Sedimentology Futures: Geoheritage, Planetary Exploration, and Technology

Marjorie A Chan[1*]
1. Geology & Geophysics, University of Utah, Salt Lake City, UT, UNITED STATES
E-mail: marjorie.chan@utah.edu

Keywords: sedimentology, geoheritage, Mars, planetary, technology, future

Looking forward, the field of sedimentology and its future must include advances in geoheritage, planetary exploration, and technology.

Of foremost importance, the many diverse landscapes where we conduct sedimentology research comprise our geoheritage – the geologic sites or areas with significant scientific, educational, cultural, and/or aesthetic value. Geoheritage sites are vital to advancing knowledge and for understanding geodiversity as well as the biodiversity the land supports. The sedimentary record at many geosites has implications for understanding climate change. Over the last few decades, a rising international geoconservation movement is bringing attention to special geological features with intrinsic value. Sedimentologists need to contribute to good stewardship of important geoheritage sites.

Sedimentology plays a key role in planetary explorations, with the discovery of more sedimentary rocks on Mars and the continuing search for extraterrestrial life. The potential for extraterrestrial life will be enhanced by more studies of microbial life in terrestrial authigenic minerals and their detection as biosignatures. Earth has a life bias throughout over three eons of geologic history, yet analyzing the variability of analogous Earth systems with the sedimentologic context for habitable environments will lead to a better understanding of sedimentary deposits on other planetary bodies.

Finally, technology will continue to change the way we conduct our research from data collection to archiving, processing, visualizing, and sharing. All sedimentology studies can benefit from the use of digital technology, accompanied by open data and more avenues for communicating what our science is about.

The more we can learn from geoheritage landscapes that have strong scientific value, the better we can apply knowledge to planetary explorations. The more we use new digital technologies, the more we can share and make new discoveries. It's an exciting frontier of sedimentology futures!

Secular evolution of tectonics and volcano-sedimentology

Peter A. Cawood[1*], Jacob Mulder[2], Priyadarshi Chowdhury[3]

1. Earth, Atmosphere and Environment, Monash University, Clayton, Victoria, AUSTRALIA

2. Department of Earth Sciences, University of Adelaide, Adelaide, SA 5005, Australia, Adelaide, South Australia, AUSTRALIA

3. School of Earth and Planetary Sciences, National Institute of Science Education and Research, Jatni, Odisha, INDIA

E-mail: peter.cawood@monash.edu

Keywords: basin, tectonics, secular change, volcanism

Sedimentary basins are a critical archive of Earth history. They lie at the interface between, and provide an evolutionary record of, the solid (crust, mantle) and surficial (atmosphere, oceans, biosphere) reservoirs of the Earth.

Types of sedimentary basin and the nature of their fill derive from the interplay of subsidence (and resultant accommodation space) and the nature of the source. Subsidence results from extension, compression or thermal cooling of the lithosphere, and is tied to tectonic environment. The scale and magnitude of subsidence is guided by lithospheric rigidity, which has evolved through Earth history.

Volcano-sedimentary basins are characterized by syn-sedimentation magmatism. They have formed throughout Earth history (irrespective of tectonic mode) either at the sites of lithospheric compression or extension, and may record post-magmatic thermal subsidence.

Rapid geochemical and isotopic analyses of sedimentary basin-fills have transformed provenance analysis, paleogeographic reconstructions, and our understanding of continental crust evolution, as well as of geological cycles within the Earth system. For example, age-dating of detrital zircons has allowed us to constrain the maximum depositional age that approaches the timing of sedimentation in volcano-sedimentary basins, which has proven especially useful in dating the non-fossiliferous Precambrian basins. Analyses of Hf-and-O isotopes in detrital zircons allow us to evaluate the relative contribution of surficial, crustal, and mantle reservoirs to the magmatic sources of volcano-sedimentary basins. Trace element systematics of zircon underpin new proxies for the crystallisation temperature, crustal thickness, aluminium saturation index, and magmatic source of zircon-bearing melts. The integrated information coming from these proxies offer a more refined evaluation of the tectonic setting of zircon crystallization, which is particularly useful for studying ancient volcano-sedimentary basins decoupled from their original geodynamic context. Although zircon remains the most widely used detrital mineral petrochronometer, inherent bias in source rock fertility and a susceptibility to recycling remain fundamental limitations of detrital-zircon provenance analysis. In this regard, ongoing developments in in situ age dating, isotopic and elemental analysis of other detrital minerals, such as apatite, rutile, monazite, and titanite, offer a more holistic view of the evolution of volcano-sedimentary basins from the detrital record as they form in a broader range of source rock compositions, are sensitive to lower temperature tectonothermal events, and are more labile than zircon within the sedimentary cycle.

Evolution of the volcano-sedimentary basin settings and fills provide salient clues about continental freeboard conditions, composition of the emerged crust and the atmosphere-ocean chemistry. For example, early episodes of transition from dominantly sub-marine to sub-aerial volcano-sedimentation at craton-scale during the Mesoarchean provided direct clues about the first episodes of continental emergence, basin formation due to thermal subsidence and terrestrial sedimentation, and the concomitant instances of transient atmospheric-ocean oxygenation (O2-whiffs) and glaciation. Subsequently, the widespread emergence of the continental crust and resultant weathering and sediment transport in the Neoarchean-early Paleoproterozoic likely exemplified larger-degree of tectonic (compressional) control on basin formation and had a profound impact on the atmosphere and oceans that has been linked to glaciations, the Great Oxygenation Event, and enhanced supply of bio-essential nutrients to the oceans.

Spatiotemporal changes of hydroclimate in East China since late Miocene

Shucheng Xie[1*]
1. School of Earth Sciences, China University of Geosciences, Wuhan, Hubei, CHINA
E-mail: xiecug@163.com

Keywords: geobiology, bacteria, archaea, hopanoids, tetraethers, drought

The East Asian Monsoon systems in late Cenozoic are paid great attention to for decades of years. The loess-paleosol sequences in North China and the marine sediments in South China Sea provide critical records to decipher the evolution history of the monsoon systems in China. However, it remains largely unknown about the spatiotemporal evolution of the hydroclimate driven by the East Asian Summer Monsoon in East China where is heavily populated. In the past years, we proposed a series of hydroclimate proxies on the basis of the microbial lipid biomarkers extracted from soils, peat deposits, lacustrine sediments as well as the cave sediments (Xie et al., 2012, 2013; Yang et al., 2014; Dang et al., 2016). These proxies enable us to explore the spatiotemporal changes of the hydroclimate in East China since the late Miocene (Tang et al., 2017; Zhu et al., 2017; Lu et al., 2021). We found the anti-phased trends on the hydroclimate changes in the Middle Yangtze regions in comparison with those in the North and South China on both the millennial and tectonic time scales, known as the tripole patterns as observed in modern days rainfall (Zhang et al., 2018; Lu et al., 2021).

Carbonate diagenesis: why we need to look small, think big and remember to process!

Cathy Hollis[1*]
1. Earth and Environmental Science, University of Manchester, Manchester, Great Manchester, UNITED KINGDOM
E-mail: cathy.hollis@manchester.ac.uk

Keywords: Diagenesis, Carbonate, Fluid flow

Carbonate diagenesis embraces all physical, chemical and biogenic processes that modify a sediment after deposition. It begins at the seafloor, continues during burial and uplift, and can dramatically transform mineralogy and rock physical properties. Over the last 20 years, there have been major advances in our understanding of carbonate diagenetic process, through high resolution imaging, micro-sampling and geochemistry. There has also been significant progress in the integration of hydrogeological and geochemical modelling, particularly via reactive transport models. These have dramatically improved our ability to interpret the genesis and distribution of diagenetic products. This raises the opportunity - and challenge - to use our knowledge of basin-scale fluid flow and reaction to interpret high resolution, micro-sampled data in the context of an understanding of diagenetic process. Conversely, construction of reactive transport models using robust information on stratigraphic architecture, palaeoclimate and burial history, alongside calibration of model outputs with geological data, improves confidence in the modelling process. In totality, sampling, analysis, modelling and interpretation of data should be conducted within the framework of our knowledge of the tectonostratigraphic and palaeo-environmental evolution of a basin allowing us to move away from generic, conceptual models.

In this talk, a number of case studies will be used to show how multi-scale characterisation and analysis of mineral phases can be integrated with conceptual and numeric models to map and predict the distribution of diagenetic products in time and space. In all cases, analysis began at the basin scale, through evaluation of the tectonic and burial history, palaeoclimate and stratal architecture of the basin. Through integration of hydrogeological concepts, reaction pathways and kinetics it is possible to the map the diagenetic pathway of strata, taking into account sedimentary, tectonic and diagenetic inheritance and feedback mechanisms. In all cases, detailed petrographical analysis and representative microsampling were vital to ensuring that micron-scale analysis of diagenetic products provided critical information as to the timing and mechanism of fluid flow. Concept testing using forward models was then integral to the final interpretation. Ultimately, this presentation will emphasise the criticality of systematically building knowledge from multi-proxy, multiscale sources to predict the distribution of diagenetic products, rather than fitting results to prior conceptual models. In this way, we are able to move towards predicting the occurrence and distribution of diagenetic products.

Volcanic Source to Sink: From Subaerial Eruptions to Deep-water Turbidity Currents

Kyoko S. Kataoka[1*]
1. Research Institute for Natural Hazards and Disaster Recovery, Niigata University, Niigata, JAPAN
E-mail: kataoka@gs.niigata-u.ac.jp

Keywords: Volcanic source-to-sink, Volcaniclastic Sedimentology, Sedimentary Volcanology

Volcanic or volcaniclastic sedimentology includes studies of volcaniclastic sediments focusing on facies, depositional processes, environmental impacts by explosive eruptions, and decadal to millennial-scale sedimentary and geomorphic responses to volcanism. It also encompasses studies of *lahar*, Indonesian term for sediment laden flow of volcanic materials and water, which travels down from a volcanic slope through a river valley, occasionally reaching a far-located lake or ocean. Hydrological reconstruction of lahars and volcanogenic floods approached from flood geomorphology can reveal flow volume and spatiotemporal changes during the event. These results are critical for hydrological volcanic hazard assessments of populated downstream areas and to predict the laharic events during and after an eruption.

Recent awareness of other facets of volcaniclastic sedimentology has emphasized the importance of sediment delivery to the deeper part of the subaqueous sedimentary system, such as lacustrine and marine environments by volcanic hyperpycnal flows. The nature of high sediment laden flows in volcanic settings enhances generation of density flow traveling a deep-water environment and leaves distinct event deposits among the sedimentary successions with high time-resolution owing to high sedimentation rates of background sediments. The active Adatara and Bandai volcanoes adjacent to Lake Inawshiro-ko, Fukushima, Japan offer a compact natural laboratory to understand a cascading process from subaerial eruptions and lahars to deep-water density currents during the past 50,000 years. Subaqueous density flow deposits in sediment cores from Lake Inawashiro-ko clarify their origin (source volcano) and trigger (eruption style). Classical facies analysis, grainsize, and petrography together with geochemistry using micro-XRF and clay mineralogy by XRD suggest that each density current layer can be linked to individual eruptions at Mts. Adatara and Bandai. Shorter recurrence intervals of the small-scale explosive eruptions indicating higher activity at both volcanoes was revealed, which could not be evaluated solely by proximal tephra records due to the low preservation potential of the near source area.

Thus, volcaniclastic sediments transported via water can be interface between source volcano and sink with traceable petrographic and geochemical fingerprints, even in the absence of correlative eruption records in proximal areas and/or volcanic edifice itself. A broad view from the volcanic source to the sink as a collective system of volcanic slope, fluvial, and deep-water environments dealing with eruptions, lahars, fluvial transport, and deep-water turbidity currents will attract both sedimentologists and volcanologists. The future research of water transported volcaniclastic sediments and their sedimentary sequences, especially using well-preserved core-sections, will be focus on understanding “source volcanism” from the sink of distally located alluvial, lacustrine and submarine sedimentary successions. Also, the sedimentological view and approaches will be key to reveal process and mechanism of volcanic sediment-laden flows (pyroclastic density currents, volcanic debris avalanches, lahars, and subaqueous volcaniclastic turbidity currents) as they share several common features of non-volcanic density currents except for higher temperatures of flow and density variation of volcaniclastic particles. Further, studies of volcaniclastic sediments from sedimentologists’ view may cultivate an innovative realm of “Sedimentary Volcanology”, and fusion of sedimentology and volcanology is necessary to predict and prevent volcanic cascading hazards.

Observing source-to-sink processes of terrigenous siliciclastics and particulate organic carbon in the deep sea

Zhifei Liu[1*], Yulong Zhao[1], Yanwei Zhang[1], Baozhi Lin[1], Thomas M. Blattmann[2], Jiaying Li[1], Xiaodong Zhang[1], Jingwen Zhang[1], Chen Ling[1], Junyuan Cao[1], Pengfei Ma[1], Xun Yu[1], Jiawang Wu[1], Christophe Colin[3], Timothy I. Eglinton[2]

1. State Key Laboratory of Marine Geology, Tongji University, Shanghai, CHINA

2. Geological Institute, ETH Zürich, Zürich, SWITZERLAND

3. Laboratoire Geosciences Paris-Saclay (GEOPS), Université Paris-Saclay, Orsay, FRANCE

E-mail: lzhifei@tongji.edu.cn

Keywords: terrigenous siliciclastics, particulate organic carbon, source-to-sink process, deep-sea mooring observation system, South China Sea

Source-to-sink transport processes of deep-sea sediments are of great scientific significance for understanding land-to-sea material fluxes, marine carbon cycling, and global environmental change. The lateral transport of solid material from land to sea, dominated by terrigenous siliciclastics, and the vertical sinking of suspended particles from the photic zone, composed mainly of particulate organic carbon, intersect in the deep sea and jointly affect global sediment fluxes, biogeochemical cycles, and climate change. However, observations of these two deep-sea processes and their interactions are scarce, hindering the general understanding of the deep-sea environment and its influence on the formation of deep-sea sediments. Here, we select the South China Sea, the largest marginal sea in the western Pacific, where we have performed in-situ time series observations of deep-sea currents and their transport of sediments for more than 10 years through deployment of deep-sea mooring systems equipped with sediment traps, acoustic Doppler current profilers, and other observation facilities.

These observations have shed light on significant deep-sea sedimentary dynamics and biogeochemical processes that have not been previously confirmed or observed in the deep sea. (1) Contour currents are observed for the first time to have tunnel-like velocity structures that dominate the long-distance along-slope transport of deep-sea sediments in passive continental margins, like the South China margin in the northern South China Sea. (2) Typhoon rainfall can be the direct trigger of the frequent development of turbidity currents in deep-sea canyons, such as the occurrence of turbidity current events four times a year in the Gaoping Submarine Canyon in the northeastern South China Sea. (3) Terrigenous phyllosilicates undergo differential transport, such as the deep basin of the South China Sea, where illite and chlorite are transported mainly by deep currents, while smectite is transported mainly by surface currents. These transport mechanisms control the distribution pattern of clay minerals on the deep seafloor. (4) The fate of terrigenous organic carbon in deep-sea sediments is controlled by phyllosilicate minerals, such us pedogenic organic carbon being stripped form smectite mineral surfaces while petrogenic organic carbon being tightly associated with illite and chlorite upon their dispersal and sedimentation in the deep South China Sea. (5) Zooplankton fecal pellets are an important form of marine organic carbon export, for example, the monsoon climate driven fecal pellet production and sinking in the southern South China Sea, where the repackaging and producing of deep-dwelling communities in mesopelagic and bathypelagic zones may contribute to higher export of particulate organic carbon to the deep sea.

The genetic mechanism of the Oligocene sedimentary hiatus in the western Pacific seamounts: Evidence from the cobalt-rich crust of the Weijia Guyot

Bin Zhao[1*]
1. Ministry of Natural Resources Key Laboratory of Marine Mineral Resources, Guangzhou Marine Geological Survey, Guangzhou, Guangdong, CHINA
E-mail: zbin_a@mail.cgs.gov.cn

Keywords: Sedimentary processes,Cobalt-rich crust growthing hiatus,Eocene-Oligocene transition,Paleoclimate change,Western Pacific seamounts

Sedimentary process of seamounts is a new direction to explore the occurrence of global climate events since Cenozoic and to predict future global climate change due to its close relationship with global climate change. Eocene-Oligocene transition (E/O) global cooling event is one of the most important climate events experienced by the earth. Some studies indicate that Oligocene sedimentary hiatus exists at western Pacific seamounts, and the cobalt-rich crusts developed at the summit of seamounts occur more than one growthing hiatus since Eocene. However,there are not adequate researches on the genetic mechanism and internal relation between these two sedimentary events. This research will consider the accomplishment form recently ocean scientific research, deep-sea drilling data and other related studies. The study will focus on the oceanic sedimentation rate and the growth process of cobalt-rich crusts in Weijia Guyot since Cenozoic at the Magellan Seamounts, which is located in the Western Pacific Ocean. The study content will be compared with the important global geological events and geological records during the E/O in order to clearly explore the influence of global climate cooling event during E/O on seamount deposition and cobalt-rich crusts growth. Additionally, study the genetic mechanism of Oligocene sedimentary hiatus at western Pacific seamounts, which also provides a possible new basis for E/O global climate change events.

