further control the early exposure and dissolution of shoal facies reservoirs. On the basis of the research on the main controlling factors of the reservoir, further use the 2D and 3D joint seismic data, and based on the formation thickness, use the Chang 1 and Chang 2 grain-to-ground ratios to correct the trend surface respectively, and carry out the restoration of the Changxing two-period paleomorphology. , and finally clearly describe the sedimentary evolution characteristics of the reservoir under the two reservoir modes in this area.

Karst paleogeomorphic characteristics and their effects on reservoir seismic response in the Gaoshiti-Moxi-Longnüsi area

MengXiang Yang[1*], Hong Liu[1], Lei Tan[1]
1. School of Geoscience and Technology, Southwest Petroleum University, Cheng Du, Si Chuan, CHINA
E-mail: 810055809@qq.com

Keywords: Karst paleogeomorphic characteristics,Seismic Response Characteristics,Amplitude property

Affected by the TongWan Phase II movement, the fourth member of the DengYing Formation in the Gaoshiti-Moxi-Longnüsi area experienced tectonic uplift and was leached by atmospheric fresh water. The secondary dissolution pores, caves and fractures formed after karst transformation are the main storage space types in the fourth member of Deng 4 Member. Since the interior of the DengYing Formation has suffered multiple exposures and denudations, there is a large error in the restoration of the ancient landform by the 'residual thickness method'. Therefore, this study adopts the "impression method" to restore the karst paleogeomorphology of the Dengying Period. During the large-scale transgression of the Cambrian, the overlying QiongZhusi and CangLangpu formations filled in the denuded landforms in the Dengying period. The bottom boundary of Canglangpu appeared as a strong wave trough on the seismic profile, which is easy to track and compare in the whole area. , so it was selected as the datum surface of the impression method. On the basis of fine tracing of the bottom boundary of CangLangpu, the karst paleogeomorphology was restored, and the GaoMo area was divided into three zones to study the seismic response characteristics of the reservoir. The development of the reservoir at the top of Deng 4 is characterized by the weakening of the peak amplitude of the Cambrian bottom boundary and the wide and gentle trough in the middle. The karst paleogeomorphology restoration results show that the Dengying Formation is characterized by low north and high south, west low and east high. In relatively low-lying areas, the mudstone with higher mud content deposited at the bottom of QiongZhusi has a higher GR value, its impedance value is lower. On the basis of zoning, statistics of reservoir development, seismic response characteristics and amplitude energy of the fourth member of Deng 4 in real drilling are carried out. Set different valve fingers, extract amplitude plane attributes, and accurately describe the range of "weak amplitude" to predict favorable areas for reservoir development.

Lower Cambrian Red Beds in South China: distributions, features, and their palaeoenvironmental significance

YiLin Li[1], Fei Li[1*]

1. School of Geoscience and Technology, Southwest Petroleum University, Chengdu, Chengdu, Sichuan, CHINA

E-mail: lifei@swpu.edu.cn

Keywords: "Red Beds" database,redox condition,middle Age 3,Yangtze region

Massive ‘red bed’ deposits are of unique value in reconstructing paleoenvironment conditions due to their potential role in indicating the changing marine redox conditions, especially in the deep-time records. The Cambrian explosion is one of several critical events in the evolution of life, and the redox conditions can be seen to play a vital role in regulating the distribution and development of marine organisms. Multiple geochemical proxies have been applied to reveal the redox variation in early Cambrian. Still, the marine redox state has not been well constrained, possibly due to ubiquitous heterogeneity of oxygenation levels in different regions and times. The study on lower Cambrian ‘red bed’ characteristics may provide a new perspective to understand the marine redox fluctuation at that time. For this purpose, we constructed a systemic database regarding the records of red beds in the lower Cambrian strata of South China, and almost all records indicate that their sedimentary episodes were in middle Age 3. Furthermore, we examined the petrological and mineralogical characteristics of red beds and neighboring strata and carried out a series of element geochemical studies to assess the environmental conditions, i.e., redox, climate, and nutrient level, for ‘red bed’ sedimentation in middle Age 3.

Identification, characterization and geological modeling of intergranular pore type and intrafossil pore type in bioclastic carbonate reservoir

Zhou Lyu[1*], Nan Li[1], Nai Wang[1], Shudai Peng[1], Yukun Lan[1]
1. Department of Middle East E&P, Research Institute of Petroleum E&D, CNPC, Beijing, CHINA
E-mail: lyuzhou827@163.com

Keywords: Intergranular pores, Intrafossil pores, Bioclastic carbonate, Reservoir characterization and modeling

Intergranular pores and intrafossil pores are two important pore types in bioclastic carbonate reservoirs. The deposition and diagenesis of these two types of pores are different, and the corresponding reservoir properties and micro pore structure are also significantly different. This study takes the Cretaceous H formation of the H oilfield in southern Iraq as an example. Both intergranular pore-dominated reservoir and intrafossil pore-dominated reservoir were developed in this formation, resulting in strong heterogeneity. On the basis of core observation, thin section analysis and mercury intrusion experiment, the coring well pore type was identified. Through core calibration logging, conventional logging curves, gamma spectrometry, nuclear magnetic and other special logging, comprehensively carrying out neural network learning, the logging pore type characterization is completed. Based on seismic inversion data, through sedimentary facies analysis, sedimentary water depth characterization, and the relationship between dissolution and sequence boundary, the distribution characterization and geological modeling of pore types are completed. Based on the sensitivity analysis of numerical simulation, the accuracy of pore type characterization results is verified by production performance data. The research results show that the differences in sedimentary environment and bioclast types are the material basis for the differences in the types of intergranular pores and intrafossil pores. Differences in micrite content, dissolution and cementation are the main controlling factors for the differences in microstructure and reservoir properties between intergranular and intrafossil pore types. It is an effective means of high-precision identification, characterization and geological modeling to integrate various types of static and dynamic data.

E-mail: aicha.chalabi@gmail.com

Keywords: Carbonate platform, Celebes Sea, Facies, Reef complex, Quickbird

Remote-sensing analysis of high-resolution satellite imagery of Modern carbonate platforms in the Celebes Sea, east of Sabah, Borneo, Malaysia, aimed at mapping geomorphology and sediment. Unsupervised classifications of satellite images interpreted in the context of environments facies of seven isolated carbonate platforms and calibrated using analyses of surface sediments. One hundred and forty (140) sediment samples were collected, analyzed for grain-size distribution, and sorting. The grain-size analysis showed that sediment varied among geomorphic elements: island, island/volcano, reef complex, carbonate sand shoal, grass-covered sand shoal, shallow lagoon, and deep lagoon. To generate carbonate sediment texture maps, the proportion of mud and the grain-size attributes of each sediment sample (mean grain size and sorting) provides a basis to classify it into a rock-equivalent texture. Integrated remote sensing, field, and sedimentological data were used to characterize texture distribution maps and depositional facies maps, where mainly mudstone to wackestone have occurred in the deep lagoon; wackestone to packstone is dominant in the shallow lagoon; carbonate sand shoal is characterized by packstone to grainstone and the reef complex is made up of boundstone to rudstone. These results help in estimating proportions of potential reservoirs and heterogeneity in facies distribution, based on the size of various recent carbonate platforms. Diagenesis notwithstanding, ancient analogs of Selakan and Maiga platforms could be potential reservoirs, whereas Selakan and Gaya platforms display more facies classes and most probably represent a poor potential reservoir

Keywords: Cameroon Volcanic Line, low-Mg calcite, rare earth elements, spring deposits, trace elements, travertines

Terrestrial carbonates and particularly spring carbonates are deemed to be good geological repositories of paleoclimate and paleoenvironmental reconstruction (e.g., Brasier, 2011) and for the characterisation of the interaction of biotic and abiotic processes, and they preserve evidence of the velocity of the flow and the chemical composition of the spring water.

This study focuses on non-marine carbonates from fossil and active springs from the Bongongo and Ngol areas along the Cameroon Volcanic Line in South-West Cameroon (Bisse et al., 2018). Here, hydrothermal fluids reach the surface giving rise to small thermal springs, with temperatures between 31°C and 49°C, and streams creating waterfalls, terracettes, and barrage carbonate deposits (Bisse et al., 2018).