Late Miocene reorganization of lake hydrological systems in the northern Tibetan Plateau linked to topographic growth

Tao Zhang[1], Siyuan Han[1], Wenxia Han[2*], Weilin Zhang[3], Chunhui Song[1], Xiaomin Fang[3]
1. School of Earth Sciences, Lanzhou University, Lanzhou, Gansu, CHINA
2. School of Resources and Environment Sciences, Linyi University, Linyi, Shangdong, CHINA
3. State Key Laboratory of Tibetan Plateau Earth System Science, Resources and Environment, Institute of Tibetan Plateau Research, Chinese Academy of Sciences, Beijing, CHINA
E-mail: wenxia_han@163.com

Keywords: Paleohydrological systems, Reorganization, Topographic growth, Late Cenozoic, Tibetan plateau

The hydrological cycles of lakes in the Tibetan Plateau have had profound impacts on the climatic and environmental evolution of the Asian interior and hence they are crucial for the well-being of the large human population of the region. The Late Miocene is regarded as the most recent interval when the Tibetan Plateau was extensively occupied large paleolakes. However, it is unclear when and how these mega paleolakes shrank and the environment evolved into its present status of dominant desert and semi-desert. To address these issue we conducted detailed analyses of diffuse reflectance spectroscopy, sedimentology, paleomagnetic-based tectonic rotation, and geochemistry of a Middle to Late Miocene sedimentary sequence in the Xining Basin in the North-eastern (NE) Tibetan Plateau, supplemented by a spatiotemporal comparison of the results with equivalent records from adjacent regions. The results reveal a clear transition of the lacustrine system in the Xining Basin at ~11 Ma, characterized by decreased water level and an increase in the oxidation state of the depositional environment. A synthesis of these observations with available evidence of lake evolution from the NE Tibetan Plateau leads us to conclude that a fundamental reorganization of lake hydrological systems in the NE Tibetan Plateau occurred at ~11 Ma, and that tectonic activity and topographic growth-rather than changes in climate or solar insolation, as previously proposed-was the principal factor responsible. This hydrological reorganization was of profound significance for the regional hydrological cycle and the climatic and ecological environment of Asia, because due to the elevated topography, the NE Tibetan Plateau was unable to reattain its Middle Miocene paleohydrological configuration.

Tectonic and orbital forcing on South Asian monsoon in the late Oligocene

Chun-Sheng Jin[1*]

1. Key Laboratory of Cenozoic Geology and Environment, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, CHINA

E-mail: csjin@mail.iggcas.ac.cn

Keywords: Asian monsoon, Tibetan Plateau, Nima Basin, orbital cycles, uplift

The modern pattern of the Asian monsoon was thought to be formed around the Oligocene/Miocene boundary, which has been generally attributed to Himalaya-Tibetan Plateau (H-TP) uplift. However, the timing of the ancient Asian monsoon over the TP and its response to orbital forcing and tectonic uplift remains poorly known because of the paucity of well-dated orbital-scale records from the TP interior. Here we present a ~2-thousand-year resolution cyclostratigraphic results from the Nima Basin to show that the South Asian monsoon (SAM) precipitation has already advanced to the central TP (32ºN) at least at ~27.4 million years ago (Ma) which is indicated by periodical arid-humid fluctuations with orbital cycles based on environmental magnetism parameters. The lithology shift and amplified amplitude of proxy around ~25.5 Ma as well as a hydroclimate transition from obliquity and precession dominated cycles to oscillations paced by a combination of eccentricity, obliquity, and precession confirm that the SAM has intensified at ~25.5 Ma, suggesting the TP might have reached a paleo-elevation threshold for enhancing the coupling between the uplifted plateau and the SAM by then. Eccentricity-paced precipitation variability was argued to be mainly driven by eccentricity-modulated low-latitude summer insolation rather than glacial-interglacial Antarctic ice sheet fluctuations. Our new monsoon data provide key evidence to link the Asian monsoon intensification with regional tectonism and conclude a combination of tectonic and orbital forcing on the SAM evolution on variable timescales in the late Oligocene.

From mega-fresh lake to salt playa: when and why does the paleolake evolution in the Qaidam Basin cross a possible tipping point?

Wenxia Han[1*], Xiaomin Fang[2], Erwin Appel[3]
1. School of Resources and Environment Sciences, Linyi University, Linyi, Shandong, CHINA
2. Key Laboratory of Continental Collision and Plateau Uplift, Institute of Tibetan Plateau Research, Chinese Academy of Sciences, Beijing, CHINA
3. Department of Geosciences, University of Tübingen, Tübingen, D-72074, GERMANY
E-mail: wenxia_han@163.com

Keywords: Linear and non-linear time series analysis, Orbital forcing, Ice sheet expansion, System regime change

The Qaidam Basin in the NE Tibetan Plateau is now dominated by a desert condition with sporadic salt lakes, however, a large paleolake existed in this 120,000 km^2 vast basin during most of the Cenozoic. Determining when and how the paleolake system collapsed and evolved to its modern condition is crucial for understanding the drying processes of the inland Asia and the associated formation of salt resources in this region. A deep Sino-German drilling core retrieved from the depo-center of the western Qaidam Basin (spanning 2.7 to 0.08 Ma) provides a unique window to address these issues. Here we performed comprehensive linear and nonlinear analyses (i.e., statistical, cluster, wavelet and recurrence quantification analyses) on a large amount of published and newly obtained data of the core. The results show that the lake evolution and salt deposits in the Qaidam Basin experienced four critical periods at ~2.2, 1.2, 0.8-0.6 and 0.3 Ma, and crossed a possible tipping point at 0.6 Ma, characterized by striking changes in proxy variations and regime change at 0.6 Ma. We suggest that the co-occurrence of low obliquity amplitudes and low eccentricity is responsible for the identified transitions in the paleolake evolution of the Qaidam Basin, by facilitating the ice sheet expansion in the Northern Hemisphere and its subsequent effects on the Westerlies. These results are further corroborated by our ECHAM5 general circulation modeling. Our study provides new evidence on the evolution process and related mechanisms of past climatic evolution in inland Asia. The presented comprehensive linear and nonlinear data analysis on a large quantity of paleoclimatic-environmental data demonstrated that the data integration analysis can reveal more important information hidden in the primitive paleoclimate data, and thus has great prospects in related research in the future.

Chemical weathering of the Mekong River basin with implication for East Asian monsoon evolution during late Quaternary: Marine sediment records in the southern South China

Pham Nhu Sang[1], Zhifei Liu[1*], Christophe Colin[2]
1. School of Ocean and Earth Science, Tongji University, Shanghai, CHINA
2. Université Paris-Saclay, Géosciences Paris Sud, Paris, FRANCE
E-mail: lzhifei@tongji.edu.cn

Keywords: clay minerals, major elements, chemical weathering, East Asian monsoon, Mekong River, southern South China Sea

Clay mineralogy, major-element geochemistry, and Sr-Nd isotopic compositions from Core MD05-2896 collected in the southern South China Sea have been utilized to investigate discrimination of sediment provenance and to reconstruct a history of chemical weathering in the Mekong River basin over the last 45 ka. Our results display that the clay mineral assemblage of the core is characterized by abundant smectite and illite, with moderate kaolinite and chlorite and 87Sr/86Sr ratios and εNd values narrowly vary in the range of 0.7232 to 0.7272 and from –10.9 to –9.6, respectively. Clay mineralogy and Sr-Nd isotopic composition analyses indicate that the Mekong River is the main terrigenous sedimentary source to the southern South China Sea, with no detectable change over the time span of the study, despite strong sea-level fluctuations. Based on clay mineralogy and elemental geochemistry, higher smectite/(illite + chlorite), smectite/kaolinite, TiO2/K2O, and SiO2/K2O ratios during the Marine Isotope Stage (MIS) 3 and 1 suggest enhanced chemical weathering, while lower values of these ratios during MIS 2 indicate weakened chemical weathering. These proxies reveal a close relationship with the available climate records of the East Asian monsoon evolution, implying that the East Asian monsoon evolution significantly controls the chemical weathering of the Mekong River basin that mainly causes terrigenous sediment variations in the southern South China Sea.

Eocene Paratethys Sea transgression-regression revealed by eolian dust records from the Altun Mountains, northern China

Benhong Guo[1], Junsheng Nie[1*]
1. College of Earth and Environmental Sciences, Lanzhou University, Lanzhou, Gansu, CHINA
E-mail: jnie@lzu.edu.cn

Keywords: Environmental magnetism, Altun Mountains, Paratethys Sea, Red clay, Eocene

General circulation model simulations show that the Paratethys Sea retreat plays as important a role as uplift of the Tibetan Plateau in affecting Eurasian climates over the Neogene. The Paratethys Sea was larger and experienced dramatic transgression and regression over the Eocene, which could have had major impact on Eocene central Asian climate and environments. However, no consensus has been reached regarding its first order transgression/regression feature. Here we report a set of environmental magnetic records of the Eocene eolian dust in the Xorkol Basin within the Altun Mountains, near easternmost maximum boundary of the Eocene Paratethys Sea. We found that the hematite content and dust accumulation rate variations of this record are consistent with proposed Paratethys sea level variations over the Eocene, with higher sea level corresponding to lower hematite content. Because hematite forms in dry environments and our hematite and dust accumulation rate records have independent age model as the Paratheys sea level record, the consistent variations between them are best interpreted as their capturing the transgression/regression variations of the Paratethys Sea over the Eocene. Furthermore, the hematite record shows high frequency variations that is absent from the previously reconstructed Paratethys sea level record, which we attribute to detailed variations of the Paratethys Sea transgression/regression. This study not only demonstrates that dramatic dry-wet variations occurred in central Asia over the Eocene, it also clarifies the detailed Paratethys Sea transgression/regression history over this time interval and demonstrates its dominant control over central Asian climate.

Keywords: Middle Miocene, Astronomical time scale, Orbital cycles, Jiuxi Basin, Northeastern Tibet

High-precision chronostratigraphy is key to the study of the uplift and concomitant environment and climate change that have affected the Tibetan Plateau during the Cenozoic Era. Magnetostratigraphic studies have established the geomagnetic polarity time scale for fluvial-lacustrine sedimentary deposits around the northeastern Tibet Plateau. Complementary cyclostratigraphic studies have reconstructed an astronomical time scale to improve chronostratigraphic precision from 100-kyr to 10-kyr scale. To date, these cyclostratigraphic studies (Nie et al., 2017; Wang et al., 2018, 2019, 2021) cover most of the Miocene Epoch but a significant age gap remains from 17Ma to 14Ma, corresponding to the Miocene Climate Optimum period. To bridge this gap, we investigate the orbital cycles recorded in lacustrine mudstones from the Middle Miocene Epoch in Jiuxi Basin. We construct lithological color rank series of green-red mudstone rhythms, and establish a 3.6 Myr-long astronomical time scale from 16.0 Ma to 12.4 Ma. Time series analysis reveals multiple signals with precession index, obliquity and orbital eccentricity cycles, including dominant 405-kyr cycles associated with the precession index modulation, and 173-kyr and 1.2-Myr cycles associated with obliquity amplitude modulations. The eccentricity (405-kyr cycle) and obliquity (173-kyr cycle) metronomes are proposed to have originated from insolation forcing, and recorded as orbital metronome cycles via climate-sedimentary threshold responses. Importantly, the 1.2-Myr cycles observed in the lacustrine records are in phase with the obliquity amplitude modulations of the La2004 astronomical solution, supporting the accuracy of our chronostratigraphic framework. The reconstructed astronomical time scale reveals that the recorded astronomical cycles correlate well with those from marine and aeolian archives, suggesting that lacustrine sediments (16 Ma to12Ma) in the Jiuxi Basin provide high-precision chronostratigraphic templates for deciphering Middle Miocene global climate change and the evolution of the Asia monsoon.

Cenozoic multi-stage deformation of the Qilian Shan orogenic belt, northern Tibetan Plateau: Insights from a detrital zircon provenance study of an Oligocene-Miocene intermontane basin sedimentary succession

Wei Feng[1], Chunhui Song[1*], Qingquan Meng[1], Pengju He[1], Xiaomin Fang[2], Wenqi Chen[1], Xinghong Wang[1], Qiaoxin Wang[1]

Keywords: Detrital zircon, Provenance, Tectonic deformation, Qilian Shan orogenic belt, Subei Basin

Timing and patterns of the Cenozoic deformation of the Qilian Shan orogenic belt (QSOB) in the northern Tibetan Plateau are key to elucidating the mechanism(s) of plateau growth but remain matters of debate. The Oligocene-Miocene sediments in the Subei Basin, an intermontane basin situated at the junction of the central and southern QSOB, provide direct insight into the Cenozoic deformation of the QSOB. Here, a comprehensive provenance study based on detrital zircon geochronology, paleocurrents, conglomerate components and sedimentary facies in the Subei Basin demonstrates that this region experienced three stages of tectonic events during the Cenozoic. (1) Oligocene strata contain zircons of 200-300, 400-500, 700-1000, 1600-2000 and 2400-2700 Ma, indicating primary derivation from recycled Mesozoic sedimentary rocks in the QSOB and suggesting early Cenozoic deformation in this region. (2) One sample (21.5 Ma) yields similar age populations to those of Oligocene samples, except for the complete disappearance of 200-300 Ma zircons as a result of the widespread deformation of the QSOB. (3) Two samples (18.5-13.6 Ma) show a unimodal age cluster at 400-500 Ma, while one sample (9 Ma) contains zircon ages similar to those of Oligocene samples, indicating tectonic uplift of the southern QSOB in the middle-late Miocene, which is also recorded by the sedimentary transition from fluvial to alluvial fan. Based on these findings and those of previous studies, we suggest that the entire QSOB has undergone multistage tectonic events since the early Cenozoic due to far-field effects associated with the India-Eurasia plate collision and the continued convergence.

The provenance change of sediments in Weihe Basin (central China) and their implications for the regional river drainage evolution during early Cenozoic

Keywords: Yellow River, Cenozoic, fluvial drainage organization, provenance

The evolution of continental-scale drainage systems is profoundly affected by the paleo drainage system in the early stage of tectonic deformation. Whether there is a proto Yellow River-Weihe River system connecting the northeastern Qinghai-Tibet Plateau and the Weihe Basin in the Early Cenozoic is still controversial. The Weihe Basin is located in the middle and lower reaches of the Weihe River. It has been subsiding continuously during Cenozoic. It is a possible catchment basin of the proto Yellow River-Weihe River. This study presents the detrital zircon U-Pb ages and heavy mineral assemblages of middle Eocene to middle Miocene sediments in the Weihe Basin. Quantitative estimate of potential sources shows that sediments at middle Eocene to early Oligocene show local sources of the Weihe drainage, while sediments at the middle Miocene may receive provenance from the upper reaches of the Yellow River west of the present Weihe River. Detrital zircon U-Pb age from basin sediments at the upstream of the modern Weihe River and upper reach of the Yellow River on the NE Tibetan Plateau also showed similar river drainage connection. This indicates there may be a connection between the early drainage systems of the paleo Weihe River and the paleo Yellow River at middle Miocene. We argue that this connection is probably controlled by both regional tectonic deformation and climate changes.

E-mail: maoduyan@itpcas.ac.cn

Keywords: Potash bearing strata, chronology, Simao Basin, Khorat Basin

It has long been suggested that the potash bearing strata in the Simao and Khorat basins are possibly closely related. However, their correlations, such as formation ages, origins and metallogenic regularities are still poorly constrained. Here we present detailed detrital zircon U-Pb geochronologic-magnetostratigraphic studies of the potash-bearing strata from the Simao and Khorat basins, try to establish well age constraints on the potash bearing strata and provide a better understanding on the correlation of two potash mines. Through an integrated chronological study of radiometric dating, pollen assemblage and magnetostratigraphy on a ~932-m thick outcrop in Jiangcheng, Simao Basin, the potash bearing Mengyejing Formation is well confined to be ~112 - 63 Ma; Through a detailed bio-magnetostratigraphic study of a 596 m-deep potash bearing borehole in the southeast Sakhon Nakhon Basin in central Laos, the potash-bearing Nong Boua Formation is confined to be ~92 Ma-~ 63.5 Ma, with magnetostratigraphic age of the potash bed at ~85 Ma. Thus, the deposition of the potash bearing strata in the Simao commenced ~20 Ma earlier than those in the adjacent Khorat basins, opposite to the traditional viewpoint that the former would rather correspond to the middle and lower parts of the latter. Given the paleogeographic reconstruction of likely a pan-Simao-Khorat basin during the Cretaceous, we would believe that, beside the new suggested the Middle-Late Jurassic, ~85 Ma would be another important potential period for future potash exploration in the Simao Basin.

Keywords: Tibetan Plateau, eolian dust, silicate weathering, carbon cycle

The Cenozoic uplift of the Tibetan Plateau has exerted profound effects on Asian environment change. Here, we used accurately dated Cenozoic fluvial-lacustrine sedimentary sequences in the northeastern Tibetan Plateau to study the Cenozoic long-term evolution of the Asian environment and its potential global impact. Carbonate elemental and Sr isotopic compositions and silicate Nd isotopes in river and lake sediments were used to trace the evolution of the Asian eolian dust system, and clay mineral assemblage was applied to establish silicate weathering history in the Asian inland. The results showed that the development of Asian eolian dust and continental weathering could impact the global geological carbon cycle with two important periods at the late Oligocene-Early Miocene and ~8 Ma. Our studies suggested that the uplift of the Tibetan Plateau has promoted CO_2 consumption not only through erosion-driven high silicate weathering and organic carbon burial in the tectonically active plateau but also through intensifying the enhanced weathering Asian dust systems over central-east Asia.

Keywords: Tuotuohe Basin, anisotropy of magnetic susceptibility, Tanggula Range, tectonic uplift, Tibet

The timing and intensity of deformation of the Tanggula Range and Tuotuohe Basin are in debatable but strengthening the research on them is necessary for better understanding the geodynamic models of the Tibet and the tectonic-climate connections during the Cenozoic. Here we present the anisotropy of magnetic susceptibility (AMS) records from the foreland Tuotuohe Basin to understand the tectonic uplift history of the Tanggula Range for the interval of ~37–19.7 Ma. Rock magnetic analyses indicate that the main magnetic carrier is paramagnetic and the minor is hematite. Thus, the AMS in the Tuotuohe Section (TS) can be used to track the tectonic strain related to tectonic processes. The distribution direction of the maximum principle susceptibility (Kmax) is approximately NW–SE, which intersects at about 10°with the strike of the strata and is nearly parallel to the Tanggula thrust fault system, whereas the minimum principle susceptibility (Kmin) is oriented in the NE–SW direction with a girdle distribution. This is consistent with the sedimentary fabric imprinted by the NE–SW shortening direction, representing the earliest deformation stage. AMS data in the TS can be divided into two phases at 30 Ma. From ~37 to 30 Ma, the AMS parameters indicate an active tectonic strain and the Tanggula Range uplift induced by the India–Asia convergence, whereas between 30 and 19.7 Ma, the strain is weak compared with the earlier phase. Finally, the weak strain environment between 30 and 19.7 Ma indicated by the AMS indexes of the TS and the paleoelevation evidence from the Tuotuohe Basin all together suggest that an additional 1000–2000 m of surface uplift of the basin may have begun after 19.7 Ma.

Keywords: Relative paleointensity, Radiocarbon reservoir effect, Lacustrine sediment, Hurleg lake, Tibetan plateau

An accurate chronological framework is vital if we are to use lacustrine sediments on the Tibetan Plateau (TP) for paleoclimate reconstruction. Radiocarbon (14C) dating is the most frequently used method for dating late Quaternary lacustrine sediments. However, it is often affected by potential reservoir effects. Owing to the complex hydrogeology and sedimentology processes of the lake we study in this paper, it is difficult to correct this effect. Geomagnetic relative paleointensity (RPI) method has demonstrated the potential to construct an accurate high-resolution chronological framework for sediments in the Brunhes chron. In this study, we present an RPI record as well as environmental magnetism results from a core (HL) on the Hurleg Lake in the northeast TP. We aim to determine the reservoir effect and establish an accurate timescale for the core. The RPI record was constructed by normalizing the natural remanent magnetization after 30 mT alternating field demagnetization with saturation isothermal remanent magnetization (NRM30mT/SIRM). This exhibits a general agreement with other geomagnetic intensity stacks from the world, suggesting that global-scale patterns of geomagnetic paleointensity behavior were also documented in Hurleg Lake sediments. Our RPI record can be adequately matched to RPI references to provide three additional age tie points for the HL core. We then evaluated the reservoir effect and constructed a timescale for the core using chronological controls from both RPI and 14C dating. The estimated RE age was weak below 272 cm, was 2–3 ka at the upper 50 cm, and was inferred to have increased between depths of 272 and 50 cm. Environmental magnetism sequences from core HL display a similar paleoclimatic pattern with records from core HL05-2 and core K-2 both in the Hurleg Lake area, suggesting that correction for the radiocarbon reservoir effect is accurate and timescale of core HL is reliable. Our study further demonstrates that the method of obtaining age control points from RPI is applicable to lake sediments on the TP.

5. Xi'an Institute for Innovative Earth Environment Research, Institute of Earth Environment, Chinese Academy of Sciences, Xi'an, Shaanxi, CHINA

E-mail: changh@loess.llqg.ac.cn

Keywords: Hypsometric Integral,mountainous watershed of the Yarkant River,geomorphology,tectonic activity,lithology,climate

Pamir syntaxis is an active structural belt, bearing abundant information about geomorphic evolution, and its linking to tectonic activities, climate shifts, and other factors. Yarkant River Basin (74°28'~80°54' E, 34°50'~40°31' N) is located in the east edge of Pamir syntaxis, which is divided into southern mountain basin and northern plain basin. As a whole, the development of fault zones in the Yarkant River Basin is controlled by Karakoram fault, Karakax fault and Kashgar-Yecheng transfer system from west to East. And magmatic rocks, metamorphic rocks and sedimentary rocks are widely crop out in the mountain basin. Therefore, mountainous watershed of the Yarkant River (MYR) is an ideal place to study the geomorphic characteristics of the Pamir syntaxis. The DEM data of MYR (with a spatial resolution of 30 m×30 m, the spatial reference is WGS_1984_UTM_ZONE_43N, download from http://www.gscloud.cn) were processed by using the Hydrological Analysis Tools of ArcGIS 10.2. We extracted HI values in order to quantitatively study the geomorphic development characteristics of MYR, and discuss the relationship between structure, lithology, climate and geomorphic development. We obtained 1357 watersheds, and the correlation with the mean HI value is poor (R2=0.0981). That infers that the watershed has little impact on the mean HI value in MYR. We found the HI values of watersheds in MYR range from 0.0717 to 0.6485, with an average value of 0.4056, suggests that geomorphological development trend in mature stage. And order of mean HI value of MYR is (0.4148) in strong tectonic activity areas > that average in the whole basin (0.4056) > that in weak tectonic activity areas (0.4004), which suggests tectonic activity is a factor affecting the geomorphic development of the basin, and its effect on the geomorphic development is mainly monitor by its intensity and size. The sequence of mean HI value in areas covered by different lithology in weak tectonic activity areas in MYR is metamorphic rocks (0.491353) > ice, snow and modern glaciers (0.491351) > granite (0.4426) > marine sedimentary rocks (0.4098) > continental sedimentary rocks (0.3890) > marine interbed continental sedimentary rocks (0.3813) > Quaternary sediments (0.3598). It indicates that the difference of rock erosion resistance is an important factor affecting topography. In addition, the climate conditions in MYR mainly control the regional annual volume of surface runoff through precipitation and temperature. This influences the erosion in catchment and transportation of rivers, and affects the geomorphic development. However, the average annual precipitation has less influence on the geomorphic development of the basin than the mean annual temperature in MYR. Our study provides evidence for that the mean annual temperature is the main factor of climate affecting the geomorphic development in MYR.

E-mail: huxm@nju.edu.cn

Keywords: Tethys seaway, EECO,larger benthic foraminifera,carbon isotope, southern Tibet

Tracking the demise of the Tethys seaways is essential to understand the successive tectonic evolution after initial India-Asia continental collision as well as effects on global climate and environment. Based on the extensive study of the early Paleogene sedimentary record in Southern Tibet, we constrained the age of youngest shallow-marine carbonate strata, reconstructed the demise of the Tethys seaways and discussed its potential links with the termination of peak global warmth following the Early Eocene Climatic Optimum. The youngest shallow marine carbonate strata illustrated here is located in Tethys Himalaya and represented by the Zongpu Formation exposed in Tingri, Gamba and Yadong areas (Hu et al., 2016). The youngest shallow marine carbonate in topmost of the Zongpu Formation was deposited in inner to middle ramp environment, and was constrained to SBZ12-SBZ13 (48-49 Ma) by larger benthic foraminifera, suggesting that the demise of the shallow marine carbonate sedimentation ceased by 48-49 Ma. The bulk-rock carbon isotopic values show a gradual positive shift from -0.2‰ ~1.5‰, followed by a positive carbon isotopic plateau with values ranging from 1.5‰ ~1.7‰, and then carbon isotopic values gradually decrease and approximate the pre-excursion level at the topmost of the Zongpu Formation, which was represented the Early Eocene Climatic Optimum. The demise of the shallow marine carbonate sedimentation coincides with the termination of peak global warmth following the Early Eocene Climatic Optimum, highlighting the complexity and importance of Tethys seaway circulation in the greenhouse climate of the Eocene.

Quantifying the provenance of dune sediments in the Taklimakan desert using machine learning, multidimensional scaling and sediment source fingerprinting

Yue Li[1], Yougui Song[1*]
1. Paleoenvironment, Institute of Earth Environment, Chinese Academy of Sciences, Xi'an, Shaanxi, CHINA
E-mail: syg@ieecas.cn

Keywords: Tarim, Taklimakan, multidimensional scaling, geochemistry, provenance analysis, source fingerprinting

Study of windborne sediments in the Taklimakan Desert is of great significance in the context of global change. Much effort has gone into characterizing the Taklimakan dune sediments, but quantitative understanding of the source contributions from the surrounding mountains is lacking. Accordingly, using elemental data, we applied random forest (RF), multidimensional scaling (MDS) and sediment source fingerprinting (SSF) to examine homogenization of the dune sediments in the desert, and to quantify the contributions of key sources. The results underscored the heterogeneity of geochemistry in dune sediments in the Taklimakan Desert. On the basis of dominant wind directions and the drainage network in the Tarim Basin, as well as lithologic features in the surrounding mountains, potential sources of sand dune sediments comprised three groups: “Tianshan”, “Pamirs-Kunlun”, and “Kunlun-Altun”. Using the FingerPro and MixSIAR fingerprinting models our results suggested that the contributions of the three sources to the target dune sediments were: “Kunlun-Altun” > “Pamirs-Kunlun” > “Tianshan”. However, substantial variations in the respective contributions were observed for different target dune samples. Although both the frequentist and Bayesian models performed well in the calculations of the relative source proportions based on goodness of fit (GOF) (0.97 on average for the two models respectively), virtual mixtures (VM) tests indicated that the frequentist model returned more accurate predictions. Consequently, using the frequentist results, we propose that the “Kunlun-Altun”-derived sediment (an average of 56%) is mainly delivered to the Taklimakan Desert via fluvial transport; sediment supply from the “Pamirs-Kunlun” source (33%) depends on fluvial and wind transport and that aeolian processes are mainly responsible for distribution of the “Tianshan”-derived sediment (11%) in the desert by transporting the fine fraction. Our findings thereby highlight the interaction between fluvial and aeolian transport within the Tarim Basin.

Eocene sedimentary-tectonic evolution of the Jianchuan Basin in southeastern Tibetan Plateau

Gaozheng Liu[1,2], Huan Xu[1,2], Bihui Zhang[1,2], Hongbo Zheng[1,2*]
1. Yunnan Key Laboratory of Earth System Science, Yunnan University, Kunming 650500, Yunnan, CHINA
2. School of Earth Science, Yunnan University, Kunming 650500, Yunnan, CHINA
E-mail: zhenghb@ynu.edu.cn

Keywords: Southeastern Tibetan Plateau, Eocene, Jianchuan Basin, Sedimentary-tectonic evolution

The southeastern margin of the Tibetan Plateau plays an important role in understanding the region's basin-orogen coupling. As a representative Cenozoic basin in the southeast margin of the Tibetan Plateau, the Jianchuan Basin is of great significance for studying the tectonic evolution of the Tibetan Plateau. In this study, we carried out a comprehensive study of the Eocene strata and sedimentary systems in the Jianchuan Basin, and obtained the results as follows: (1) The Eocene stratigraphy of the Jianchuan basin can be subdivided into the early to middle Eocene Baoxiangsi Formation, the middle to late Eocene Jinsichang Formation, Jiuziyan Formation, Shuanghe Formation and the Jianchuan Formation in ascending order. (2) The Baoxiangsi Formation, as the most widely distributed and thickest strata in the basin, developed alluvial fan, desert, fluvial, delta and lacustrine sedimentary systems from the basin margin to the center. These deposits are vertically arranged into several fining upward cycles, indicating an extensional tectonic setting. (3) The Jinsichang, Jiuziyan, Shuanghe and Jianchuan formations limited present in the southeast of the basin are composed of fluvial, lacustrine, marsh and volcaniclastic deposits, which suggest a rapid decrease of depositional accommodation and shrinking of the basin. (4) The Jianchuan basin died out in the latest Eocene due to the regional uplift of the Tibetan Plateau. The Eocene sedimentary-tectonic evolution of the Jianchuan basin was consistent with the coeval tectonic uplift of the southeast margin of the Tibetan Plateau.

4. Institute of Tibetan Plateau Research, Chinese Academy of Sciences, Beijing, 100101, CHINA
E-mail: xinw@lzu.edu.cn

Keywords: Paleoclimate, Cenozoic, Paratethys, Pamir-Tian Shan orogen, Westerlies, Central Asia

The Cenozoic Asian aridification has been related to the retreat of the Paratethys, the uplift of the Tibet, and/or global cooling. However, the details of the mechanisms responsible for this paleoclimate shift remain poorly constrained. Modern observations indicate that interactions between mid-latitude westerlies and the Pamir-Tian Shan Mountains significantly impact hydroclimate patterns in central Asia today, and may have played an important role in driving Asian aridification during the Cenozoic. However, the timing when this topographic-atmospheric framework was established remains poorly constraints. Here, we present magnetostratigraphy, U-Pb geochronology, thermochronology, paleoclimatology, stable carbon and oxygen isotope geochemistry, and climate modelling techniques to the Cenozoic sedimentary sequences in the Tajik Basin. Our results show that: 1) the penultimate and ultimate retreat of the Paratethys from central Asia occurred at ~41 and ~37.4 Ma, respectively; 2) the Pamirs have experienced active deformation and accelerated exhumation during the late Oligocene to early Miocene; 3) the windward (western) side of the Pamir and Tian Shan has been characterized by a wetter climate changes, whereas, the leeward (eastern) side of the orogen has been characterized by more arid conditions since the Late Oligocene; 4) This distinct east-west hydroclimate differences, when integrated with climate modeling results, suggests that at least part of the Pamir-Tian Shan mountains had reached elevations ≥ 3 km and acted as a moisture barrier for the westerlies since ~25 Ma. We suggest that the interactions between the westerlies and the Pamir-Tian Shan orogen played an important role in driving Asian aridification since the Late Oligocene.

Sedimentary record, Provenances and Paleoclimatic Response of Holocene Sediments in the Inner Shelf of the East China Sea

Qi Li[1*], Zhenjun Zhu[1], Jian Li[1]
1. School of Ocean Sciences, China University of Geosciences, Beijing, CHINA
E-mail: liiq@cugb.edu.cn

Keywords: The inner shelf of ECS, Grain size, Clay minerals, Source areas, the East Asia Monsoon

Holocene sediments from the inner shelf of the East China Sea (ECS)with its high deposition and continuously sedimentary record which is sensitive to enviromental changeis an important recorder of regional responses to global paleoclimatic and paleoenvironmental changes. Based on the precise AMS14C dating data, We analyze grain size, clay minerals and trace elements of S05-3 sediment cores, investigating the sediment provenances of the the southern inner shelf of ECS, deducing the evolution of East Asia Monsoon in the past 4.7ka. Comparing the clay minerals in the southern inner shelf of ECS with one from different potential source areas, the results indicate that sediments in the study area came from the Yangtze River, the Yellow River and rivers from Taiwan, while every potential source area making contribution in the different periods. In the period of 4.7-4.2ka, sediments from the Yantze River and Taiwan's river is the main source of sediments. From 4.2ka to 3.2ka, sediments of study area mainly consist of the sediments of the Yanze River and the Yellow River. Since 3.2ka, sendiments from all of potential source areas had some response on the study area.

The evolution of East Asia Monsoon in the past 4.7ka can be deduced based on the grain size sensitive components, the ration of Rb/Sr and montm orillonite/kaolinite. Refering to the δ18O of GSP2 and stalagmite of Dongge Cave and the evidence of cooling of different materials in other regions, 9 high values could be recognized corresponding to the cooling events caused by the East Asia Monsoon. The core S05-3 records 4 strengthen periods of the East Asia Monsoon: weak and stable during 4.7-4.2ka BP; increased and began to fluctuate during 4.2-3.2ka; a little weak with highly fluctuation during 3.2-2.0ka BP; the East Asia Monsoon incresed slighly with fluctuations weakened.