Petrographic analyses of these carbonates revealed that they are made up of stacked laminae of fibrous coarse crystals of low-Mg calcite and laminae of alternate microsparite and micrite. The fibrous coarsely crystalline calcite, often with feather-like fabric, grows from thin layers of micrite and peloids. Filaments of putative microbial origin are preserved within this peloidal micrite. The laminated microsparite and micrite microfacies are characterised by an intricate mesh of hollow filaments of microbial origin.

The long feather-like crystals of calcite formed in fast-flowing water where the enhanced CO2 degassing has favoured the precipitation of CaCO3. The laminated micrite and microsparite, on the other hand, are likely formed in ponds where degassing and CO2 removal was lower and the calcite precipitation was fostered by microbial activity. The fast-forming carbonates show higher Ce contents and very low total rare earth elements, revealing a preferential uptake of Ce with respect to other rare earth elements. This would explain the positive or null Ce anomaly in continental spring carbonates elsewhere.

The geochemical composition of these carbonates can be used as proxy for the characterisation of fluid/rock interactions between the groundwater and the substratum and for the characterisation of the sources of calcium and other elements that constitute tufa and travertines. The samples from Ngol are characterised by light rare earth element enrichment while those from Bongongo are overall enriched in heavy rare earth elements. Carbonates from both localities have a strong positive Eu anomaly (>4), suggesting a contribution from deep-seated, hydrothermal, crustal fluids in contact with volcanic rocks and the breakdown of plagioclase from the Cameroon Volcanic Line alkali basalts.

This study has demonstrated that the strong CO2 degassing, promoted by fast flowing water, resulted in the rapid growth of coarsely crystalline calcite, characterised by overall ∑REE depletion and Ce enrichment. The fast-forming calcite fabrics are therefore characterised by a higher Ce anomaly when compared to the slow forming fine grained, laminated fabrics. It can therefore be concluded that Ce(III) oxidation and scavenging into the coarse carbonates is promoted by fast flowing water and strong CO2 degassing (turbulence). This is an important finding for the interpretation of REE distribution in continental carbonates and provides an alternative explanation for the presence of a positive Ce-anomaly that favours precipitation rates over organic matter contents.

Sequence architecture and depositional evolution of the Cambrain carbonate platform and its response to sedimentary palaeogeomorphology, climate change and sea-level change, Tarim basin, NW China

Wu Xuqiao[1], Lin Changsong[1*], Xu Fan[1], Li Hao[1]
1. School of Ocean Sciences, China University of Geosciences(Beijing), Beijing, CHINA
E-mail: lincs@cugb.edu.cn

Keywords: sequence architecture, carbonate platform evolution pattern, Tarim Basin

A comprehensive analysis of sequence stratigraphy and sedimentary evolution is conducted by using field outcrops, drilling, core and seismic data of Cambrian system in Tarim Basin. Research shows that Cambrian carbonates of the basin can be divided into 3 secondary-sequences which are defined by large-scale unconformity surfaces and 6 composite sequence, each sequence contains a regional sedimentary cycle, and it mainly consists of transgressive systems tract (TST) and highstand systems tract (HST), and can be further subdivided into 16 third-order sequences according to the secondary transgression-regression cycle at the carbonate platform marginal zones. The Cambrian system in study area is mainly consisted of carbonates, orderly depositing evaporated platform, restricted platform, open platform, platform margin and slope sedimentary facies belt from interior of the carbonate platform to basin. Inheriting the differentiation of east-west sedimentary pattern of Sinian, the marginal slope at the west of Manjiaer rift controlled the development of the Cambrian carbonate platform margin, which underwent the evolution process of ramp, non-rimmed platform, weak-rimmed platform and rimmed platform. Due to the wide-slow slope in the north and the narrow-steep slope in the south, the platform margin in Lunnan-Caohu area rapidly migrated eastward, which is obviously different from the vertical growth pattern in Gucheng area. Owing to the high yield of carbonate in Xiaoerbulake formation, it forms a series of low-angel progradation sediment at the north of manxi margin area. Combined drilling data and 3D seismic data, palaeobathymetric can be measured by flattening paleo-water level which could rebuild the paleogeomorphy of the slope and describing the shape of progradation volume with compaction-restoring calculation. The result shows that the paleo-water depth of manjiaer area in Xiaoerbulake formation is 1053 meters, within range of shelf slope environment, which is apparently different to the opinion of many studies supporting it belongs to bathyal or abyssal sea. Sedimentary paleogeomorphology, sea-level change and climate change collectively control the sedimentary system, which restricts the type and growth style of carbonate platform. Due to the vital influence of paleo-water level and water circulation environment to the carbonate yield and sediment lithofacies, the sedimentary paleogeomorphology plays an important role in controlling the sedimentary types and distribution style of sedimentary facies belt. In addition, the transgression-regression cycles of the entire Cambrian carbonate system are comparable and occur almost simultaneously in the whole basin, indicating that the sequence structure of the cycle is basically controlled by the rise and fall of sea level. In terms of climate, it is obvious that the interior of the Cambrian carbonate platform is a semi-confined and confined environment, but the extensive development of evaporated lagoons and evaporated tidal flat in the Middle Cambrian indicates that the arid climate environment in the Middle Cambrian had a significant impact on the sedimentary evolution.

E-mail: wang110769@163.com

Keywords: Graph Theory,Rolling Maximum Inscribed circle Algorithm,seismic geomorphology,Tidal Channel system,Quantitative Characterization

This paper presents the first graph theory based rolling maximum inscribed circle algorithm on and applies it to the quantitative characterization of seismic geomorphology in tidal channel system located at the MB1 layer of the Mishrif Formation in the Middle East A oil field. In this paper, the morphological characterization problem of tidal channel system is transformed into a graph-theoretic algorithm, and the quantitative characterization problem of channel parameters is transformed into a rolling maximum Inscribed circle mathematical algorithm, and the automated statistics of channel parameters are performed by establishing a geometric model of channel parameters. The graph theory-based rolling maximum inscribed circle algorithm is a method that uses graph theory algorithms to decompose the skeleton of the geometric centerline network into points and edges for graph construction, and uses rolling maximum inscribed circle for each edge to perform intelligent statistical calculation of parameters. The statistical parameters include length, width, vector distance, curvature, thickness, aspect ratio, and width-thickness ratio. The algorithm is applied for quantitative characterization of tidal channel system in the study area to study the variation pattern of river parameters. Within the tidal channel system, five types of tidal channel genesis units can be identified: river mouth tidal channel, main tidal channel, branch tidal channel, break tidal channel and delta tidal channel. The geological and geomorphological characteristics of these tidal channels are as follows: river mouth tidal channels are characterized by large width and low curvature; main tidal channels are characterized by large length and thickness of filled granular tuffs; branch tidal channels are characterized by relatively high curvature. The channel parameters of the break tidal channel and delta tidal channel are relatively close, their lengths, widths and thicknesses are small, and the curvature of the channel is low. As an intelligent algorithm, the graph theory based rolling maximum inscribed circle algorithm is more accurate and faster than the traditional manual quantitative seismic geomorphic analysis method. The graph theory based rolling maximum inscribed circle algorithm uses pixel points as the basic calculation unit, which greatly improves the accuracy of the river parameter statistics and greatly increases the statistical efficiency with the powerful computing power of computers. As an extension of the application, the algorithm can also be applied to the quantitative geomorphology study of global river-delta channel system based on remote sensing data. Therefore, the graph theory based rolling maximum inscribed circle algorithm based is of great significance in promoting the development of quantitative geomorphology techniques.