Palynological Assemblages from the Neogene in Western Songliang Basin and their Paleoclimatic Characteristics

Zhang Yan[1], Wan Chuan biao[2*]
1. College of Earth Sciences Jilin University, Jilin University, Changchun, Jilin, CHINA
2. Geological Laboratory, Exploration and Development Research Institute of Daqing Oilfield Company Ltd, Daqing, Heilongjiang, CHINA
E-mail: cb8262011@qq.com

Keywords: western Songliao Basin, Miocene, Pliocene, Palynological, paleoclimate

The Neogene deposit in the Songliao Basin was developed in the atrophic stage. Since the Upper Cretaceous Mingshui Formation was deposited, the Songliao Basin had been uplifted and eroded. Until Oligocene, it began to be filled gradually in the Yi'an area, north part of the basin. The depositional areas extended southward and westward in the Neogene, therefore the western slope area of the Songliao basin is the most developed area of the Neogene deposit. Due to the poor preservation, most of the Neogene palynomorphs were identified only in the family level, and the assemblage characteristics were obscure.

Based on the new material of Neogene palynomorphs in recent years, two assemblages are identified separately from the Da'an Formation and the Taikang Formation. Such as: 1) Momipites coryloides—Caryapollenites simplex—Celtispollenites sp. Assemblage. This assemblage is composed of angiosperm pollen (34.4-82.76%), gymnosperm pollen (15.17-64.8%), algae (0-5.51%) and fern spores (0-3.15%). The above assemblage in the Dan'an Formation shows diverse terrestrial vegetation including aquatic algae. The angiosperms are mainly composed of temperate and north tropical tree of Juglandaceae (Caryapollenites, Juglanspollenites) and temperate tree of Ulmaceae (Ulmipollenites, Celtispollenites), Betulaceae (Alnipollenites, Carpinipites) and Fagaceae (Quercoidites, Faguspollenites). Some xerocole shrub represented by Zygophyllaceae (Nitrariadites) and some aquatic plants such as Potamogetonacidites indicated a warm and humid climate with seasonal draught. Since there are not any tropical elements such as Dicolpopollis, Florshuetzia, Lagerstroemia and Verrucatosporites found in this assemblage, the climate might be warm temperate or north subtropical. The vegetation might be mesophytic deciduous broad-leave forest mixed with some evergreen broad-leave trees and conifers. 2) Betulaceoipollenites sp.—Artemisiaepollenites minor—Carpinipites sp. Assemblage. This assemblage bearing in the Taikang Formation consist of angiosperms pollen (33.33-90.45%), gymnosperms pollen (7.87-65.96%), ferns spores (0.44-9.86%) and algae (0-9.33%). This assemblage in the Taikang Formation is similar to that in the Da'an Formation in general. However the content of Rosaceae widely distributed in the temperate and subtropical forest in north hemisphere increased obviously, and the content of Caryapollenites which distributed in the north subtropical area reduced slightly. In addition, the content of Artemisiaepollenites, a kind of xerocole herb in composite family increases obviously; and other xerocole plants such as Nitrariadites, Ephedripites and Chenopodipollis are common. This indicates that the climate of the Taikang Formation is slightly cooler and drier than that of the Da'an Formation. This climatic change is consistent with the background of Neogene climatic evolution in eastern China.

Keywords: Eocene paleoclimate, grain size, SEM, Huangyanghe section, aridification

Eocene paleoclimate changes are of great significance for understanding the evolution of paleoclimate in Asia. Paleogenic-Neogenic fluvial and lacustrine sediments of Huangyanghe section in the Wuwei Basin in the east of the Hexi Corridor of northwestern China were investigated by grain size measurement and scanning electron microscope (SEM). Additionally, the grain size distributions (GSDs) of detrital fractions were subjected to parametric end-member modeling analysis (EMMA) using the Analysize software. Results show that typical aeolian shapes such as irregular dish-shaped depressions and pockmarks were observed on the surface of quartz sand. Fine-grained components of the lacustrine sediments in the middle Huangyanghe section are aeolian and aqueous origins, and can be divided into three stages based on the vertical variations in sedimentary facies and particle components. The grain size increases along the profile, possibly indicating the shift of climate from humid to dry. Moreover, EMMA shows that the grain size was composed of three end-members (EM) . EM1 (mode particle size is 6.32 μm) may be the clay suspension components by high-altitude wind and the silt component by regional wind; EM2 (mode particle size of 112.47 μm) may be those sediments transporting into lakes by surface runoff; EM3 (mode particle size of 224.4 μm) may represent coarse-grained saltation components deposited by flood or redeposited by secondary perturbation in lake. The EM1 components were compared with loess sediments from the Chinese Loess Plateau, producing that the separated aeolian components are approximately consistent with the era of aridification of Altyn red clay (Li et al, 2018) and Xining Basin (Dupont-Nivet et al, 2007). This study provides an improtant guide for studying the process of aridification in the Hexi Corridor and the reconstruction of the paleoclimate in this area.

Shifting of Marine Phosphorus Storage Through the Cenozoic

Keywords: Phosphorus, phosphorite, phosphatization, phosphogenesis, weathering, ferromanganese crust

Previous records of phosphorus burial derived from continental margin sediments, seamount phosphorites and pelagic sediments are asynchronous. To better understand the spatiotemporal evolution of marine phosphorus burial, we investigated the timing and mode of phosphatization in two hydrogenous ferromanganese (Fe-Mn) crusts dredged from Pacific seamounts. With all archives considered together, three episodes of peak phosphogenesis can be identified: E1 during the first half of Eocene, E2 during the late Eocene and late Oligocene, and E3 during the middle Miocene and late Miocene. These episodes are asynchronous but complementary to each other: E1 was recorded in all three archives; E2 was recorded on Pacific seamounts but in neither continental margin nor pelagic sediments, and E3 was recorded in continental margin sediments and Atlantic seamounts but not on Pacific seamounts or in pelagic sediments. E1 occurred during a greenhouse climate with a large oxygen minimum zone (OMZ) and shallow carbonate compensation depth (CCD), likely linked to large-scale orogenesis. E2 occurred during rapid seafloor spreading that resulted in intense glaciation, leading to the formation of the Antarctic ice sheet and fast ocean overturning, which, together with the lowered sea level, compressed the OMZ to smaller sizes. The lowered sea level led to decreased continental margin sedimentation and pushed P into deeper OMZ water, leading to a hiatus of P burial in marginal areas but a peak phosphogenesis on seamounts. During E3, P storage location shifted from the deep Pacific to the continental margin and Atlantic seamounts due to even stronger ocean circulation in response to the cooling climate and the opening of the Drake Passage leading to the establishment of the Antarctic Circumpolar Current and enhanced upwelling in the Atlantic. The temporal shift of P storage location among oceanographic settings means that previous approaches of using P burial rate derived from a single setting to reconstruct global riverine P input flux may lead to large uncertainties. Instead, a composite P burial curve built from multiple archives is needed.

Sedimentary Records of aridity in Asia inland in the Cenozoic-A case study of the Aertashi section in Xinjiang

Bi hui Zhang[1,2], Huan Xu[1,2], Gao zheng Liu[1,2], Hong Bo Zheng[1,2*]
1. Yunnan key Laboratory of Earth System Science, Yunnan University, Kunming, Yunnan, CHINA
2. School of Earth Science Yunnan University, Yunnan University, Kunming, Yunnan, CHINA
E-mail: zhenghb@ynu.edu.cn

Keywords: Aridity in Asia inland, Sedimentary Records,Aertashi section.

In the Cenozoic, the inland areas of Asia experienced a remarkable climate change from humid to dry. However, the starting time, evolution process, and controlling factors of aridity in Asia inland are hotly debated. In this study, a detailed sedimentological study was carried out in the Aertashi section in the southwest of Tarim. The Aertashi section, 9.5 km long and 5.2 km thick, can be subdivided into Eocene Wulagen Formation, Bashibulak Formation, Oligocene Wuqia Group and Neogene Xiyu Formation in ascending order. 22 lithofacies types and 16 lithofacies associations have been identified and grouped into 6 depositional systems, including coastal depositional system, alluvial fan depositional system, fluvial depositional system (braided river, and high-energy shallow water river), delta depositional system, lacustrine depositional system (shore shallow lake, salt lake, and hyperpycnal flows) and eolian depositional system. These depositional systems show a transition from coastal depositional systems to deltaic, lacustrine, desert, lacustrine, deltaic, fluvial ,alluvial fan, lacustrine ,fluvial and alluvial fan depositional systems, indicating frequent shift of dry-wet climatic cycles flowing the regression of the Para-tethys. The occurrence of high-energy shallow fluvial deposits in the top part of the Wuqia Group represents the onset of the aridity in Asian inland. The above climatic changes suggest that the regression of the Para-tethys only resulted in a short-term effect on the aridity, instead of playing a decisive role in aridity in Asian inland. The uplift of the Tibetan Plateau and global cooling may be the main controlling factors.

Paleogeographic characteristics of key time nodes of Neogene in Qilian Shan area, northeastern margin of Tibet Plateau

Jiwei Liang[1*], Zhenwei Feng[1], Hao Zong[1], Hanlin Li[1], Xiaobin Chang[1], Meng Zheng[1]
1. School of Earth Science and Resources, Chang'an University, Xi'an City, Shaanxi Province, CHINA
E-mail: jiweil@chd.edu.cn

Keywords: Qilian Shan and its adjacent areas, Neogene, key time nodes, aridification, paleogeographic characteristics

The Neogene is a key period for the formation of the current tectonic landform on the northeast edge of the Tibet Plateau and the arid pattern in the interior of Asia. During this period, Qilian Shan and its adjacent areas have experienced different stages of tectonic uplift and climate changes. These processes have a good coupling relationship with major global tectonic climate events. The study of paleogeographic characteristics of Neogene key time nodes in the northeast margin of the Tibet Plateau is of great significance to understand the formation and development of modern environmental model and the growth of the Tibet Plateau. In this study, 22 Ma (initial aridity in inland Asia) and 8 Ma (large-scale aridity in inland Asia) are selected as the key time nodes. Based on the systematic collection of regional geological survey reports and previous research results in the study area, the Neogene stratigraphic characteristics, sedimentary evolution in the study area are analyzed by means of stratigraphy and sedimentology, combined with previous studies on tectonic background and paleoclimate, the paleogeographic pattern of the key time nodes of Neogene in the study area is restored, and the coupling history of sedimentation, structure and climate in the study areas since Neogene is comprehensively discussed. The main achievements are as follows:

The Neogene strata in the study area are divided into Qaidam, Hexi Corridor and Guide-Lanzhou-Xining stratigraphic division, and the Neogene stratigraphic sedimentary sequence of the study areas is established. According to the facies markers, the sedimentary environment in the study area can be divided into Alluvial fan, Fluvial, Delta and Lacustrine.

22 Ma is the development stage of Qilian Shan and its adjacent lacustrine basins. A large area of lacustrine deposits are developed in the study area, and aridification has occurred in some areas. At 8 Ma, the tectonic movement became strong, and the Qilian Shan and its adjacent lacustrine basin began to shrink. The sedimentary facies are mainly alluvial fan facies and fluvial facies, and the phenomenon of aridification intensified.

The Neogene sedimentary-tectonic-climate evolution history of Qilian Shan and its adjacent areas can be roughly divided into three stages: 22-20 Ma tectonic uplift period: the tectonic uplift event occurred in Qilian Shan and its adjacent areas, and the initial uplift of Qilian Shan, Altun Shan and Laji Shan in the area. And at this stage, the phenomenon of aridification has appeared in Qilian Shan and some adjacent areas. 20-13 Ma lacustrine basin expansion period: the tectonic movement of Qilian Shan and its adjacent areas was relatively calm, the basins in the area develop stably, gradually expand to their peak, and mainly develop lacustrine facies mixed with delta facies. Strong uplift period since 13-8 Ma: the tectonic movement in the study area was strong, the large lakes in the area begin to shrink, and enter the lake regression period. The sedimentary environment was dominated by alluvial fan facies and fluvial facies, and the aridification in the interior of Asia was intensified.

Biomarker evidence for late Miocene-Pliocene temperature and aridity evolution from the Maxian Mountains, NE Tibetan Plateau

Bingyan Han[1], Tingjiang Peng[1*], Zhichao Liu[1], Churu Han[1], Xiaomiao Li[1], Zhantao Feng[1]
1. College of Earth and Environmental Sciences, Lanzhou University, Lanzhou, Gansu Province, CHINA
E-mail: pengtj@lzu.edu.cn

Keywords: Biomarker, Temperature, Hydroclimate, NE Tibetan Plateau

Late Miocene-Pliocene environmental change is critical to understand the interactions among the global cooling, regional tectonic activity and Asian climate evolution. However, their relationship remains uncertain due to scarcity of quantitative temperature and hydroclimate conditions, thereby, limiting our further understanding of the Asian climate evolution. Here we quantitatively reconstruct the late Miocene-Pliocene (~6.2-3.6 Ma) temperature and hydroclimate history via based on the Xiaoshuizi red clay GDGTs evidence from the Maxian Mountains, NE Tibetan Plateau. Our results indicate that the mean annual temperature (MAAT) can be divided into two stages: the MAAT decreases from 20.6 ℃ to 13.5 ℃ during the interval of 6.2-4.0 Ma, subsequently replaced by the increased trend since 4.0 Ma. Meanwhile, the relative low Ri/b values reveal that the hydroclimate condition is generally humid and stable during 6.2-4.0 Ma. Then the obvious enhancement of Ri/b proxy demonstrates the onset of climate aridification since 4.0 Ma. So our integrated results reveal that the Xiaoshuizi climate turn into warm-arid condition during 4-3.6 Ma, which is contradictory with the global cooling and regional humid hydroclimate in the eastern Chinese Loess Plateau and Qaidam basin. We ascribe this abnormal warm-arid event during 4-3.6 Ma to the rain shadow effect of growing topography in the Maxian Mountains caused by the tectonic uplift of NE Tibetan Plateau. Our results not only emphasize the importance of quantitative terrestrial climate record during the interval of late Miocene-Pliocene, but also highlight the necessity of combining tectonic and geomorphological background for illustrating the paleoclimate evolution in NE Tibetan Plateau.

A case study using monomineral chemical composition to reconstruct Paleogene weathering history in a thick sedimentary sequence with frequently changing facies and lithologies in the northern Qaidam Basin

2. Key Laboratory of Continental Collision and Plateau Uplift, Institute of Tibetan Plateau Research, Chinese Academy of Sciences, Beijing, CHINA
E-mail: yechch1991@shnu.edu.cn

Keywords: Chemical weathering, Illite chemistry index, Chlorite, Global cooling, Qaidam Basin

An integrated multiproxy dataset involving both mineralogical and geochemical investigations of the northern Tibetan Plateau helps in assessing regional weathering processes linked to topographic evolution and environmental change. However, changes in landscape and drainage reorganizations caused by active tectonics and remarkable climate change during the Cenozoic characterize the basins in and around the Tibetan Plateau by frequent facies changes and coarse lithologies, which largely limit the reliability of bulk geochemical indicators for revealing the regional weathering history. To minimize the influence of these factors (e.g., grain size and sortings) in long sedimentary sequences, a better approach is to use the variation in the chemical composition of a certain mineral in response to weathering (e.g., Rieu et al., 2007).

In this study, we present some monomineral indices to reconstruct Paleogene (54-26 Ma) weathering history in a sedimentary sequence with frequent interbedded conglomerates and facies changes in the Qaidam Basin, northern Tibetan Plateau. The studied sequence contains the Lulehe, Xiaganchaigou, and Shangganchaigou Formations. The Lulehe Formation is coarse-grained and generally consists of conglomerates, sandy conglomerates, sandstones, and purple mudstones, indicating alluvial fan–fan delta facies. The Xiaganchaigou and Shangganchaigou Formations contain lacustrine sediments, the former contains brownish–red and purple mudstones and interbedded sandstone while the latter contains brown-yellow and brown mudstone with gray sandstone. The monomineral indices, illite chemistry index (e.g., Wan et al., 2010), chlorite chemistry index (e.g., Ye et al., 2018), and chlorite Mg/Al ratios of hydrochloric acid (HCl) leachates (e.g., Li et al., 2008) collectively present a continuously decreasing trend. The intense weathering process occurred in the early Eocene (54-49.5 Ma), followed by a long-term decrease from the middle to late Eocene (~49.5-34 Ma), and finally a weakened stage at ~34-26 Ma. The weakening weathering process during the Paleogene is mainly attributed to the decreasing global temperature and decline in precipitation caused by global cooling (Fang et al., 2019). Our study further suggests that monomineral chemical variation serves as an efficient proxy in regional chemical weathering reconstruction, even in thick sedimentary sequences with frequently changing facies and lithologies.