The Middle-Upper Cambrian boundary in the Tarim Basin, NW China: changes in geological characteristics and the global Cambrian SPICE event correlation

Yaxin Shang[1], Zhiqian Gao[2], Keyu Liu[1*], Chenjia Zhang[3]
1. School of Geosciences, China University of PetroleumEast China, Qingdao, Shandong, CHINA

E-mail: liukeyu@upc.edu.cn

Keywords: Middle-Upper Cambrian boundary, unconformity, Carbon isotope excursion, Tarim Basin, Global comparability

The subdivision and correlation of the Cambrian System have long been controversial globally with multiple schemes. This is especially the case for the Tarim Basin, western China where regional and global correlations of the Middle-Upper Cambrian boundary are hampered by incomplete biostratigraphy. The Middle-Upper Cambrian boundary (T_8^1) in the Tarim Basin is characterized by an abrupt switch of lithological and sedimentary facies, a sudden change of wireline log responses, and as well as the contrasting seismic features, structural styles and carbonate platform architectures. This boundary is also marked by a negative excursion of $\delta^{13}C$ from 0.1‰ to -0.2‰ and a positive excursion of $\delta^{18}O$ from -6.1‰ to -5.8‰. The T_8^1 boundary can be identified all over the Tarim Basin and manifests in various forms and styles including syn-sedimentary unconformity, overlapping unconformity, tectonic unconformity, multi-stage superimposed unconformity, parallel unconformity and conformity. According to the characteristics of the tectono-sedimentary evolution from the Nanhua to Ediacaran periods, it is shown that each manifestation type of the T_8^1 boundary was influenced by at least one of these factors including paleo-geomorphology, tectonic movement, eustacy, and climatic change. Therefore, each manifestation type can also be used as a marker for the evolution characteristics of tectono-sedimentary sequences. By correlating with changes in carbon isotopes and sedimentary characteristics in various regions worldwide, we propose that the $\delta^{13}C$ weak negative excursion after the sharply positive excursion of the Late Cambrian SPICE event can be used as an isotope stratigraphic marker for the T_8^1 boundary. The top of the Awatag Formation (the top of Middle Cambrian) in the western Tarim Platform should thus be correlated to the top of the Mohershan Formation in the eastern Tarim Basin, corresponding to the top of the Miaolingian Stage. We also conclude that the absence of the SPICE event in the western part of the Tarim Basin may have been caused by the development of the basin-wide unconformity of the T_8^1 boundary.

Keywords: late Carboniferous, South China, sedimentology, paleoclimate, precipitation.

Located in the northeastern Paleo-Tethys Ocean and near the paleo-equator during the late Paleozoic, the South China Block is an ideal region to study the paleoclimate and paleoceanographic conditions of the late Paleozoic ice age. Here, we present detailed sedimentological and biostratigraphic works of a late Carboniferous succession from the southeastern South China Block to explore its sedimentary responses to paleoclimate variations. The Outangdi succession consists predominantly of various shallow-marine carbonate facies, episodically interlayered with fine-gravel to coarse-sandstone facies. Fusulinid and conodont biozones indicate that the succession formed during an interval of the middle to late Moscovian. Detailed facies analysis suggests that the succession was deposited on a carbonate ramp, but episodically punctuated by braid delta sedimentation. We interpret that the abrupt increase in coarse-grained siliciclastic influx during the late Moscovian resulted from an enhanced precipitation event. Regional and global correlation of changes in magnitude of sea-level fluctuation reflects a change in paleoclimate regime during the middle to late Moscovian.

Depositional processes of the mixed siliciclastic-carbonate system in the Xiannüdong Formation in the northern Sichuan Basin, South China

Li Ting[1], Hua Yao zou[1*]
1. Geoscience, China University of petroleumBeijing, Beijing, CHINA
E-mail: huayaozou@cup.edu.cn

Keywords: Mixed siliciclastic-carbonate systems, depositional facies, Oolite, calcimicrobial–archaeocyath bioherms, Xiannüdong Formation, Sichuan Basin

Mixed siliciclastic-carbonate systems contain significant heterogeneity of facies associations which complicates the interpretation of depositional environments and platform evolution. The Early Cambrian Xiannüdong Formation (Fm) in the northern Sichuan Basin develops the hybrid depositional system which is characterized by the non-skeleton grain (ooids and microbialites) dominated carbonates mixed by siliciclastic rocks. Such a depositional system provides a template to decipher the depositional process and facies variability. Based on facies analysis in outcrops and cored wells and observation of thin sections, sixteen lithofacies were identified and grouped into six lithofacies associations which representing a shallow-marine environment dominated by wave and storm activities. The distribution of the terrigenous materials indicates that the provenance of the terrigenous deposits is mainly supplied by the Kangdian and Bikou massifs. The vertical facies stacking pattern of lithofacies in the Xiannüdong Fm shows a regressive cycle during the deposition of Xiannüdong Fm and this regressive cycle can be subdivided into four sub-cycles (S1 to S4). The four sub-cycles were appeared to the upward-shallowing pattern and bounded by flooding surfaces. The spatial distribution of lithofacies suggests a low-angle ramp with widespread hybrid oolites and calcimicrobial–archaeocyath bioherm. The ramp was separated from the western massifs (Kangdian and Bikou) by the Mianyang-Changning trough. The migrating ooid shoals together with the storm activities prevent the ramp from evolving into a rimmed shelf.

The mixture of carbonate and siliciclastic sediments occurs at compositional scale. The detrital proportion is higher in the lower part of Xiannüdong Fm (S1 and S2) than in the upper part (S3 and S4). This difference in detrital proportion is likely produced by the relative sea-level fluctuation. The coupled relationship between terrigenous content and growth of calcimicrobial–archaeocyath bioherms suggests the nutrition supplied by the input of terrigenous matters controls the growth of bioherms in the Xiannüdong Formation. High siliciclastic sediments influx would also influence the ooid growth by serving as nuclei and promoting abrasion, which resulted in a smaller ooid size compared to the relatively pure oolite. Meanwhile, the difference in density of carbonate and siliciclastic grains promotes smaller siliciclastic grains deposited together with larger carbonate grains.

Evolution of of the Late Oligocene carbonate system on the Xisha Islands in the South China Sea

Feng Wu[1*]
1. College of Oceanography, Hohai University, Nanjing, Jiangsu, CHINA
E-mail: finncug@hotmail.com

Keywords: Carbonate system, Sequence stratigraphy, Coral reef, South China Sea

Sedimentological, paleontological, and mineralogical data from core XK-1 in the Xisha Islands allow for a detailed lithologic and sequence stratigraphical analysis on the Late Oligocene interval in the Xisha Islands. In this study, 13 facies are differentiated and a depositional model of a carbonate-dominated system is established. Variation in facies stacking patterns, changes in composition and grain size, and fluctuation in abundance of terrigenous matter are analyzed, and sequence division is interpreted at two different hierarchal levels. In the Late Oligocene interval of core XK-1, a total of thirteen small-scale sequences and three medium-scale sequences are divided out, with one medium-scale sequence mainly composed of four small-scale sequences. Based on the available timing constraints, the durations of the small- and medium-scale sequences are estimated to be 100 kyr and 400 kyr, respectively. These small-scale and medium-scale sequences are thus inferred to be primarily controlled by orbital forcing. The long-term evolution between 24.3 and 23.6 Ma was controlled by the eustatic sea level, while it was more influenced by a tectonic subsidence linked to the ridge jump event in the South China Sea after 23.6 Ma. Our study demonstrates that eustatic sea level fluctuations had a significant impact on the initial carbonate development at various scales in the northern South China Sea, while tectonic movement also played an important role in shaping the secular carbonate evolution.

E-mail: jtchen@nigpas.ac.cn

Keywords: Late Paleozoic Ice Age (LPIA), South China, late Pennsylvanian, early Permian, Sedimentology, δ13Ccarb

The Late Paleozoic Ice Age (LPIA) recorded a critical transition from icehouse to greenhouse climate states during the late Carboniferous to early Permian. Reliable carbonate carbon isotopes ($\delta^{13}C_{carb}$) can provide valuable information on variations in global carbon cycling, and thus the paleoclimate and paleoceanographic conditions. However, the $\delta^{13}C_{carb}$ values are not only related to the global carbon cycle, but also controlled by regional water cycle and diagenesis. During the LPIA, advance and retreat of the Gondwanan ice sheets resulted in cyclic sea-level changes with multiple periods of significant depositional hiatus in low-latitude regions. Frequent subaerial exposures and stratigraphic discontinuities potentially altered the primary $\delta^{13}C_{carb}$ signals, which hampers a valid global correlation. In this study, we present high-resolution sedimentary facies and $\delta^{13}C_{carb}$ records on three continuously deposited carbonates slope successions from South China to explore sedimentary responses to glacio-eustatic changes and evaluate the reliability of $\delta^{13}C_{carb}$.