Keywords: River reorganization, palynology, tectonics, late Miocene, Southeast Asia

Palynology is a sensitive proxy for the reconstruction of paleovegetation and paleoclimate changes. The comprehensive palynological comparison at multiple points in a large space is very important for further clarifying the vegetation-climate macro pattern and basic evolutionary trend, and can provide an important reference for understanding the regional and even global climate change background of plateau uplift and its climate effects.

River reorganization occurs frequently in Southeast Asia, due to the rugged topography and heavy precipitation. However, accurately constraining the age of past reorganization events is difficult. Here we apply a novel palynological approach to evaluate how rivers evolved during the late Cenozoic (~12–0 Ma), based on three deep-sea drilling cores from the South China Sea (SCS): International Ocean Discovery Program (IODP) Sites U1499 in the north and U1433 in the central SCS (Miao et al., 2017), and Ocean Drilling Program (ODP) Site 1143 in the south (Luo and Sun, 2007). A rapid, dramatic runoff reorganization event at 8.5 Ma is identified in the cores by a sharp decrease in terrestrial pollen and freshwater algae input in the northern SCS, coeval with a contrasting increase in the South SCS, which is supported by contemporaneous changes in neodymium isotopes composition (ε_{Nd}) (Clift et al., 2002; Liu et al., 2017; Liu et al., 2007), and sediment rates and budgets across the SCS (Clift, 2006). At the same time, no similar changes are observed in palynological records in the inland or Sea of Japan. We postulate that the reorganization of rivers was the main dynamic driver of rapid changes in palynomorph assemblages, which took place against a background of tectonic and climatic changes.

E-mail: daisher@lzu.edu.cn

Keywords: Northeastern Tibetan Plateau, Jiuxi Basin, Oligocene, magnetostratigraphy, Baiyanghe Formation

Cenozoic sediments of internal and external basins in the Tibetan Plateau sensitively archive the spatial-temporal patterns of the deformation and surface uplift processes during the India-Asia collision. The Jiuxi Basin, located at the northeastern margin of the plateau, is the northernmost area responding to plate collision effect and preserves crucial information on the extension processes of the NE Tibetan Plateau. The Oligocene Baiyanghe Formation are widely distributed in Hexi Corridor and Qilian Shan areas. These strata generally rests unconformably on the underlying Huoshaogou Formation in the northern Jiuxi Basin and southern Jiudong Basin, and directly unconformities over the Mesozoic and older strata in the other areas, and is overlain by the Shulehe Formation in a conformity. Existing work on the tectono-sedimentology and tectonic evolution of the Jiuxi Basin and Qilian Shan regions has severe limitations because of the lack of systematic and precise chronology control. The controversial ages of Baiyanghe Formation have been reported by magnetostratigraphy at Ciyaokou section (30.9-23.8 Ma) and Sunan section (27.8-24.6 Ma) in southern Jiudong Basin, and Caogou section (>24.2-17 Ma) in northern Jiuxi Basin. In this study, we focus on the Baiyanghe section in the southern margin of the Jiuxi Basin and the section is the type section for the Baiyanghe Formation without dating works, which is dominated by a set of approximately 430 m thick fluvial and lacustrine deposits with thick gypsum. We carried out the high-resolution magnetostratigraphy analysis on the Baiyanghe Formation with an aim to establish the precise chronology framework. We identified 13 normal magnetic chrons (marked as N1-N13) and 12 reverse magnetic chrons (marked as R1-R12) from 257 out of 328 paleomagnetic samples in the Baiyanghe section, with each magnetozone defined by two or more specimens. According to the sedimentary facies, sedimentary rate, gypsum marker bed and age limitation of underlying Huoshaogou Formation and overlying Shulehe Formation, we constrained the new age of Baiyanghe Formation between approximately 22.6-29.5 Ma. This age determination is in good agreement with those obtained from the Ciyaokou section and Sunan section, but older than that in the Caogou section. The results are of great significance for understanding the Oligocene tectonic evolution of the northeastern Tibetan Plateau.

Early-middle Miocene oceanic red beds: Evidence of CCD evolution and deep basin subsidence in the South China Sea

Jirawat Deemuenwai[1], Zhifei Liu[1*], Wei Shu[1], Xuan Lyu[1], Baoqi Huang[2]
1. State Key Laboratory of Marine Geology, Tongji University, Shanghai, CHINA
2. Department of Geology, Peking University, Beijing, CHINA
E-mail: lzhifei@tongji.edu.cn

Keywords: Oceanic red beds, Grain size, Carbonate compensation depth (CCD), South China Sea, International Ocean Discovery Program (IODP)

International Ocean Discovery Program (IODP) Expedition 367 recovered early-middle Miocene oceanic red beds at Site U1500 in the South China Sea. The red beds stand out compared to other parts of the sedimentary sequence at this site and similar age interval deposits previously discovered in the South China Sea. The 77.15 m thick red beds (22.8-11.8 Ma) at Site U1500 were subjected to grain size and carbonate content analyses to understand deepwater sedimentary environment throughout the early-middle Miocene.

The mean grain size varies from 1.2 to 3.6 μm over the red beds interval, while the carbonate content ranges from 0 to 63.7 %. There are four lithological units identified: (1) 22.8-18.5 Ma, reddish chalk (~20.0-63.7% carbonate, average 31.3%) with relatively fine mean grain size (2.0 μm); (2) 18.5-16.0 Ma, reddish-brown calcareous-rich claystone (0.8-29.9% carbonate, average 16.2%) with very fine mean grain size (1.6 μm); (3) 16.0-13.0 Ma, dark-reddish-brown claystone (almost 0% carbonate) with fine mean grain size (1.8 μm); (4) 13.0-11.8 Ma, dark-reddish-brown silty-claystone (almost 0% carbonate) with relatively coarse mean grain size (2.2 μm). The sedimentation rate varies from 0.7 cm/ka for chalk, 0.5 cm/ka for calcareous-rich claystone, 0.4 cm/ka for claystone, and 1.9 cm/ka for silty-claystone. Because of the very fine mean grain size together with the low sedimentation rate, the early-middle Miocene oceanic red beds are thought to have formed in a pelagic environment in the South China Sea.

Carbonate mass accumulation rate is utilized to reconstruct the CCD (carbonate compensation depth) level change. The carbonate mass accumulation rates in reddish chalk (22.8-18.5 Ma) are larger than 0.5 $g/cm^2/ka$, indicating the red beds evolved above the CCD level. The decreased mass accumulation rates (0.1-0.5 $g/cm^2/ka$) in reddish-brown calcareous-rich claystone might be attributed to CCD shoaling between 18.5 and 16 Ma. After 16 Ma, the carbonate mass accumulation rates significantly dropped close to zero, implying that the red beds developed below the CCD level. Considering the regional tectonic history, we suggest the drop of carbonate accumulation rate in this interval occurred from the rapid subsidence of the deep basin following the cessation of the South China Sea spreading. This study provides insights into the deepwater sedimentary properties of pelagic red beds developed in the South China Sea, significantly related to the CCD level change and tectonic evolution.

E-mail: fangxm@itpcas.ac.cn

Keywords: Lunpola Basin, tuff and magnetostratigraphy, central Tibetan Plateau, late Oligocene-Miocene rapid uplift

Understanding the Tibetan Plateau (TP) topographic history is essential to determining its building mechanisms and its role in driving regional climate, environments and biodiversity. The Lunpola Basin (central-southern Tibet) is the key place to constrain the Tibet building because it deposits the most complete Cenozoic stratigraphy sequence in the central TP and bears many layers of tuffs, abundant fossil plants and mammals and paleosols. It is also the first place that stable isotope based paleoaltimetry was applied to, which suggested that similar to present elevation was attained in the central TP at least 35 Ma ago, implying a much earlier uplift of the TP than before. This view was soon widely accepted by international society but was challenged by recent discoveries of low elevations tropical fossil apparently deposited at 25.5 Ma. However, we use magnetostratigraphic and radiochronologic dating to robustly revise the chronology of regional elevation estimates both from the stable isotope and fossils in the Lunpola Basin. The results indicate that both ages estimated for the stable and fossil based elevations are wrong with the former from ~40 Ma revising to ~26-21 Ma and the later from ~26 Ma to ~40 Ma. Thus this revised chronology demonstrates that central Tibet was generally low (<2.3 km) since at least ~40 Ma and became high (3.5-4.5 km) since at least ~26 Ma. This supports the Eocene existence of a lowland between the Gangdese Shan and Tanggula Shan until their early Miocene uplift. This later uplift of central-southern Tibet has important implications for Tibetan Plateau (TP) growth mechanisms and agrees well with recently updated studies of the TP-imposed impacts on Asian atmospheric circulations, surface processes and biotic evolution and diversification differentiation.

Multistage tectonic activity of the eastern Qilian Shan during the late Eocene to middle Miocene: insight from Wuwei Basin stratigraphy and provenance

Shuang Dai[1*], Xiaojun Ma[1], Xin Fan[1], Yilin Wang[1]
1. School of Earth Sciences, Lanzhou University & Key Laboratory of Strategic Mineral Resources of The Upper Yellow River, MNR, Lanzhou University, Lanzhou, Gansu Province, CHINA
E-mail: daisher@lzu.edu.cn

Keywords: Wuwei Basin, Qilian Shan, Cenozoic stratigraphy, provenance, tectonic activity

The northeastern Tibetan Plateau is a key area to understand the Cenozoic uplift and environmental effects of the plateau, in which developed a series of sedimentary basins. The study of tectonic evolution of these basins is an important way to recover the uplift process of the plateau in the past. In recent years, the Cenozoic stratigraphy of Hexi Corridor basin has been focused on Jiuquan Basin in the west, but less attention has been paid to Wuwei Basin in the east. The Cenozoic strata of Wuwei Basin are mainly distributed in the southern margin of the basin, including the Paleogene Xiliugou Formation and Huangyanghe Formation, and Neogene Xianshuihe Formation. In this study, four outcropping profiles in the southern margin of Wuwei Basin were investigated in detail, and the relationship between basin evolution and the faults in the northern margin of Qilian Shan and the uplift of the northern Tibetan Plateau was discussed by analyzing the heavy minerals, palaeoflow and composition of gravels. The results show that the Xiliugou Formation mainly consists of orange sandstone and fine sandstone interbedded with maroon mudstone. The lithology of Huangyanghe Formation is mainly composed of giant thick bedded orange-red conglomerate and sandstone, interbedded with orange-yellow sandstone and maroon-red mudstone. The Xianshuihe Formation is mainly brownish red to brownish yellow sandstone, brown red mudstone, intercalated with gray white sandstone. Alluvial fan, fluvial and lacustrine facies are developed in this area. The analysis of heavy minerals, palaeoflow and composition of gravels shows that the sediments of Xiliugou and Huangyanghe Formations in the southwestern Wuwei Basin are mainly derived from the Proterozoic and Early Paleozoic strata in the south of Basin. The Xianshuihe Formation strata are characterized by multiple provenances. According to the information of stratigraphy and provenance changes in the southern Wuwei Basin, multi-stage tectonic activities occurred in the eastern Qilian Shan during the late Eocene to middle Miocene. In the late Eocene, the Wuwei Basin, Lanzhou basin to the east and Xining Basin to the south became active, indicating the initial uplift of the eastern segment of Qilian Shan. The deposition of Huangyanghe Formation indicates that the eastern Qilian Shan was active again, and this event is synchronous with the western Qilian. The absence of strata in the early Oligocene may be a response to the large-scale uplift of the plateau. Subsequently, the deposition of the southern part of the basin ended after the Xianshuihe Formation, again suggesting the uplift of the Qilian Shan in the south.

Orbital- and millennial-scale Asian winter monsoon variability across the Pliocene–Pleistocene transition

Hong Ao[1*]

1. State Key Laboratory of Loess and Quaternary Geology, Institute of Earth Environment, Chinese Academy of Sciences, Xi'an, China, Xi'an, Shaanxi, CHINA

E-mail: aohong@ieecas.cn

Keywords: Pliocene–Pleistocene transition,Asian winter monsoon,orbital-and millennial-scale periodicities

Onset of major Northern Hemisphere glaciation (NHG) across the Pliocene–Pleistocene transition (PPT) is the most profound late Cenozoic climate shift. It led to the rise of modern climates and ecosystems on Earth and hominin lineage in Africa. Here, we report on a centennial-resolution grain size record from the Chinese Loess Plateau that enables to assess orbital- and millennial-scale Asian winter monsoon (AWM) evolution between 3.6 and 1.9 million years ago in detail. We find a persistent coexistence of distinct ~40- and ~100-thousand-year cycles in the long-term AWM record in response to ice sheet forcing. Major NHG did not shift orbital-scale AWM periodicities but instead drove long-term AWM strengthening across the PPT. Our results suggest that the orbital-scale AWM variability was superimposed by sustained millennial-scale oscillations, during both the warm (higher CO_2) late Pliocene and cold (lower CO_2) early Pleistocene—a broad range of climate-cyrospohere boundary conditions.

Early Cenozoic Onset of Tectonic Deformation and Topographic Growth of the Qilian Shan in the Northeastern Tibetan Plateau Derived from Low-temperature Thermochronology

Pengju He[1*], Chunhui Song[1], Yadong Wang[2], Qingquan Meng[1]
1. School of Earth Sciences, Lanzhou University, Lanzhou, Gansu, CHINA
2. Northwest Institute of Eco-Environment and Resources, Chinese Academy of Sciences, Lanzhou, Gansu, CHINA
E-mail: hepj@lzu.edu.cn

Keywords: Tibetan Plateau, Qilian Shan, Thermochronology, Exhumation, Cenozoic

The evolution of topography throughout the Tibetan Plateau remains debated for the causality with plate collision, plateau growth, intracontinental deformation, and climate effects. The Qilian Shan serves as a topographic boundary on the northeastern Tibetan Plateau, and the processes of its upper crustal deformation and related formation of its high topography are crucial for understanding the progress of plateau growth and its geodynamic mechanisms. However, when deformation and relief growth began and how it has developed in this pivotal region remain controversial. To assess the histories of tectonic deformation and topographic development in the Qilian Shan, we applying apatite fission-track (AFT) and (U-Th)/He (AHe) thermochronology to rocks in the Qilian Shan and adjoining basins.

Detrital AFT analysis was performed on Cenozoic sediments in the northern Qaidam Basin and Subei Basin, where detritus is sourced from the Qilian Shan. Age components of buried but unannealed detrital AFT samples in the northern Qaidam Basin reveal two static peaks (i.e., peak ages that are consistent upsection) at ca. 60–50 Ma and ca. 40–36 Ma and a moving peak (i.e., peak ages that are younger upsection) with increased lag time during ca. 30–8 Ma. Samples with unannealed detrital AFT ages in the Subei Basin reveal a dominant ~60–50 Ma age population. These detrital AFT ages integrated with the analysis of sedimentary provenance indicate that Cenozoic exhumation began in the Qilian Shan in the late Paleocene-early Eocene.

In-situ bedrock AFT and AHe analysis was performed on two primary thrust belts (Qaidam Shan and Danghenan Shan) in the southern Qilian Shan. The age-elevation relationships of the two transects both show enhanced exhumation in the late Paleocene-early Eocene, followed by rapid exhumation in the middle-late Miocene. Thermal modeling of the Danghenan Shan transect shows an episode of rapid cooling in the late Paleocene-early Eocene. Thermal modeling of the Qaidam Shan transect shows slightly accelerated cooling in the early Eocene and rapid cooling since the middle Miocene. The results indicate two pulses of enhanced thrust of major thrust belts in the southern Qilian Shan in the late Paleocene-early Eocene and middle-late Miocene.

An integration of new detrital and in-situ thermochronologic data and published data indicates that terranes in the Qilian Shan experienced prominent tectonism-driven exhumation in the late Paleocene-early Eocene, which imply an early Cenozoic onset of tectonic deformation and topographic growth in the Qilian Shan. These results suggest that the northeastern Tibetan Plateau responded to the India-Asia collision almost instantaneously and the northeastern boundary of the Tibetan Plateau was roughly established since the early Cenozoic.

Late Paleogene Climate Change and Its Driving Mechanism in the Ningnan Basin, Northeastern Tibetan Plateau

Wu Xiaoli[1*], Li Rongxi[1]
1. School of Earth Science and Resources, Chang'an University, Xi'an, Shaanxi Province, CHINA
E-mail: wxlgeo@163.com

Keywords: Climatic change, Sali,ne lacustrine basin, Tibetan plateau uplift, Late Paleogene, Ningnan Basin

The sedimentary record of the saline lacustrine Qingshuiying Formation is the perfect object for the study of the late Paleogene climate change and its driving mechanism in the Ningnan Basin, northeastern Tibetan Plateau, which is taken as the research target in this study. Through field geological investigation, sample collection, and the tests of the major elements and strontium isotopes in gypsum, the chemical weathering and paleoclimate changes recorded in sedimentary strata are analyzed. Based on the comparison with the global climate change and the uplifting process of the Tibetan Plateau, the driving mechanism of the late Paleogene climate change in the Ningnan Basin, northeastern Tibetan Plateau is studied. The results show that the indices of Al_2O_3/SiO_2, Al_2O_3/Ti_2O, K_2O/Na_2O, and $^{87}Sr/^{86}Sr$ well reflect the late Paleogene climate change. During the 5 periods of 38-36 Ma, 34.5-33 Ma, 32-31 Ma, 30-27 Ma, and 26-23 Ma, the chemical weathering decreased, and the climate was arid, while during the 4 periods of 36-34.5 Ma, 33-32 Ma, 31-30 Ma, and 27-26 Ma, the chemical weathering increased, and the climate was humid. During the late Paleogene 38-26 Ma, the climate change in the study area was mainly driven by the global climate change. While during 26-23 Ma, the climate change in the Basin was affected by the Tibetan Plateau uplift.

Late Miocene sedimentary chronology and paleoclimate significance of the Jianzha Basin in the northeastern margin of the Tibetan Plateau

Chaofeng Fu[1*], Yangfeng Yang[1], Xiaoke Qiang[2]
1. School of the Earth Sciences and Resources, Chang'an University, Xi'an City, Shaanxi, CHINA
2. State Key Laboratory of Loess and Quaternary Geology, Institute of Earth and Environment, CAS, Xi'an City, Shaanxi, CHINA
E-mail: fucf@chd.edu.cn

Keywords: Northeast of Tibet Plateau, Jianzha basin, Late Miocene, Chronology, Plaeoclimate change

Jianzha Basin is located in the northeastern part of the Tibetan Plateau and contains a thick sequence of Cenozoic sediments which are crucial for investigating the growth of the Tibetan Plateau and the record of the evolution of the Asian inland arid environment. Magnetostratigraphic results show that Late Cenozoic sedimentary sequence from the Jianzha Basin has recorded a continuous geomagnetic polarity sequence from C5r.3r to C3r, the section spans the interval from 11.8-5.8 Ma in the Late Miocene. Based on the high precision paleomagnetic dating framework and frequency susceptibility index (cfd), the cycle stratigraphy of Jianzha Basin was studied, whose results show the cfd of the deposit sediment displays a significant periodic change at around 7.2 Ma, which the record reveals that the East Asian summer monsoon (EASM) is dominated by 41 ka obliquity period before ~7.2 Maand controlled by 100 ka short eccentricity period after 7.2 Ma. Spectral analysis of oxygen isotope records of benthic foraminifera from the South China Sea shows strong short eccentricity period and weak obliquity period between ~5.8 and ~7.2 Ma, and strong obliquity period and weak short eccentricity period between ~7.2 and ~11.8 Ma, which is consistent with the spectral analysis of frequency susceptibility (cfd) from the Jianzha Basin. In addition, it is found that the EASM climatic transition from 100,000-year orbital period to 40,000-year obliquity period occurred around 7.2 Ma, which is similar to the climatic transition around 0.9 Ma in the Middle Pleistocene. Therefore, the climate change result will provide a new similar model for predicting future monsoon climate changes. This study was supported by projects funded by the Second Tibetan Plateau Scientific Expedition (STEP) program (2019QZKK0704); and supported by the National Natural Science Foundation of China (Grants 41772167); and supported by the Central University Research Foundation, Chang’an University (Grants 300102272901).

Carbon, oxygen and strontium isotopic and elemental characteristics of the Cambrian Longwangmiao Formation in South China: Paleoenvironmental significance and implications for carbon isotope excursions

Pengyuan Zhang[1*], Yongli Wang[1]
1. Key Laboratory of Cenozoic Geology and Environment, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, CHINA
E-mail: zhangqlnice@163.com

Keywords: Isotope geochemistry, Paleoenvironment, Redlichiid–Olenellid Extinction Carbon Isotope Excursion, Cambrian Toyonian, South China

The biosphere experienced episodic perturbations during the Neoproterozoic–early Cambrian, accompanied by major fluctuations of the carbon cycle. However, compared to the Ediacaran–early Cambrian, geochemical records of the Cambrian Toyonian Stage (Longwangmiao), which contains the significant Redlichiid–Olenellid Extinction Carbon Isotope Excursion (ROECE), are scarce. To address this data gap, we conducted measurements of carbon, oxygen and strontium isotopes and element contents of a continuous series of carbonate samples from the Longwangmiao Formation of Well HS2, located in the central Sichuan Basin of South China. Our specific aims were to reconstruct the paleoenvironment and to determine the origin of the ROECE. Strict sample screening was used to ensure that the isotopes and elements were not affected by diagenesis. The $^{87}Sr/^{86}Sr$ values of Well HS2, and for sites elsewhere, show that sea level gradually decreased during the Cambrian Toyonian Stage. Additionally, the pronounced negative $\delta^{13}C$ excursion in the late Toyonian is globally associated with the ROECE, which is widely thought to have resulted from extinctions caused by a transgression. However, a transgression is not shown in the $^{87}Sr/^{86}Sr$ profile of Well HS2, which we attribute to local karst formation and erosion caused by frequent regional regressions. The interrelationships among several paleoenvironmental proxies show that continental weathering was climatically controlled, which affected the supply of terrigenous detritus, and that the carbonate platform was semi–restricted. Furthermore, profiles of paleoenvironmental proxies indicate that the environment was warm and humid, favoring high biological productivity and diversity during Interval I (early Toyonian), and that it gradually became colder and drier during Interval II (middle Toyonian). We suggest that by the time of Interval III (late Toyonian), the adverse effects of a cold and arid environment were superimposed on the transgression, triggering the ROECE. Our results provide a reference and possible interpretation for other carbon isotope excursion events.

Another look at Cenozoic source-to-sink history of the Qaidam Basin, NE Tibet: Insights from solute Sr isotope

Yudong Liu[1], Yibo Yang[1*], Rongsheng Yang[1], Albert Galy[2], Zhangdong Jin[3], Xiaomin Fang[1], Bowen Song[4]
1. Chinese Academy of Sciences, Institute of Tibetan Plateau Research , Beijing, CHINA
2. Centre de Recherches Pétrographiques et Géochimiques, CNRS-Université de Lorraine, Nancy, FRANCE
3. State Key Laboratory of Loess and Quaternary Geology, Institute of Earth Environment, Chinese Academy of Sciences, Xi'an, Shaanxi, CHINA
4. Institute of Geological Survey, China University of Geosciences, Wuhan, Hubei, CHINA
E-mail: yangyibo@itpcas.ac.cn

Keywords: Qaidam Basin, Tibetan Plateau, Cenozoic, Sr isotope

The Qaidam Basin on the northeastern Tibetan Plateau comprises vital information about the Cenozoic history of the northern Tibet uplift and Asian climate change due to its exceptionally long and continuous terrestrial sediment records. However, the paleolake evolution in the basin and the associated source-to-sink history remain highly debated. We provide a novel perspective of solute Sr isotopes to reconstruct source-to-sink history in the Qaidam Basin, which is notably different from a particulate perspective constrained from traditional methods, e.g., zircon U-Pb ages, paleocurrent, Nd isotopes. The Sr isotopes of basin water are a mixture of the input from various sources. Based on the remarkable contrasts of the solute Sr isotope regime with a high 87Sr/86Sr source from the Qilian Shan to the north and a low 87Sr/86Sr source dominantly from the southern sources, we reconstructed basin paleo-water solute Sr using bulk carbonate from two parallel outcrops in the northern basin. Our results show that solute Sr isotopes of basin paleowaters fluctuate between 0.711 and 0.715 since ~54 Ma, during which most of the interval remains constant at ~0.713, which is similar to the 87Sr/86Sr ratios of modern lakes supplied solely by the Qilian Shan. However, two low 87Sr/86Sr ratio periods at ~44.5-~32 Ma and after ~16 Ma suggest the existence of two paleomegalakes with hydrological connections between the northern and southern sources. The two low 87Sr/86Sr paleomegalakes followed a south-eastward migration of the basin depocenter due to tectonic uplift, which implies a more complex solute versus particulate provenance history in a large basin than expected.

Late Cenozoic deposition of the Nihewan basin in the North China

Zhenqing Chi[1*]
1. Chinese Academy of Geological Sciences, Institute of Geology, Beijing, CHINA
E-mail: zqchi@263.net

Keywords: Nihewan basin, Late Cenozoic stratra , sedimentary environments, paleogeography, North China Craton

The Nihewan basin is an important part of the Neogene NE-SW-trending Weihe-Shanxi graben system between the Taihangshan and Lüliangshan uplifts around the Ordos block in the west and the Paleogene North China plain in the east. It hosts late Cenozoic nonmarine sediments in a highly subsiding basin formed due to the Oligocene-Pleistocene rifting. The main basin-fills are the Pliocene Yuxian Formation, early Pleistocene Nihewan Formation, middle Pleistocene Xiaodukou Formation, and late Pleistocene Haojiatai Formation. The Yuxian Formation unconformably overlies Pre-Cretaceous strata and is dominated by erythrinus silty clay with a variable thickness of ca. 9-100 m from the margin to the interior of basin, containing hipparion fauna fossils. The Nihewan Formation with a thickness of ca. 70-90 m is subdivided into three units. The lower unit comprises gravel-bearing medium- to coarse-grained sand with planar cross-beddings at the lower part, grading upward into brown clay with interlayers of gray-yellow silt. The middle unit consists of thick interlayers of green clay silt and yellow silty clay with abundant calcareous and fine-grained sand layers, characterized by parallel laminations. The upper unit consists of interlayers of gray-yellow, yellow-brown and yellow-green silty clay and clay silt with fine-grained sand and gravel-bearing coarse-grained sand lenses. The Xiaodukou Formation has a thickness of <40 m and consists of grey-yellow coarse-grained sands with abundant fine gravels and fossils of mammals and mollusks at the lower part, which grade upwards into yellow-brown silty sands and interbedded clay silty sand with parallel laminations. The <40-m-thick Haojiatai Formation is characterized by dark-gray, gray-green and gray interlayers of silt and clay with gravels at the bottom, grading upward into gray-yellow, yellow-green, gray-green, and gray clay silt with brown clay silt. Lenticular gypsum occurs in the upper and lower portion of the Haojiatai Formation. In addition, the middle and upper units of the Niehewan Formation is thickening towards of the interior of basin, whereas the Xiaodukou and Haojiatai formations are thinning. Paleocurrent data demonstrate a southward origin for the Nihewan, Xiaodukou, and Haojiatai formations perpendicular to the trend of the basin, but they show a northward and southward origin along the trend of basin respectively. Detrital zircon U-Pb age data demonstrate that they are dominated by detritus derived from a mixed source of early Cretaceous, early Permian and Paleoproterozoic in age. These results indicate that Pleistocene sediments deposited in a fluvial environment initially that subsequently evolved into a lacustrine environment upwards with a southwestward-facing paleogeography, and the Nihewan basin and associated graben system developed during the Pleistocene and were dominated by sediments from uplifted Pre-Cretaceous rocks in North China Craton.

Clay mineralogy of the Middle Miocene to Early Pliocene sediments in Xunhua Basin, Northeastern Tibetan Plateau and its paleoclimatic implications

Fei Hu[1], Ke-xin Zhang[2*], Wei Huang[1]
1. Basic Geological Survey Division, Guangdong Geologic Survey Institute, Guangzhou, Guangdong, CHINA
2. Institute of Geological Survey, China University of Geosciences(Wuhan), Wuhan, Hubei, CHINA
E-mail: kx_zhang@cug.edu.cn

Keywords: the Middle Miocene-Early Pliocene, clay minerals, Xunhua Basin, aridification, global cooling, uplift of Tibetan Plateau

To reveal palaeoclimatic evolution and aridification events of the Middle Miocene to Early Pliocene in the northeast margin of Tibetan plateau, micro-morphology, relative content and VCh+I/VKao+S value of clay minerals in Xunhua Basin were investigated using scanning electron microscopy SEM and X-ray diffraction XRD. Clay mineralogy shows that the Middle Miocene and Early Miocene sediments are composed of illite, smectite, chlorite and kaolinite. All the clay minerals were detrital formation and less influenced by diagenesis. And the source area is close to the study area, which belongs to near-source transport. The relative content and Ch+I/Kao+S value of clay minerals in the Xunhua Basin can effectively reflect paleoclimate change in the study area. Combined with pollen record, sedimentary rates, geochemistry ratio of sediments in Xunhua Basin and δ18O isotope record from the global deep-sea, the palaeoclimate evolution in Xunhua Basin can be divided into 3 stages as follows: I, relative cold and dry period 14.6~12.5Ma; II, relative warm and humid period 12.5~8Ma; III, cold and dry period 16.0~13.2 Ma. Comparing with the regional geological records, we consider that the drying environment in the Xunhua Basin was controlled by global cooling and uplift of Tibetan Plateau, respectively. The relative wetting and humid stage may be influenced by the orographic interception around the Xunhua Basin.

Luminescence dating of loess deposits from the eastern margin of the Tibetan Plateau

Shengli Yang[1*]
1. Key Laboratory of Western China's Environmental Systems (Ministry of Education), Lanzhou University, Lanzhou, Gansu, CHINA
E-mail: shlyang@lzu.edu.cn

Keywords: OSL dating, loess, mass accumulation rate, Tibetan Plateau

Extensive loess deposits exist in the eastern margin of the Tibetan Plateau (ETP), which are one of the most important terrestrial archives regarding past dust activity and environmental changes in East Asia. However, they remain insufficiently known and poorly understood. Herein, we conducted detailed optically stimulated luminescence (OSL) analysis on two typical loess sequences. Our results show that: 1) The quartz OSL signals of the loess at the eastern Tibetan Plateau are dominated by the fast component with good performance for De measurements by single aliquot regenerative dose protocol. 2) The bottom ages of the studied loess sequences are ~60 ka, indicating an important dust event in the ETP. 3)The mass accumulation rate (MAR) significantly varied during the last glacial period. The highest MAR occurred in Marine Isotope Stage (MIS) 2, and the MIS 3 MARs were relatively low and stable. The discrepancy in the MARs of the ETP loess since the last glacial period compared with that of the Chinese Loess Plateau may imply different dust deposition processes in the Tibetan Plateau.

Provenances and Paleoclimatic Response of Holocene Sediments in the Inner Shelf of the East China Sea: Evidence from clay minerals and foraminifera species.

Qi Li[1*], Zhenjun Zhu[1], Jian Li[1], Zili Zhang[1]
1. School of Ocean Geosciences, China University of GeoSciences, Beijing, CHINA
E-mail: liqi@cugb.edu.cn

Keywords: Provenances, Grain size, Clay minerals, benthic foraminifer, the East Asia Monsoon, Inner shelf of ECS

Holocene sediments from the inner shelf of the East China Sea (ECS)with its high deposition and continuously sedimentary record which is sensitive to enviromental changeis an important recorder of regional responses to global paleoclimatic and paleoenvironmental changes. Based on the precise AMS^{14}C dating data, We analyze grain size, clay minerals and trace elements of sediment cores, investigating the sediment provenances of the the southern inner shelf of ECS, deducing the evolution of East Asia Monsoon in the past 4.7ka.

Comparing the clay minerals in the southern inner shelf of ECS with one from different potential source areas, the results indicate that sediments in the study area came from the Yangtze River, the Yellow River and rivers from Taiwan, while every potential source area making contribution in the different periods. In the period of 4.7-4.2ka, sediments from the Yantze River and Taiwan's river is the main source of sediments. From 4.2ka to 3.2ka, sediments of study area mainly consist of the sediments of the Yanze River and the Yellow River. Since 3.2ka, sendiments from all of potential source areas had some response on the study area.

Using benthic foraminifer cold and warm water indicator species and Taiwan warm current representative species analysis, we obtain Cold water combination*Protelphidium tuberculatumCribrononion vitreum Bulimina marginataFlorilus spp.Eggerella advena* sensitive to climate change, has a good indicator.The evolution of East Asia Monsoon in the past 4.7ka can be deduced based on the grain size sensitive components, the ration of Rb/Sr and montm orillonite/kaolinite. Refering to the δ^{18}O of GSP2 and stalagmite of Dongge Cave and the evidence of cooling of different materials in other regions, 9 high values could be recognized corresponding to the cooling events caused by the East Asia Monsoon. The core records 4 strengthen periods of the East Asia Monsoon: weak and stable during 4.7-4.2ka BP; increased and began to fluctuate during 4.2-3.2ka; a little weak with highly fluctuation during 3.2-2.0ka BP; the East Asia Monsoon incresed slighly with fluctuations weakened.