Keywords: Shidao Xisha Islands, Laolongtou, carbonate karst, precious geological relics, top ecological landscape, countermeasures

Karst landform corresponds to Guilin landscape and Yunnan Shilin. It is a synonym of top geological relics and ecological landscape and the result of carbonate karst.The best oil and gas reservoir formed by underground deep carbonate karst is the research object of petroleum industry for decades.

This paper focuses on the karst of modern Marine carbonate-ecological landscape, and points out that the karst restoration of queen head calcareous mudstone in Yeliu Park, Kaohsiung, Taiwan failed, resulting in thin neck or broken neck. South China Sea modern Marine reef carbonate rock shocking karst from the Shi island of Xisha Islands.

Shidao is a small island with the highest altitude in the South China Sea. It stands in a weak consolidated reef - carbonate rock - Laolongtou that looks like a dragon head. Laolongtou is the only dragon rock found in nature on earth so far, which has become a symbol of national totem. Therefore, Laolongtou is a top ecological landscape and precious geological relic resources. In global climate change, however, the context of rising sea levels, the south China sea two-way monsoon, semidiurnal tide, the harsh tropical storm surge wave flow, high temperature, high humidity and high salt and fresh water leaching dissolution eight natural force to old faucet, is happening from loss, damage, damage to the karst collapse destroyed, become old faucet regression.

This paper is the first public report on the investigation and monitoring of surface and underground karst in Laolongtou for more than ten years and the characteristics of its current situation. It puts forward that inverse karst: theoretical research, natural restoration, nano geological ecological engineering restoration, and construction of theoretical and engineering technology system.

Evolution and characteristics of Late Oligocene-Miocene carbonates in the southern continental margin of the South China Sea

yuantao Liao[1,2*], Jianye Ren[1], Dianjun Tong[1], Hao Fan[1]
1. College of Marine Science and Technology, China University of Geosciences (wuhan), Wuhan, Hubei, CHINA
2. Hubei Key Laboratory of Marine Geological Resources, China University of Geosciences (Wuhan), Wuhan, Hubei, CHINA
E-mail: ytliao@cug.edu.cn

Keywords: South China Sea, carbonates,Tectonic evolution

Numerous shallow-water carbonates were extensively developed in the southern margin of the South China Sea during the late Oligocene-Miocene. The development and demise of carbonate deposition provide good constraints on the paleo-environment and tectonic-sedimentary evolution for the southern margin of South China Sea. Although a few previous studies about carbonates deposition focused in the shelf area, the depositional models of carbonate systems in the deep-water basin have not been fully illustrated because of limited data. The purpose of this stduy is to investigate the temporal and spatial distribution characteristics and development of the late Oligocene-Miocene shallow-water carbonates in the southern margin of South China Sea based on high-resolution multichannel seismic data and recently published drilling data.

Two types of carbonates which are carbonate platform and reef as well as sub-types are identified.The reefs developed in the study area are divided into five types: pinnacle reef, patch reef, horseshoe reef, atoll reef and platform marginal reef. According to the tectonic genetic environment classification, the carbonate platform developed in the study area can be divided into different types, including fault block platform, thrusting top and forebulge platform, offshore isolated platform and magma diapir platform.

The development of carbonates in the study area almost experienced initial development stage, flourishing stage and extinction/sustainable development stage. However, relatively differential carbonate systems have evolved in each basin of south margin. The development and evolution of carbonates in the southern part of the South China Sea are considered to be closely related to the regional tectonic evolution of the southern margin, South China Sea. Since the closure of Proto-South China Sea possibly occurred in a "scissor-like" fashion from northwest to southeast, and the South China Sea basin gradually expanded from southeast to northwest, the southern continental margin sedimentary basins were depressed as differential tectonic history, which resulted in the remarkable difference in the development history of carbonates in each basin. In the Liyue basin, the thermal subsidence stage initiated in the early late Oligocene and the tectonic activity was stable, so carbonates began to grow. In the Zemgmu basin, the foreland basin stage began in the late Eocene and few carbonates began to develop at the same time. After the Sabah Orogeny movement, the structure of Nankang platform tended to be stable, and the carbonates were developed widely. Finally, the passive continental margin was developed, and a large amount of clastic sediments from Sarawak hinterland have been deposited, which inhibited the development of carbonates. In the Beikang basin, the foreland basin began to form in the early Miocene, and carbonates began to grow on the structure high. During the late Miocene, the rapid rise of relative sea-level induced by rapid tectonic subsidence terminated development of carbonates.

Keywords: carbonate platfroms, Cretaceous, Iran

The type of carbonate platform had repeatedly changed from carbonate ramp to rimmed platform during the Cretaceous. The pervious studies interpreted that the transitions were caused by sea level rising which drown carbonate platform in part. However, the rate of sea level rising should never outpace the production rate of carbonate in an ‘ice-free’ world. Thus the mechanism between the transitions of carbonate platform types remain unsolved.

To solve this problem, we take the Albian-Cenomanian carbonate strata exposed in south Iran as the target. The studies reveal the following trends by microfacies analysis and carbon isotope stratigraphy: (1) there are three sea-level rising events during the Albian-Cenomanian; (2) the carbonate deposited in a carbonate ramp during the Albian, and switched into a rimmed platform during the Cenomanian; (3) The organism association was changed from orbitolinid and green algae with positive $\delta^{13}C$ excursion to rudist during the Cenomanian with negative $\delta^{13}C$ excursion.

The orbitolinids lived in a mesotrophic environment whereas the rudists lived in an oligotrophic environment. The covariation of carbon isotope and the organism association also confirm the changed nutrient level. During the Albian, the mesotrophic environment favors the high primary production, therefore the carbon isotope shifted positively for the burial of abundant organic carbon. The carbon isotope shifted negatively in the Cenomanian for the lowered primary production within an oligotrophic environment. Furthermore, the types of carbonate not changed during the three sea-level rising events. Therefore, it is the nutrient level, not the sea level changes, that influences the transition from ramp to rimmed platform.

Keywords: Amu Darya Basin, Callovian-Oxfordian stage, Facies analyses, Depositional setting, Carbonate platform

The Middle-Upper Jurassic Callovian-Oxfordian stratum, consisting of carbonate sedimentary assemblage, is the most important hydrocarbon-bearing formation in the Amu Darya Basin. It is unconformable contact with the underlying the Middle-Lower Jurassic coal-bearing clastic rock that can act as source rock, and in conformable contact with the overlying Upper Jurassic Kimmeridgian gypsum-salt rock that can act as caprock. The Callovian-Oxfordian stage in the study area developed 8 layers form bottom to up, which are XVI, XVa2, Z, XVa1, XVhp, XVm, XVp and XVac. According to the logging curve and lithological combination, the target layer is divided into three sequences in which the water body becomes shallower (SQ1, SQ2, SQ3). Of these sequences, SQ1 is composed of four lithologic layers (XVI, XVa2, Z, XVa1) that are equivalent to the Callovian, SQ2 consists of three lithologic layers consists of three lithologic layers (XVhp, XVm, XVp) that are equivalent to the early period of the Oxfordian, and SQ3 is comprised of one lithologic layer (XVac) that are equivalent to the late period of the Oxfordian. By observing and characterizing core and conducting well log interpretation, it is found that, under the control of the high paleo-geomorphology, a set of carbonate rock with distinct features of shallow platform facies was deposited in the study area. Shallow water platform facies zone contains evaporitic platform, restrict platform and open platform. Evaporitic platform is present in the XVac layer in the east of the study area only, which develops some sets of thick anhydrite. Restricted platform is present primarily in the XVac layer throughout the whole study area, and is dominated by interbedded gypsum and limestone. Open platform is present broadly in various layers, which is dominated by granular limestone deposited in high energy bank environment, such as oolitic limestone and bioclastic limestone. Longitudinal, whether from the three sequences (SQ1, SQ2, SQ3) or the entire target layer in the study area, the sea level falls during the Callovian-Oxfordian stage. Horizontally, the landforms in the western and central parts of the study area are similar, manifesting as open platforms and restricted platforms. While the eastern part of the study area is closer to the platform margin with higher landforms, developing open platforms, restricted platforms and evaporitic platforms.

Middle Ordovician carbonate slump structures and their transformational successions from the northwestern margin of the North China Block

Wenjie Li[1*], Jitao Chen[1], Paul M. Myrow[2]

1. State Key Laboratory of Palaeobiology and Stratigraphy, Nanjing Institute of Geology and Palaeontology, Nanjing, Jiangsu, CHINA

2. Department of Geology, Colorado College, Colorado Springs, Colorado, UNITED STATES

E-mail: wjli@nigpas.ac.cn

Keywords: Slope facies, carbonate, slump, debris flow, soft-sediment deformation structures

A variety of carbonate mass-transport deposits, including slumps, debrites and deep-channel-confined density flow deposits, occur in Middle–Upper Ordovician slope deposits in the western margin (Wuhai, Inner Mongolia, China) of the North China Block. This talk focuses on the slump structures in the Darriwilian (Middle Ordovician) Kelimoli Formation which is characterized by thin-bedded lime mudstone interbedded with marl in the lower member and black shale in the upper member. The slumps from the Xilaifeng section host remarkable folds, chaotic beds and imbricated beds that reflect differences in both rheology and position on the slope. Based on the laterally successive exposure, the spatial and genetic relationships of different deformational structures are analyzed. We noticed that individual slump sheets show gradations between undulating laminae, inclined and recumbent folds, highly deformed folds, and chaotic textures upslope from the toe region. Debrites are commonly interbedded with slump deposits, whereas imbricated beds are present in the middle and lower parts of the toes of slump sheets near the terminal wall. Reconstruction of the downslope architecture of a slump toe, in combination with stratigraphic trends in the type of deformation structures, reveals aspects of the evolution of the sedimentary system through time. The stratigraphically upward increase in abundance and bed thickness of slump sheets, and general intensity of deformation in the Xilaifeng section, suggests an increase in sediment supply, tectonism and possibly the gradient of the palaeoslope over time.

Keywords: Ordos Basin,Danudi gas field,Majiagou Formation,Carbonate,sedimentary facies

Due to the unclear sedimentary facies of the middle and lower assemblage of Majiagou Formation in Daniudi Gas Field, Ordos Basin, which seriously hinders the development of the next step, comprehensively using core, thin section and logging data,a detailed analysis of the carbonate rock types and logging response characteristics of the middle and lower assemblages of the Majiagou Formation in this area was carried out, and seven sedimentary microfacies were further divided.The 1st member of Majiagou Formation to the 3rd member of Majiagou Formation are evaporative platform subfacies, mainly depositing salt lake, gypsum dolomite flat and gypsum lake microfacies from bottom to top;The 4th member of the Majiagou Formation is an open platform subfacies, mainly depositing limed flat, limed dolomite flat and a small amount of dolomite limed flat and gypsum dolomite flat microfaciesdolomite limed flat and gypsum dolomite flat microfacies are mainly distributed in the upper part of the 4th member of the Majiagou FormationThe 5th member of the Majiagou Formation is a limited platform subfacies, and the microfacies of dolomite flat, gypsum dolomite flat and dolomite limed flat deposit are deposited.The changes of sea level from the 1st member of the Majiagou Formation to the 5th member of the Majiagou Formation show periodic fluctuations.The study found that the fluctuation of sea level not only controls the changes of sedimentary subfacies, but also controls the changes of microfacies within each subfacies.The division of the carbonate sedimentary facies of the middle and lower assemblages of the Majiagou Formation in the Daniudi gas field in the Ordos Basin has promoted the development of the next step and also provided a strong geological basis for the later research.

Sequence stratigraphy and depositional evolution of a terminal Ediacaran platform in the Central to Northern Sichuan Basin, Southwest China

Caijun Lan[1], Huayao Zou[1*]
1. College of geosciences, China university of petroleum-Beijing, Beijing, CHINA
E-mail: huayaozou@cup.edu.cn

Keywords: lithofacies, depositional system, platform evolution, Dengying Formation, Sichuan Basin

The succession in the late Ediacaran Dengying Formation in the Sichuan Basin provides well-preserved sedimentary records for the investigation of Precambrian microbialites and platform evolution. However, in the central to northern Sichuan Basin where an intraplatform rift trough developed, the depositional evolution of the platform has not been fully illuminated, as previous studies mainly focused on the broad platform-basin architecture. Based on drilling wells and outcrops data, twenty lithofacies are identified and grouped into eight lithofacies associations including peritidal flat, shallow subtidal flat, lagoon, mixed tidal flat, slope, basin, coast and shallow sea. Moreover, two transgressive-regressive depositional cycles (i.e., Cycle 1 and Cycle 2) are recognized based on the five shallowing-upward (i.e., type A-E cycles) and three deepening-upward cycles types (i.e., type F-H cycles). A ramp-like epeiric platform with a gentle slope developed in Cycle 1 dominated by the shallow subtidal grainstones and peritidal microbialites. In the transgression of Cycle 2, a siliciclastic-dominated environment consisting of the coast and shallow sea developed on the shelf. Then it evolved to a rimmed platform in the regression of Cycle 2 with the accumulation of shoal grainstones and peritidal microbialites in the platform margin. The water mass was thus restricted to be a lagoon with scattered shoals and peritidal flats towards the proximal platform. In the distal setting, slump structures and cherts are identified in the steep slope and basin environment, respectively. Eustatic sea-level fluctuation and climatic change controlled the lithological transitions between carbonate and siliciclastic deposits. The platform configuration change is the result of intense differential subsidence and sedimentation rates between the trough and platform which were caused by activities of pre-existing basement rifts and coeval growth faults. This study provides a detailed depositional history of the Ediacaran Dengying Formation around the intraplatform rift trough and contributes to the Precambrian carbonate platform research.

Distribution characteristics of sedimentary microfacies of carbonate rocks in the 4th member of the Cretaceous Sen-Norman order M group in A oilfield in Iraq

Zhaoheng Liu[1], Dong Wu[1*], Kaixuan Cao[1], meiyan Fu[1], Guanghui Duan[1], Pei Chen[1]
1. School of Energy, Chengdu University of Technology, Chengdu, Sichuan Province, CHINA
E-mail: lisandpw@163.com

Keywords: Iraq Region,The Cretaceous Sen-Norman order,Carbonate,sedimentary microfacies

The M group reservoirs in A Oilfield are highly heterogeneous and difficult to develop, mainly due to unclear sedimentary microfacies types and fuzzy sedimentary environment.Based on a large number of cores, thin sections and logging data, through the analysis of particle assemblages, sedimentary fabrics, etc., and combined with the logging response characteristics, the sedimentary microfacies of carbonate rocks in the Cretaceous Sen-Norman order M Group 4 in the A Oilfield in Iraq were identified, divided into four types of microphases.The algae-poor bioclastic shoals are mainly distributed in the middle and upper part of the 4th member of the M group, and contain a lot of biological debris, mainly echinoderms, foraminifera and bivalves, etc., and the algae content is less than 40%.The algal debris shoals are mostly found in the middle and upper part of the fourth member of the M group, with a particle content of 50% to 80%. The inter-shoal microfacies are mainly distributed in the lower part of the 4th member of the M group, which are relatively low-lying deposits between the shoals, with low energy, fine sediment particle size, low particle content, high stucco content, and low porosity.The biological layer is found in the middle and lower part of the 4th member of the M group in the structural high position, the particle content is more than 80%, the biological types are diverse, the pore combination type is poor, the pore connectivity is poor, the heterogeneity is strong, and relatively rare, the biolayer has strong hydrodynamic conditions. The mud content is low.The study found that the distribution of sedimentary microfacies in the plane is relatively stable, mainly controlled by tectonic movements; it is more variable in the vertical direction, mainly controlled by the change of sea level. The division of the carbonate sedimentary facies of the fourth member of the M group in the A oilfield has promoted the development of the next step, and also provided a strong geological basis for the later research.

Keywords: Late Paleocene- Early Eocene, Lithofacies, Microfacies, Depositional Model

The late Paleocene–early Eocene carbonate system in the North- East of Sultanate of Oman: An overview from the outcropped Jafnayn Formation

Introduction

In Oman, there are some exploration activities taking place in North- West Oman in carbonate rocks (Late Paleocene- Early Eocene) like in Umm er Radhuma (UER) Formation in North Oman. These explorations give a promising future in oil production. The spatial and temporal distribution and types of diagenetic changes and the subsequent effect on the porosity and permeability amounts and distributions within depositional facies and sequence stratigraphy of Umm er Radhuma carbonate rocks reservoirs are still poorly investigated.