Paleoenvironmental and paleoclimatic evolution during late Oligocene to early Miocene: indicated by trace element ratio of Ostracod shells in the western Qaidam Basin

Chen Wei[1], Wang Xiao Feng[1*], Ma Jin Long[2]
1. Department of Geology, Northwest University, Xi'an City, Shanxi Province, CHINA
2. College of Earth Sciences, Lanzhou University, Lanzhou City, Gansu Province, CHINA
E-mail: wangxf@nwu.edu.cn

Keywords: Paleohydrology, Paleoenvironment, The Ostracods, Trace elements, The Qaidam Basin

The restoration of paleohydrological condition in sedimentary basins has a very crucial significance for reconstructing the regional paleoenvironment and paleoclimate evolution. For closed-inland lake in arid and semi-arid area, the effective precipitation rate (Precipitation/Evaporation) and runoff flowing into lake are the primary factors affecting water level change, and the variation of water level directly affect water chemistry, salinity and redox status (Jeremy M C et al., 2019). On the contrary, the paleo-salinity and paleo-redox implied by sediments can be used to indicate paleohydrological change in sedimentary basins and further to infer regional paleoclimate. In this study, we use Sr/Ca, Ba/Ca and U/Ca, Mn/Ca of Ostracod fossil shells as paleo-salinity proxy and paleo-redox proxy respectively to reconstruct paleohydrology and paleoclimate of middle and upper section of Shangganchaigou Formation in the western Qaidam Basin. Based on paleomagnetic age studied by Ji et al.(2017) and combined with average deposition rate of drilling, we determined the sedimentary age for Ostracod shells ranging from 29.32 Ma to 20.01 Ma.

The Sr/Ca, Ba/Ca, U/Ca and Mn/Ca of Ostracod shells have obvious three phases, and the average value of those ratios are I phase (0.00228, 0.00054, 0.000012, 0.00105, n=4), II phase (0.00322, 0.00072, n=8; 0.000024, 0.00323, n=10) and III phase (0.00335, 0.00206, 0.000005, 0.00981, n=3). In the phase I(29.32-26Ma), the ancient lake of the western Qaidam Basin was deep lake environment with low salinity, strong reducibility and high water level, and the climate was relatively warm and moist; In the phase II(23-21.75Ma), the ancient lake was shallow lake environment as a whole with high salinity, strong oxidability and low water level, and the overall climate was hot and arid, and at the end of this phase, the salinity and oxidation of lake water decreased with the water level rising, and the arid degree reduced; In the phase III(21.75-20.01Ma), the salinity and oxidation of lake water increased with the water level dropping, and the climate changed to cold and arid. At the same time, the aridity starting from about 26Ma in II phase corresponds to the aridification of inland Asia that was studied by previous researchers(Qiang et al., 2011; Zhang et al., 2014).

Tracing the source of Asian dust using the chemical composition of single-particle muscovite

XIAOYU ZHU[1], LIANWEN LIU[2*]
1. Faculty of Environmental Earth Science, Nanjing University-Hokkaido University, Sapporo, Hokkaido, JAPAN
2. school of earth science and engineering, Nanjing University, Nanjing, JIANGSU, CHINA
E-mail: liulw@nju.edu.cn

Keywords: Asian dust, Single-particle muscovite, Aridification, Loess

Debates persist surrounding the source and long-term stability of Asian dust (e.g. loess). However, the chemical compositions of muscovite, a widely-distributed characteristic mineral, in loess have the potential to trace its provenance. In this study, the chemical composition of single-particle muscovite in loess on the Chinese Loess Plateau (CLP) and potential sources areas was analyzed using the electron microprobe method to better understand the provenance of the CLP – the largest aeolian deposit in the world. Results show that the chemical compositions of muscovite in potential sources have significant regional characteristics. The content of phengite (muscovite with a Si atom number greater than 3.3) in potential source deserts (ie. Taklimakan Desert, Qaidam Basin, Tengger Desert and Mu Us Desert) near the northern margin of the Tibetan Plateau and the upper Yellow River is relatively high (from 3.41-9.68%), whereas there is almost no phengite in the Horqin Sandy Land or Gurbantunggut Desert. The RSI (the ratio of Si atom number between 3.1-3.2 to the Si atom number less than 3.1) of the Tengger Desert, Mu Us Desert and Horqin Sandy Land is about 1, while the RSI of other samples deviates significantly from 1. Loess on the CLP contains about 10% phengite, and the RSI is about 1. Examination of the phengite, RSI and Nd isotope values (alone and in combination) reveals that the provenance of the loess on the CLP is mainly from the Alxa Plateau desert region. In addition, analysis of the muscovite in loess also shows that the provenance of CLP has not experienced significant changes since at least 8 Ma, and the existing spatial distribution of deserts in Western China has remained relatively stable over this period.

Turbidite cycles in Pliocene–Pleistocene sediments of the South China Sea: constraints from magnetostratigraphy of IODP Expedition 349 drill sites

Xixi Zhao[1*]
1. Ocean science and Engineering, Southern University of Science and Technology, Shenzhen, Guangdong, CHINA
E-mail: xzhao@tongji.edu.cn

Keywords: Turbidite, South China Sea, Magnetostratigraphy, International Ocean Discovery Program

Turbidites provide a mechanism for assigning a tectonic and depositional setting to ancient sedimentary sequences as they usually represent deep water rocks. Turbidites can represent a high resolution record of seismicity as they generally require some form of tectonism to trigger density-based avalanches. International Ocean Discovery Program (IODP) Expedition 349 investigated the tectonic and oceanographic evolution of the South China Sea (SCS). Paleomagnetic results show that sediments from the sites drilled by Expedition 349 contain both reversely and normally magnetized samples. Thus, paleomagnetic directions can be used to construct magnetostratigraphy for dating sediments. The similarity of results between Holes U1431A and U1431D for the upper 30 m, which is characterized by graded, fining-upward turbidite cycles, strongly attests to the fidelity of the paleomagnetic records. In order to examine the frequency distribution of graded turbidite cycles, an integrated magnetostratigraphy, biostratigraphy, and sedimentology of the Site U1431 was conducted. At Site U1431. the average frequency of turbidite distribution during Pleistocene ranges from about 9-24 cycles/ka. These records reflect the magnitude, intensity, duration and extent of the frequency distribution of graded turbidite cycles in Site U1431. Our magnetostratigraphic work should help to refine the ages of sedimentation events and tectonic activities within and beyond the South China Sea basin.

Paleomagnetic constraints on the Late Devonian and Early Carboniferous paleo-position of South Qinling Belt and its implications for the evolution of the Central China Orogenic Belt

Jie Zhao[1*]
1. School of Earth Science and Resources, Chang'an University, Xi'an, Shaanxi, CHINA
E-mail: zhjie04@foxmail.com

Keywords: South Qinling Belt, Late Devonian-Early Carboniferous, Paleomagnetism, Mianlue Suture, South China Block, North China Block

To define the paleo-position of the South Qinling Belt (SQB) and thereby constrain the spatial configuration of the middle segment of the Central China Orogenic Belt, we carried out a paleomagnetic investigation on Upper Devonian and Lower Carboniferous limestones from the South Qinling Belt, central China. Characteristic remanent magnetizations (ChRM) resolved from limestones of Upper Devonian Lengshuihe Formation and Lower Carboniferous Jiehejie Formation both passed the fold test and suggested a primary origin. These results show that the SQB was located at a paleolatitude of 12.9°N±3.3° and -1.1°N±2.5° during the Late Devonian and Early Carboniferous separately. The paleolatitude of the SQB is close to that of the North China Block but is relatively different to that of the South China Block during the Late Devonian to Early Carboniferous, demonstrating that SQB is in proximity to the NCB but is away from the SCB. Combined with geological and geochronological evidences, paleomagnetic constrains indicate that the SQB lies on the southern margin of the NCB and is separated from the SCB by the Mianlue Suture during the Late Devonian and Early Carboniferous.

Cenozoic episodic uplift and kinematic evolution between the Pamir and Southwestern Tien Shan

Dongliang Liu[1*], Haibing Li[1], Zhiming Sun[2], Yong Cao[2], Jiawei Pan[1], Marie-Luce Chevalier[1]
1. Institute ot Geology, Chinese Academy of Geological Sciences, Beijing, CHINA
2. Institute of Geomechanics, Chinese Academy of Geological Sciences, Beijing, CHINA
E-mail: pillar131@163.com

Keywords: Magnetostratigraphy, Anisotropy of magnetic susceptibility, Paleomagnetic rotation, Pamir-Southwestern Tien Shan, Uplift and kinematic evolution

The Pamir Salient and Southwestern Tien Shan belong to different systems, which collided due to the continuous northward drift of the Indian Plate during the Cenozoic, resulting in a shortening of ~300 km. The uplift history and kinematic evolution of the Pamir-Southwestern Tien Shan remain unclear. In this study, we chose the 2025 m-thick Pakabulake formation in the East Wuqia section, in the southern-most margin of the Southwestern Tien Shan system, to obtain a high-resolution magnetostratigraphic record, spanning ~16.61 Ma to ~9.78 Ma. Based on high sedimentation rate, stable ca. E-W paleocurrents and stable magnetic susceptibility values, the nearby Southwestern Tien Shan was inferred to have undergone stable uplift during this period of sedimentation. Combining our results with the previous low-temperature thermochronology, magnetostratigraphy and re-calculated block rotations, we conclude that four episodic uplift events occurred in the Pamir-Southwestern Tien Shan during the Cenozoic, at times of ~50–40 Ma, ~35–16 Ma, ~11–7 Ma and <5 Ma, and that the first episodic uplift only occurred in the Pamir Salient. In addition, the Pamir Salient underwent a tectonic transformation from an entire- to a half-oroclinal bending rotation process during the Miocene, caused by the activity along the Karakorum Fault and Kashi-Yecheng Transfer System.

4. Instituto Geológico y Minero de España, IGME, CSIC, Madrid, SPAIN
E-mail: jnie@lzu.edu.cn

Keywords: Pliocene, Spain, Teruel Basin, alluvial sediments, magnetic enhancement, climate change

The Pliocene is considered an analog for future climate. Insolation is found the dominant forcing for Asian precipitation over the late Pliocene, evidenced by magnetic enhancement of Chinese loess caused by formation of nanometer-scale ferrimagnetic grains during pedogenesis corresponding to high precipitation. However, lack of European loess limits understanding of Pliocene European climate. We identified likely similar magnetic enhancement mechanism between Pliocene alluvial sediments from Spain and Chinese loess despite different depositional settings. This provides an opportunity to improve understanding of Pliocene climate in Europe. Spectral analysis shows that European wet-dry variations during the early Pliocene were forced by insolation and during the late Pliocene by both insolation and ice sheet development. During the Quaternary, in contrast, the forcing was dominantly from high latitude. These results demonstrate the importance of insolation during warm climates and the growing importance of ice sheets with global cooling in controlling NH precipitation changes.

A Sedimentary Funneling Effect and the Biogeochemical Remanent Magnetization in Mariana Hadal Trench

Dunfan Wang[1], Yutong Jiang[1], Peiling Xie[1], Zeheng Ruan[1], Qingsong Liu[1*]
1. Centre for Marine Magnetism (CM2), Department of Ocean Science and Engineering, Southern University of Science and Technology, Shenzhen, Guangdong, CHINA
E-mail: qsliu@sustech.edu.com

Keywords: Subducting carbon, Biogeochemical remanent magnetization, Sedimentary funnel effect, Hadal trench.

Abyssal subduction zone, known as the subduction factory, is a very important channel for the transportation of fluid and material from upper mantle to the lower, which consequently affect the element input and fluid property of the lower mantle. One of the most important scientific issue in this process is the subducting carbon, in which the move carbon from the sedimentary and oceanic crust is transformed into fluids, magmas, volcanic gases and diamonds and then disappear into subduction zones. However, the sedimentary rate in surface sediment of hadal trench is still poorly known which hampers the understanding of the carbon flux in there. Precise age model of the abyssal sediments is a prerequisite for robust determination of the materials deposition rate and recycle of subducting carbon in the hadal trench. Previous study has suggested that the sedimentary rate in Mariana trench is relatively high. But other studies showed that the sedimentary rate is very slow in there. Due to the lack of research materials and comparison with the surrounding sedimentation rate, the sedimentary process in hadal trench is still an enigma. Here, we have selected two sediment columns near the Mariana trench and obtained the sediments age by magnetostratigraphic study. The results show that deposition rates in hadal trenches is higher than elsewhere, suggesting a sedimentary funnel effect. It provides a significant insight on the carbon subduction in hadal trench. Furthermore, we also find a well-crystallized biogenic magnetite in a kind of hollow Fe–Mn micronodules. It may represent a unique process about biogeochemistry and a new important biogeochemical remanent magnetization in the special hadal trench environment.

Keywords: Paleomagnetism, Paleogeographic reconstruction, Paleo-Asian Ocean, Central Asian Orogenic Belt

The Paleo-Asian Ocean (PAO) separated North China and Tarim from Mongolia and Siberia. Dating the closure of the PAO is critical to our understanding of East Asian tectonics during the formation of Pangea, yet existing estimates differ by up to 130 Myr (380 Ma to 250 Ma). In this study, we report two robust paleomagnetic results from 320-280 Ma volcanic-sedimentary strata in the South Mongolia-Xing'an Belt. Stable characteristic remanences of both results are likely primary and characterized by positive fold tests, consistent polarity with the Kiaman Superchron (~318-262 Ma) and average paleosecular variation. The new results indicate that the northward motion of North China and Mongolia paralleled Laurussia from the Late Carboniferous to Early Permian. The N-S width of the PAO in the east-central segment (reference site: 43°N/114°E) was ca. 2700 km during the Late Carboniferous to Early Permian. The existence of this wide oceanic basin impeded floral and faunal interchange between North China and Mongolia. The PAO finally closed and formed a unified North China-Amuria block at ca. 250 Ma.

Keywords: Conglomerate-sandstone transition, foreland basin, Tian Shan, seismic profile

The conglomerate-sandstone transition (CST) preserved in foreland basins records the stratigraphic equivalent of the gravel to sand transition (GST) which migrates in response to shortening in steady state orogen-foreland basin systems. Two seismic profiles in the southern Junggar foreland basin provide the first seismic record of migrating CSTs and an opportunity to quantify its migration history in response to the growth of the northern Tian Shan. We identify the horizontal positions of the CSTs based on the distinct seismic signature of conglomerate versus sandstone and estimate their ages according to magnetostratigraphic sections. The linear regression analysis reveals that the CSTs migrated northward at 0.4 ± 0.1 mm/yr along 84°E from ~23 Ma to ~6 Ma and at 4.0 ± 1.2 mm/yr along 87°E from ~3.1 Ma to ~0.7 Ma. The discrepancy relates to variations in crustal shortening along strike of the range. Temporal deviations in the CST positions suggest the second-order impacts of climatic change.

An unusual case of wide liquefaction caused by the M5.1 earthquake: mobilization effects of salt dissolution on liquefaction

Keywords: Liquefaction, M5.1 earthquake, mobilization, salt dissolution, Hami

Earthquake liquefaction threshold is a very important scientific problem, it is generally believed that the M5 earthquake will not form a large area of liquefaction. On December 14, 2009, a M5.1 moderate-sized earthquake just 4 km in depth occurred in the city of Hami, Xinjiang, Western China. It struck an area roughly 12,000 km2 in size, and formed large quantities of spectacular, noticeable, randomly-oriented, and polygonal sand dikes that were wedge-like and oblique (on average 75.10°) in vertical section, as well as relatively well-sorted and from tens of centimeters to more than two meters in plane. Typically, they occur almost exclusively in a fine-grained rich salted sand gravel layer (SSGL) by liquefaction and fluidization differentiation, which are extremely susceptible to liquefaction in brine, albeit with no fine-grained caps and parent depositional sand bodies. The maximum epicentral distance of liquefiable sites may well extend to at least 80 km, and probably as far as 120 km, which is equivalent to that of M7.0~8.0 earthquake. Undeniably, the formation of Hami sand dikes and especially unusual significant liquefaction and fluidization is mainly attributed to the five unusual advantages: (1) salt mobilizations of SSGL prone to liquefaction and fluidization. The brine can largely decrease the shearing ability of sands, on average 58.30~70.0% and reduce the liquefaction threshold value of the earthquake to 0.060~0.083g. Thus, this is favoured for liquefaction and meanwhile, the brine may also reduce the minimum fluidization velocity (Umf) of 12.51~21.58% in the fresh water and thus is favoured for fluidization; (2) widely-distributed salt and detrital mixture cap (SDMC); (3) very shallow earthquake source (only 4 km deep); (4) very shallow basement (c. 0-3 m deep); (5) widely-distributed salted sandy gravel layer (SSGL), and (6) special sandwich texture of SDMC+SSGL+ basement. Otherwise, we obtained a map of fluidized distribution and fluidized boundary of different granular sand grains within a LSSGL and find that the sands mainly come from LSSGL below the bottom of the sand dikes, not the LSSGL on either side.