Objective

Jafnayn formation in Oman is a Tertiary carbonate rocks mainly composed from marl, shale, dolomite and limestone (Nolan et al., 1990). This formation distributed from north East of Oman (called Jafnyan) to North West of Oman (Called Umm er Radhuma). During the Maastrichtian all the proto- Oman mountains have been subjected to subaerial erosion and weathering which cause a gradual subsidence followed by deposition of Early Tertiary sediments. In Paleocene and Early Eocene, the subsiding of sediments is less rapid which cause to form a shallow carbonate shelf facies (Jafnayn Formation) (Nolan et al., 1990). So, this studies will investigate the carbonate depositional environment of this formation and compare it with equivalent formation at the North- West of Oman to reduce hydrocarbon exploration uncertainty through integrating regional geological understanding of the Jafnayn formation with the time equivalent subsurface reservoir. This will help both potential (offshore) and proven (onshore) reservoir to be well-understood.

Methodology

This studies will investigate the same formation but in North- East Oman. Collecting data from Late Paleocene- Early Eocene surface outcrops (North to South-west Oman) by field work and by describe the petrography by using data of more than 85 samples/ thin section to bring together a wide variety of approaches to improve our understanding of petrophysical properties of the carbonate reservoir and quality prediction in outcrop equivalents in the Late Paleocene to Early Eocene rocks.

Discussion

The detailed evaluation of the mineral content (i.e., carbonate constituents and diagenetic alterations) and the texture of this reservoir will be combined with facies analysis using petrography in a sequence stratigraphy context and geochemical Analysis (major, minor, and trace elements as well as stable and radiogenic isotopes) to create a predictive model for the distribution of reservoir quality.

Result

These rocks are mostly wackestones/packstones rich with large foraminifers. The lithology shows that it composed mainly of a carbonate sequence with thin layers of marl/ shale unit. These carbonates are slightly dolomitic limestone which can give a good porous bed. The marine fossils indicate that the depositional environment is a shallow marine environment.

Microfacies and facies-zone analysis of the Upper Bassein carbonate succession, Bombay Offshore Basin across the Eocene-Oligocene Transition (EOT)

Sreetama Aich[1*], Sudipta Dasgupta[1], Kumar Hemant Singh[1]
1. Earth Sciences, IIT Bombay, Mumbai, Maharashtra, INDIA
E-mail: sreetama2k15@gmail.com

Keywords: Standard microfacies, facies zonation, Eocene-Oligocene transition (EOT), carbonate ramp, Bombay Offshore basin, Bassein Formation.

The Cenozoic sedimentary succession of the Bombay Offshore basin developed over the undulating topography of the Deccan Traps. In this basin, the hydrocarbon-producing middle Eocene subsurface Bassein Formation of the Mukta Field is, as encountered in the wells, dominantly composed of limestone and minor mudrock intercalations deposited along a homoclinal ramp – in both open and restricted settings. The limestones are compact and indurated, with moderate to poor porosity developments, where the primary and most of the secondary porosities are occluded by different phases of cementation. Carbonate sediments, with their significant biogenic contents, e.g., benthic foraminifera, corals, algae, and bryozoan fragments, were deposited in an open-marine setting. Carbonate lithounits, which is predominantly benthic-foraminiferal wackestone with micritic matrix, are intermittently intercalated by deposition of more argillaceous lithounits marking turnover into the restricted-marine condition at the platform interior. The study has been carried out on the offshore Upper Bassein horizons of the Mukta field. Microfacies analysis is used here for characterizing the standard microfacies types (SMF; sensu Wilson, 1975). Using multiple independent proxies, e.g., microfacies analysis and major changes in the fauna, the transitions occurring across EOT can be established.

The Bassein carbonates encountered belong to the SMFs 8 (wackestone with whole organisms, fine micritic matrix), 10 (packstone/wackestone with coated and abraded skeletal grains), and 16 (non-laminated packstone with small-sized peloids). SMFs 8 and 10 belong to the facies zone (FZ; Flugel, 2010) 7, i.e., open-marine setting within platform interior. SMF 16 pertains to the FZ 8 of the restricted region in the platform interior. Both these FZs belong to the inner ramp above the fairweather wave base. Apart from the SMF classification, the biotic assemblages provide with biostratigraphic age determination, paleobathymetry, and paleoenvironment of deposition. The high abundances of Lituonella sp. along with Coskinolina sp., Halkyardia sp., lockhartia, miliolids suggest a middle Eocene, tropical, shallow restricted-marine carbonate ramp setting; whereas the abundance of Nummulites sp. with Asterigerine sp., Bigerina sp., Heterostegina sp., Lepidocyclina sp., Operculinoides sp., Cibicides sp. refers to an early Oligocene tropical shallow open-marine environment. Thus, a biotic reorganization and facies change across the boundary suggest a change in relative sea level. The early Oligocene succession unconformably overlies the middle Eocene succession. The restricted shallow marine condition prevailing in the middle Eocene is succeeded by an erosional late Eocene relative sea-level fall and consequent unconformity, which cannot be delineated in the core because of congruent facies superposition. However, the event resulted in the development and abundance of open vugs and fracture porosity in the upper part of the middle Eocene interval. The early Oligocene brought about a relative sea-level rise by reestablishment of the open ramp condition.

This integrated multi-proxy approach, involving microfacies, facies zones, and biostratigraphical study of the shallow carbonate ramp Bassein Formation, document the relative sea-level fluctuations and transition from restricted marine to an open marine setting across the EOT separated by late Eocene forced regression. This causes modifications in the shallow-marine biotic productivity, thereby, leading to a biotic reorganization above and below the unconformable boundary.

Keywords: microfacies, sea-level change, South Qinling belt, eastern Paleo-Tethys, LPIA

The Paleo-Tethys experienced major geographic, climatologic, and environmental changes during the Permian. A newly documented carbonate-dominated succession (> 3km) in the Xikou section, Zhen'an, Shaanxi, central China is a complete Permian aged rock record and provides a unique opportunity to document its depositional environment, sea-level changes, and associated paleogeography and paleoclimate in eastern Paleo-Tethys. Eighteen microfacies were recognized within the Xikou section, which can be grouped into a (mixed-) inner, middle, or outer ramp facies. Their distributions in the Xikou section represent an evolution involving thirteen depositional phases and indicate a fluctuated sea-level during the Permian, which dropped slightly in the Asselian to Sakmarian and then gradually rose from the Artinskian to middle Capitanian with a distinct rising at the Kungurian. The sea-level then significantly dropped during the late Capitanian to early Wuchiapingian, which was followed by a gradually increasing trend superimposed with high-frequency fluctuations and reached its maximum during the middle Wuchiapingian. The sea level then gradually dropped until the middle Changhsingian and returned slightly during the late Changhsingian.

The sea-level curve in the Xikou area reflected the global climatic changes and was associated with eastern Paleo-Tethys evolution. The relatively low sea level associated with high-frequency fluctuations during the Asselian to Artinskian may relate to the expansion of glacial (P1 and P2), while the followed significant rising at Kungurian may reflect the major deglaciation of the Permian glacial or even the Late Paleozoic Ice Age (LPIA). The abrupt falling of sea level at the end of the Capitanian was globally synchronous and may be relevant to mid-ocean ridge spreading and superimposed with global cooling (P4), which was in accord with the skeletal grain replacement of the fusulinaceans and dasyclads by small foraminifers and *Gymnocodium*, and was considered as a major reason for Middle Permian Extinction. The early Wuchiapingian characterized by densely mixed sequences of carbonate strata and siliciclastic strata had a highly frequent fluctuating sea level, which may be influenced by high frequent short-term climatic variations. The sea-level falling after it reached its highest stand during the middle Wuchiapingian, was suggested as a result of a regional tectonic transition from extension to compression relevant to the eastern Paleo-Tethys evolution, or as a far-field response to the expansion of the Permian glacial episode P4. In addition, the overall rising trend of the sea level and the thick succession in the Xikou area suggest that the South Qinling belt was primarily under an extensional setting during the Late Carboniferous to Early Triassic, in response to Tethys rifting, which may imply the subduction of Mianlue Ocean was possibly beyond the Permian.

Evolution of an Aptian mixed carbonate-siliciclastic carbonate ramp in a shallow marine bay setting

Álvaro García-Penas[1*], Samuel Zamora[2], Marcos Aurell[1]
1. Ciencias de la Tierra, University of Zaragoza, Zaragoza, SPAIN
2. Geología y Subsuelo, Instituto Geológico y Minero de España (IGME), Zaragoza, SPAIN
E-mail: alvarogpenas@gmail.com

Keywords: Aptian, Iberian Basin, climate.

The sequence stratigraphy and palaeogeographical evolution of an Aptian shallow-marine ramp, developed in a shallow marine bay in the Western Tethys, has been reconstructed through detailed analysis and correlation of 10 high-resolution logs spanning the Forcall and Oliete formations of the Oliete subbasin (Maestrazgo Basin, Eastern Iberia). Tow long-term transgressive-regressive (T-R) cycles have been identified. The siliciclastic-dominated Forcall Formation represents a highly asymmetric T-R cycle, with a short transgressive hemicycle culminating in a condensation level with diverse ammonite faunas of the Deshayesites forbesi biozone, and a regressive hemicycle representing the transition from distal and mid-ramp environments, characterized by silts and marls and cm-thick sandstone levels with hummocky cross-stratification, to inner ramp environments characterized by sandy floatstones with orbitolinids, echinoids, and disarticulated endobenthic bivalves (Pholadomyidae, Trigoniidae), and cross-stratified coarse bioclastic sandstones. A prominent discontinuity surface on top of the Forcall Formation marks a sharp change in the depositional system towards the carbonate-dominated bioclastic packstones and marls of the lowermost Oliete Formation (Cabezo Negro member), which contain colonial corals and abundant Thalassinoides. These levels represent the transgressive hemicycle of a second T-R cycle, which culminates in a marl-dominated interval (La Dehesa member) preserving an abundance of articulated gastropods and endobenthic bivalves, as well as scarce ammonites of the P. melchioris and A. nolani late Aptian biozones. The regressive hemicycle is represented by bioclastic-cortoidal packstones and grainstones (Los Estancos member), which are topped by a karstified discontinuity surface recognizable basinwide. Periodic siliciclastic-carbonate alternations in the Forcall and Oliete formations have been tentatively linked to climate oscillations.

Abrupt Middle Eocene climatically-controlled facies shift: the Middle Eocene Climatic Optimum (MECO) in a shallow carbonate platform

Jihede Haj Messaoud[1*]
1. ANPERC, King Abdullah University of Science and Technology, Jeddah, SAUDI ARABIA
E-mail: jihede.hajmessaoud@kaust.edu.sa

Keywords: Middle Eocene Climatic Optimum, Nummulites, Cenozoic warming events, Facies analysis, Carbon isotope stratigraphy.

In the Southern Neo-Tethys margins (Tunisia) the Middle-Late Eocene deposits are arranged in NW–SE oriented facies belts with clear variations in terms of thickness and facies. Shallow carbonate platform facies of the Cherahil Formation (Fm.) pass gradually into globigerinids-clays of the Souar Fm. along a homoclinal ramp. Synsedimentary tectonics, sea-level oscillations, and warming event have imposed major controls on the central Tunisia platform. Facies associations are attributed to at least three sedimentary models. Sequential analysis of the Cherahil Fm. point towards shallowing upward trend interrupted during the lower Bartonian by a major transgression. This sea-level rise coincides with a shift towards a short maximum nummulite carbonate production absent since the nummulitic limestones of the El Garia Fm. (Ypresian). The lower Bartonian transgression is marked by the lithostratigraphic unit named the Siouf member (Mb.) and its lateral equivalent the Reneiche Mb., which is the primary target for hydrocarbon explorations in central Tunisia and the Gulf of Gabes. The Reneiche/Siouf Mb. has been proved as a reliable level for platform-to-basin correlation, although it was not present in the deepest parts of the basin. Proximal facies of dominant lumachellic marls shift to a thickening-upward sequence of transgressive facies culminating in a maximum nummulitic carbonate production during the middle Eocene transgression and coincides broadly at the global scale with the occurrence of the Middle Eocene Climatic Optimum (MECO). The position of the Reneiche/Siouf Mb. is confirmed also by the bulk carbon isotope record (δ13C) characterised by negative carbon isotope excursion in the middle of the Siouf Mb. followed by a positive excursion at the top of this member which is comparable to the δ13C record through the MECO in the northern and eastern Neo-Tethys and also in the Atlantic Ocean.

An Ordovician chronostratigraphic record of carbon- and oxygen isotopes for the western Tarim Basin, China

Yuefeng Shen[1*], Fritz Neuweiler[2], Adrian Immenhauser[3]

1. School of Resources and Environmental Engineering, Hefei University of Technology, Hefei, Anhui, CHINA
2. Department of Geology and Geological Engineering, Laval University, Quebec City, Quebec, CANADA

E-mail: yuefengshen@hfut.edu.cn

Keywords: Great Ordovician Biodiversification Event (GOBE), carbonate factory, drowning, black-shale, algae evolution

Here we explore depositional facies and diagenesis in concert with a first component-specific data-set of $\delta^{13}C$ - $\delta^{18}O$ values for Middle to Late Ordovician of the western Tarim Basin. By integrating filtered literature bulk-rock data, a synoptic chemo-chronostratigraphic sequence is presented along a Wheeler-diagram. There are chemostratigraphic segments lasting from tens of Myrs to several 100 kyrs. There is a long-term trend of increasing $\delta^{13}C$ values culminating in the early Katian at 3.2 ‰ followed by a steady decrease. This tipping point is associated with a precursory baseline shift that appears to interfere with the short-term Guttenberg carbon-isotope excursion (GICE) identified with caution on the basis of an associated positive shift of $\delta^{18}O$ values. The baseline shift was driven by regional effects of photosynthesis and a boosting (dasycladacean-related) production of aragonite along the Sandbian-Katian boundary interval. There is a medium-term (Darriwilian to earliest Sandbian) negative $\delta^{13}C$ excursion coinciding with both a basal positive $\delta^{18}O$ excursion and the demise of the Darriwilian carbonate ramp (*Suecicus*-Event, new term). It might represent the effects of volcanism/SO_2-outgassing (volcanic winter) during the regional switch from a passive to an active continental arc. This event masquerades the widely recorded middle Darriwilian carbon-isotope excursion (MDICE). More caution is needed to consider the Tarim realm for global Ordovician chemostratigraphy.

The upper Eocene Loza-Moraza Formation: Lacustrine-palustrine facies in a syn-tectonic compressional context (Miranda-Trebiño piggy-back basin, Western Pyrenees, N Spain)

Zuriñe Larena[1*], Juan Ignacio Baceta[1], Xabier Murelaga[1]
1. Department of Geology UPV/EHU, University of the Basque Country, Leioa, Biscay, SPAIN
E-mail: zurine.larena@ehu.eus

Keywords: Miranda-Trebiño basin, Pyrenees, lacustrine-palustrine facies, late Eocene

Interest in lacustrine-palustrine environments has increased worldwide in last years due to the high sensitivity and different responses of these continental depositional systems to tectonism, climate and marked changes in global environmental conditions. This work focusses on the stratigraphy and facies architecture of the late Eocene Loza-Moraza Formation, which is the basal unit of the thick continental sedimentary succession infilling the Miranda-Trebiño piggy-back basin, on the western prolongation of the south Pyrenean thrust front (Basque Pyrenees, N Spain). The Loza-Moraza Fm. ranges 25-286m in thickness and occurs forming a series of outcrops extending laterally for about 35km along the southern margin of the Miranda-Trebiño basin. The stratigraphic unit consists of siliciclastic, mixed and calcareous deposits representative of alluvial to palustrine-lacustrine environments, which unconformably overlay Cretaceous to Paleocene coastal to shallow marine sedimentary rocks. Previous paleontological studies allowed constraining the bulk of the Loza-Moraza Fm. within the MP 18 Biozone (Priabonian, late Eocene). With the aim of recognizing the depositional conditions and the paleogeographic evolution of the Miranda-Trebiño basin during the deposition of the Loza-Moraza Fm., this work provides information about its constituent lithofacies, the integrated sedimentary model and analyzes the potential factors that controlled the dynamics of the late Eocene lake systems. They involve the general compressional tectonic setting, the effects of local diapirism and the series of climate changes recognized for the Priabonian and the Eocene to Oligocene transition (EOT).

The three internal sedimentary sequences (SEQ1 to SEQ3) of the Loza-Moraza Fm. consist of fluvial-alluvial siliciclastics (mudstones and lithic conglomerate-sandstone packages) that grade both vertical and laterally to successions of massive to well-stratified palustrine-lacustrine carbonates (marlstones with discontinuous calcretes, intraclastic limestones and bioclastic limestones). The sequence boundaries are erosional discontinuities associated to net changes in the sedimentary regime. These major facies changes are likely indicative of pulses of generalized tectonic uplift of the basin margins, enhancement of erosional processes and terrigenous supply and a coeval sharp reduction in the areal extent of the stacked continental wetlands. In addition, the local activity of the Peñacerrada and Ocio-Buradon diapirs and the syn-sedimentary folding of the Cretaceous-Paleocene substrate strongly influenced the basin paleotopography and the distribution of the different alluvial to lacustrine environments, as recorded by the occurrence of onlap-truncation relationships and significant lateral variations in both thicknesses and lithofacies types. The studied successions also record some significant changes in the local climatic regime, which according to key facies evolved from overall semiarid to arid during SEQ1, to a higher humidity interval during SEQ2 and, finally, into enhanced drying under renewed semiarid conditions during SEQ3. Although more detailed analyses are needed, this local evolution largely agrees with the climatic conditions established for western Europe during the Priabonian stage and the global climate variations across the EOT.

E-mail: telm.boverarnal@ub.edu

Keywords: Platform carbonates, sea-level changes, eustasy, sequence stratigraphy, Aptian, Iberia

Several Lower Cretaceous basins located in different tectonic plates include incised valleys of Aptian age with depths ranging from metres to tens of metres. These incised subaerial unconformities are found in both carbonate and siliciclastic systems. In the Maestrat Basin, which is in the eastern margin of the Iberian Plate, two episodes of Aptian major relative sea-level fall and erosion were recorded in a marine carbonate succession. The first episode was of late early Aptian age (intra *Dufrenoyia furcata* ammonite Zone), occurred in less than 0.9 My according to the current Geological Time Scale and had an estimated magnitude between 60 and 70 m. This relative sea-level drop and the subsequent base-level rise have been classically studied in the Galve sub-basin (western Maestrat Basin), i.e., in the proximal platform settings of Camarillas and in the platform-to-basin transition area of Las Mingachas. In Camarillas, during sea-level fall, incised valleys were carved into inner parts of an aggrading highstand platform. Later, during the following transgression, these incised valleys were back-filled with tidal-influenced high-energy carbonate deposits. In Las Mingachas, the records of this relative sea-level fall and subsequent base-level rise correspond to a detached basin-floor component and to lowstand and transgressive platforms, respectively. Incised erosional surfaces, forced regressive wedges and lowstand platforms resulting from this late early Aptian lowering of sea level are also recognizable in other localities of the Galve sub-basin as well as in other depocentres of the Maestrat Basin such as the Morella and La Salzedella sub-basins. This contribution will also discuss the divergent interpretations that exist regarding the sequence stratigraphy of Las Mingachas outcrop. The second episode of major relative sea-level fall and rise was of early late Aptian age (upper *Epicheloniceras martini* and lower *Parahoplites melchioris* ammonite zones). The latter sea-level event had an amplitude of more than 100 m, occurred in less than 3 My and was firstly identified in the northern Morella sub-basin as a deeply incised subaerial unconformity also carved into an aggrading highstand platform. Fieldwork carried out during the last years throughout the basin has permitted to recognize this erosional subaerial unconformity in the Galve sub-basin. These two episodes of major relative sea-level change are interpreted to be mainly eustatic in origin given their basin-wide and likely global significance.

Keywords: Saiq Plateau, Wadi Sahtan, Khuff

Here a carbonate depositional model is generated based on a detailed microfacies analysis from the Saiq Plateau and Wadi Sahtan sections in Jabal Akhdar of Northern Oman. The Wadi Sahtan section is paleogeographically located more distal than the Saiq Plateau section. The two sections of the Lower Triassic Mahil Formation (Khuff outcrop equivalent (KS-1)) were measured bed by bed along with a depositional dip. A detailed sedimentological description for Saiq Plateau and Wadi Sahtan sections was performed using Dunham's classification, and lithology samples were taken every 50 cm. One hundred and eighty half-stained thin-sectioned from several lithofacies were prepared. The point-counted tool was used to reconstruct the original components of the Lower Mahil Formation. Consequently, twenty-four microfacies were identified; four are only recognized in the Wadi Sahtan logged section, twelve are restricted to the Saiq Plateau logged section, and eight are common for both sections. Microfacies were grouped into three facies association (backshoal, shoal, and foreshoal). The Lower Mahil Formation consists of the inner ramp to mid-ramp carbonate facies, with ramp crest facies restricted to the Saiq Plateau section. The inner ramp facies was characterized by microbial lamination; the ramp crest was mostly Oolitic packstone-grainstone and the mid-ramp carbonate facies was indicated by the weakly developed hummocky cross-stratified beds.

E-mail: xiawang@cdut.edu.cn

Keywords: Early reefal cements, REE, Permian, South China

During the Middle-Late Permian transition, the oceans witnessed the eruption of Emeishan Large Igneous Province and the subsequent mass extinction event. Previous researchers have performed a series of studies on the biocrisis, redox conditions, C-N-S cycles, and climate and environmental variations during this critical period, but little is known about the seawater compositions and their evolutionary trend, especially for the REE characteristics. Numerous isolated carbonate platforms with a large amount of stacked reef architecture and rare terrigenous admixtures can provide good non-skeletal carbonate materials, e.g., early cements of reefs and grainstones, for restoring seawater REE characteristics, which reliability and validity have been demonstrated in some recent studies (Li et al., 2019; Wallace et al., 2017). Here, we reported a preliminary result on the REE characteristics sourced from the early reefal cements of the Maokou, Wujiaping, and Changxing formations from Middle to Upper Permian strata in South China, which uniformly show modern seawater-like shale-normalized REE patterns and superchondritic Y/Ho ratios with various signatures of the Ce anomaly and total REE concentrations. These data may indicate the oscillated seawater REE compositions during the Middle and Late Permian transition and show the potential significance of REE signatures in revealing the change of seawater compositions in a relatively short time scale.

Keywords: lacustrine carbonate, Miss,thrombolite, stromatolite, saline lake, Qaidam Basin

To document characteristics of lacustrine microbialites and microbially induced sedimentary structures (MISS) in saline lakes in the western Qaidam Basin, numerous outcrops, cores, thin sections, and analytical laboratory data were used to evaluate the sedimentary environments of microbialites in Cenozoic saline lakes of the region. The spatial and temporal distributions of microbialites were analyzed, rock types and lithofacies assemblages were classified, and MISS were identified in addition to analysis of their internal structures. The biological, physical, and chemical influences on MISS structural diversity was also investigated. The results show that: (1) Cenozoic saline lake margins and shallow lakes in the western Qaidam Basin were conducive to the development of microbialites that primarily included thrombolites and stromatolites that were typically interbedded with granular limestone to constitute fan-controlled and lake-controlled lithofacies assemblages. (2) The microbialites in fan-controlled lithofacies assemblages were dominated by thrombolites that were large and with thicknesses in the range of ~50 cm to 3 m (maximum of 5 m). In contrast, the microbialites in the lake-controlled lithofacies assemblages were featured with coexisting of thrombolites and stromatolites and were small and with a thickness mostly between 30 to 50 cm (maximum of 2 m). Different types of microbialites developed in different sedimentary environments, thereby forming different lithofacies assemblages. (3) Eight types of MISS were identified, and it is argued that MISS types were mainly determined by internal biological attributes including the manifestation of multiple behavioral adaptations to external environments. Further, the MISS comprehensively reflected fluctuations and balance of environmental deposition rates (υenv) and microbial growth rates (υmicro). (4) The MISS also included modifications by physical and chemical influences (e.g., erosion and wrinkle marks, sponge pore) that formed due to hydrodynamic forces and physical factors (e.g., evaporation and drying), respectively. Burial dissolution and weathering dissolution occurred in the diagenetic and post-diagenetic stages, and the processes confirmed that chemical influences on structures.