Magnetite magnetofossils record biogeochemical remanent magnetization in hydrogenetic ferromanganese crusts

Wei Yuan[1*]
1. School of Ocean and Earth Science, Tongji Univerity, Shanghai, CHINA
E-mail: yuanwei@tongji.edu.cn

Keywords: Bogeochemical remanent magnetization (BRM), Hydrogenetic ferromanganese crusts, Rock magnetic, Synchrotron analysis

Records of natural remanent magnetization (NRM) and geomagnetic polarity reversals preserved within ferromanganese (Fe-Mn) crusts, together with the application of fine-resolution magnetostratigraphic analysis, have been successfully demonstrated. However, as Fe-bearing precipitates or minerals are thought to be either oxides/hydroxides precipitated from ambient oxic seawater, or detrital minerals, the magnetic properties of the ferromagnetic minerals and the genetic mechanisms remain controversial; moreover, the origin of the NRM is unclear. Here, we show that nanometer-scale magnetite crystals found in Fe-Mn crusts from the Pacific Ocean and South China Sea are magnetosome fossils based on their narrow size range, chain arrangement, chemical purity, and crystallographic perfection, as indicated by transmission electron microscopy (TEM). Furthermore, our new data of rock magnetic and electron paramagnetic resonance analyses, combined with a previously reported micro-magnetostratigraphic sequence, indicate that the magnetotactic bacteria (MTB) and their post-mortem remains contribute to a biogeochemical remanent magnetization (BRM) of Fe-Mn crusts. In addition, the results provide evidence for a previously unappreciated pathway for the biogeochemical cycling of iron in the deep ocean.

Sedimentation rates in the Central Arctic Ocean according to the paleomagnetic study

Daria Elkina[1*], Alexey Piskarev[1,2]
1. Marine Seismic Department, Gramberg All-Russian State Research Institute for Geology and Mineral Resources of the Ocean (VNIIOkeangeologia), St. Petersburg, -, RUSSIA
2. Department of Geophysics, Institute of Earth Sciences, St. Petersburg State University, St. Petersburg, -, RUSSIA
E-mail: darielfly@gmail.com

Keywords: paleomagnetic studies, Actic Ocean, Mendeleev Ridge, Lomonosov Ridge, mean sedimentations rates

Until today, understanding of the geological and environmental processes taking place in the Arctic Ocean throughout its evolution is a high-priority geological objective. Nevertheless, accurate age determination of marine sediments from the Central Arctic Ocean is still challenging and remains a subject of great debates. Due to the lack of adequate materials for biostratigraphy and stable isotope analyses, paleomagnetic reconstructions came into play here but though yielded ambiguous interpretations.

Numerous paleomagnetic studies were carried out on marine sediments from various parts of the Arctic Ocean where reverse magnetized sediments were assigned to different time scales and geochemical processes. That, as a result, led to the existence of contrasting age models, varying by an order of magnitude, for the Quaternary and, to some extreme, to discredit the application of paleomagnetic stratigraphy in the Arctic Ocean in general.

Our comprehensive paleomagnetic study carried out on a number of long sediment cores (up to 8 m) from the area of the Central Arctic Rises (Stein, 2015; Stein et al., 2010), firstly, has established sedimentation rates of 1-2 mm/kyr for the Mendeleev Ridge up to the Pliocene age, complemented with 230Th excess results (Geibert et al., 2021; Elkina et al., 2020; Elkina et al., 2019; Piskarev and Elkina, 2017; Piskarev et al., 2013).

Secondly, in contrast to the Mendeleev Ridge, in the direction of the Eurasian Basin, the calculated mean sedimentation rates increase, at the same time showing a more complex paleomagnetic record with a relevant shift to negative geomagnetic inclinations significantly deeper downcore. This could imply a relevant difference in the sedimentation regimes, at least between the Mendeleev and Lomonosov ridges, during the Quaternary.

Finally, if considering a stable sedimentation environment, such slow sedimentation rates raise a question not only about times of glaciation onsets but whether it could “age”, to some extent, seismically identified horizons in the deeper sediment cover.

Paleomagnetic constraints on the origin of Late Paleoproterozoic Xuanlong-type ironstone in the northern margin of the North China Craton

Yuhang Cai[1*], Junling Pei[1], Shuan-hong Zhang[1], Yabo Tong[1], Lifu Hou[1], Zaizheng Zhou[2]

2. College of Earth Science and Engineering, Shandong University of Science and Technology, Qingdao, Shandong Province, CHINA
E-mail: 501343541@qq.com

Keywords: Chuanlinggou Formation, oolitic hematite, paleomagnetism, rock magnetism, paleogeographic reconstruction, paleoenvironment

The disappearance of banded iron formation (BIF) at ~1.8 Ga and the emergence of granular iron formation (GIF) in Mesoproterozoic have attracted a lot of attentions. The redox state of late Paleoproterozoic GIF, the Xuanlong-type ironstone (~1.645 Ga) of the Chuanlinggou Formation has been investigated mainly by geochemical methods (Li and Zhu, 2012; Lin et al., 2019; Tang et al., 2022; Wang et al., 2022). No paleomagnetic studies have been operated on the Xuanlong-type ironstone in the in the northern margin of the North China Craton, and therefore the paleogeographic location of the Xuanlong-type ironstone was unsolved. Moreover, there are still controversies on the mechanism for the formation of hematite in the Xuanlong-type ironstone, adding difficulties to extract paleoenvironmental information.

In this contribution, we used paleomagnetism, rock magnetism and in-situ analysis technology to explore the paleogeography and environmental information of the Xuanlong-type ironstone. Two new understandings have been obtained as follow:

(1) Normal and reversed directions of characteristic remanent magnetization could be isolated for samples from the Xuanlong-type ironstone. The mean direction of this primary remanent magnetization after bedding correction was Ds=50.1°, Is=54.4° (κ=22.2, α_{95}=5.5°, n=32) and the corresponding paleomagnetic pole was at 49.5°N, 192.8°E (dm/dp=7.7/5.5, n=32). These directions have passed a C-classification reversal test (McFadden and McElhinny, 1990) and a fold test at 95% confidence radius (McFadden, 1990). This paleomagnetic pole at ~1.645 Ga fulfilled a Van der Voo (1990) value Q=6. Thus, this characteristic remanent magnetization was interpreted to be a primary remanent magnetization carried by Al-substituted hematite during the precipitation of the Xuanlong-type ironstone. A paleo-latitude of 34.93°N was obtained for the NCC at ~1.645 Ga.

(2) Rock magnetic, scanning electron microscope-X-ray energy dispersive spectrometer (SEM-EDS) and electron probe microanalysis (EPMA) analytical results revealed that the primary remanent magnetization preserved in the Xuanlong-type ironstone was a chemical remanent magnetization carried by Al-substituted hematite acquired in early diagenesis. After analyzing the possible transformation of ferrihydrite to Al-substituted hematite, we revealed that the formation of porous and dense laminae indeed reflected two source of water (hydrothermal fluids input and runoff input) that dominated differently in the pore water of sediments during the precipitation of Al-substituted hematite. This process was actually controlled by the relative sea-level changes because the Xuanlong-type ironstone precipitated in the land-ocean transitional zone.

Keywords: Magnetostratigraphy, Yellow River, Landscape evolution, Mid-Pleistocene transition, Tectonic-climate interaction

The integration between the middle and lower reaches of the Yellow River marks the final formation of the Yellow River, but the timing varies from the late Miocene-early Pliocene to the late Pleistocene (~0.15 Ma) and the underlying forcing mechanisms vary from the uplift of the Tibetan Plateau to global climate change. Here, we report magnetostratigraphy, sedimentology, and provenance data from a drill core near the Sanmen Gorge, the last gorge along the main course of the Yellow River. Our results indicate that typical river channel deposits, with detritus from the Ordos Block, started to accumulate in the Sanmen Gorge at ~1.25 Ma, which is consistent with a shift in the regional depositional environment from a closed saline lake to a fluvial-dominated system. When integrated with river terrace evidence from upstream and downstream regions, the results provide robust evidence that the final integration of the Yellow River occurred around ~1.25 Ma, consistent with the beginning of the Mid-Pleistocene transition (MPT). We propose that the accelerated lowering of eustatic sea-level during the MPT may plays as important a role as tectonism in driving the birth and development of the Yellow River.

E-mail: yanyongg@mail.sysu.edu.cn

Keywords: Paleomagnetism, Indochina Block, Mesozoic, Detrital zircon U-Pb chronology, Tectonic evolution

The collage of the Indochina Block to the Eurasia continent during the Late Triassic led to the transition from marine sedimentary environment to continental environment in the Simao and Khorat basins. Our previous work has carried out paleomagnetic constraints on the collision process and tectonic evolution. A significant southward migration of ~1200-1400 km of the Indochina Block occurred during the Mesozoic times, which was also accompanied by a clockwise rotation of 18.8° ± 7.8°. To better complement our paleomagnetic work and constrain the paleoposition of Indochina block during the Mesozoic times, we performed U-Pb geochronologic analyses on detrital zircons from Late Triassic to Late Jurassic sedimentary rocks in the Simao and Nakhon Thai basins of the Indochina Block. Late Triassic sedimentary rocks reveal a significant age cluster of Cambrian to Triassic (~ 500–220 Ma), with few Precambrian zircon grains. In contrast to Late Triassic sedimentary rocks, the detrital zircon spectra of Late Jurassic sedimentary rocks shows a number of age populations at 135-500 Ma, 950 Ma, 1800 Ma and 2500 Ma. The age distribution pattern of detrital zircons from Late Jurassic sedimentary rocks is different from that of Late Triassic sedimentary rocks, indicating that a sediment provenance transition occurred in the Indochina Block during the Middle Jurassic times. The paleomagnetic and geochronologic constraints indicates that the Indochina Block gradually collided with other Eastern Asia main blocks and received their clastic sediments during the Jurassic southward migration.

Environmental magnetism and astronomically driven magnetic records of the Lower K1sh formation in the Early Cretaceous Songliao basin, northeastern China

Shujing Zhang[1], Huaichun Wu[1*]
1. School of the Ocean Sciences, China University of Geosciences (Beijing), Beijing, CHINA
E-mail: whcgeo@cugb.edu.cn

Keywords: SK-2 borehole, lower Shahezi Formation, lower Cretaceous, environmental magnetism, cyclostratigraphy

Continuous cores of the lower Cretaceous in Songliao Basin, northeastern China, have been drilled out by the International Continental Drilling Project of SK-2 borehole, providing unprecedented geological materials for investigations of the early Cretaceous continental paleoenvironment and paleoclimate. In this study, we systematically studied the lacustrine successions of the lower Shahezi Formation (K1sh) in depth 4542-5694 m using the techniques of environmental magnetism, microscopic imaging, geochemical stratigraphy and cyclostratigraphy. Magnetic analysis reveals that there is an inverse correlation between magnetic susceptibility (MS) and lithology, where mudstones hold the largest values, and sandstones hold the smallest. The main magnetism carriers in the lower K1sh are pseudo-single-domain (PSD) and/or multi-domain (MD) ferromagnetic minerals, whilst the mainly dominant minerals of MS are paramagnetic and ferromagnetic minerals. To further explore the genesis of the environmental and climatic variations, MS was utilized as an alternative proxy to proceed with cyclostratigraphic analysis. Sedimentary cycles of 113.04 m, 34.11 m, 13.34 m and 6.00m are significant in power spectrum, which are in ratio highly accordant with long eccentricity (405 kyr), short eccentricity (124 kyr), obliquity (47 kyr), and precession (21 kyr) cycles in Early Cretaceous, proving the considerable impact of astronomical cyclicity on sedimentary rhythmicity. Long eccentricity controlled sedimentary facies, short eccentricity and precession are regarded to have mutually shaped the lake level oscillations. It should be noted that semi-precession periods identified from MS and the U sequence is most likely to directly drive the sand-mudstone alternations with the seasonal discrepancies of summer insolation. Finally, by tuning the inferred long and short eccentricity cycles to 405 kyr and 124 kyr orbital eccentricity theoretical curves, we established floating astronomical time scales (FATS) of 3356.99 kyr and 3248.80 kyr respectively, both of which fall into the range of the published U-Pb ages. Sedimentation rate was estimated ranging from 27.50 cm/kyr to 28.91cm/kyr, confirming the rapid deposition characterized within the fault lacustrine basin. In summary, our study acquired experimentally detailed magnetic characteristics of the early Cretaceous terrestrial sediments, shed new light on the astronomically forced configurations of paleoclimate on these magnetic properties, and provided a preliminary geochronological constraint for further marine-terrestrial comparison towards coeval strata.

Late Ediacaran inertial-interchange true polar wander (IITPW) event: new road to reconcile the enigmatic paleogeography prior to the final assembly of Gondwanaland

BIN WEN[1*], Cairong Luo[1], Yong-Xiang Li[2], Yanting Lin[1]
1. School of Earth Sciences, China University of Geosciences, Wuhan, Hubei, CHINA
2. School of Earth Sciences and Engineering, Nanjing University, Nanjing, Jiangsu, CHINA
E-mail: wenbin@cug.edu.cn

Keywords: Inertial-interchange true polar wander (IITPW), Paleomagnetism, Paleogeography, Late Ediacaran

The Ediacaran to Early Cambrian plate tectonics was dominated by a full dispersal of the supercontinent Rodinia and subsequent amalgamation of Gondwanaland. There is a consensus that the final assembly of the Gondwanaland did not complete until the Early Cambrian. Prior to the final assembly, however, one major uncertainty remains on the quantitative paleogeography: the mainland of Gondwana was plausibly positioned at either a high or low latitude at a single time instant to meet the dual-latitude ('high-latitude' and 'low-latitude') options of Laurentia and requirement of <600 Ma Iapetus Ocean opening between Amazonia and Laurentia. This uncertainty arises from the equivocal selections on the ca. 590-560 Ma paleopoles from Laurentia and very few paleomagnetic data from Gondwana continents. In this paper, we expanded the dataset of high-quality paleomagnetic poles on the basis of Robert et al. (2017, 2018) and Wen et al. (2020) and confirmed an inertial interchange true polar wander (IITPW) event from ca. 590-580 to 560 Ma. We then provide a continuously kinematic reconstruction in the TPW-based ('absolute') framework and thus reconciling the two enigmatic paleogeographic models in this interval. The occurrence of IITPW in late Ediacaran has important implications for understanding the co-evolution of Earth system and multi-disciplinary investigations of the IITPW associated processes are needed in future work.

Magnetic fabric and sedimentary structure constraints on the Paleozoic paleocurrent changes in the northwestern margin of the Tarim basin and their provenance implications

Zhaoyang Zhou[1], Jun Meng[1*]
1. Department of Earth Science and Resources, China University of Geosciences (Beijing), Beijing, CHINA
E-mail: jmeng@cugb.edu.cn

Keywords: Magnetic fabric, Paleocurrent, Keziertage Formation, Tarim Basin, South Tianshan Ocean

The magnetic fabric technique is widely used to measure the direction of paleocurrent and paleo-stress as its speediness, precision, and cheapness. However, there is still a lack of direct comparison between the sedimentary structure-based and magnetic fabric-based paleocurrent direction. The Early Devonian Keziertage Formation in Tarim Basin preserves a wealth of sedimentary structure information on paleocurrent directions, which provides a natural laboratory for the comparison with magnetic fabric recovery. Furthermore, it bears the provenance evolution and tectonic implications on the South Tianshan Ocean opening. Here, we report 120 sedimentary structure-based paleocurrent and 382 anisotropy of magnetic susceptibility (AMS) data from the Keziertage Formation in the Kalpin area, Xinjiang. The distribution of AMS directions suggests that the sedimentary magnetic fabrics have been subjected to incipient deformation. While in the layer of tabular cross-bedding, the imbricate direction of the minimal axis of the AMS is consistent with the sedimentary structure-based paleocurrent direction. Both the magnetic fabric and the sedimentary structure show the paleocurrent changed from WSW to NE at the mid-upper part of Keziertage Formation. It implies the significant provenance transition that occurred in the Keziertage Formation of the Kalpin basin, which may further support the opening of the South Tianshan Ocean during the Early Devonian.

Magnetostratigraphic constraints for late Carboniferous rocks of the western Junggar Basin, China

Chunyang Zhang[1], Jun Meng[1*]
1. Department of Earth Science and Resources, China University of Geosciences(Beijing), Beijing, CHINA
E-mail: jmeng@cugb.edu.cn

Keywords: late Carboniferous,Magnetostratigraphy,Kiaman ,Fengcheng formation,Jiamuhe formation,Junggar basin

The reverse polarity Kiaman Superchron has strong evidence for sparse normal magnetochrons from the middle Permian to late Carboniferous.There,we present results of geochronologic,microscopy,rock magnetic and paleomagnetic analyses of a ~454 m-thick continuous vertical drill core(MY I Well) that intersect the Jiamuhe Formation and Fengcheng Formation (late Carboniferous) of the western Junggar Basin, China. U-Pb zircon dating of tuff yielded a concordant age of 308±2 Ma; andesite yielded a concordant age of 309±2 Ma.Rock magnetic and optic microscopy experiments indicate magnetite and hematite in the mudstones, sandstone, andesite and basalt as carriers of characteristic remanent magnetization(ChRM),which is primary remanent magnetization.Stepwise demagnetization and thermally less stable magnetizations reveal the preservation of a dual polarity ChRM in 180 samples. These are used to construct a magnetostratigraphic profile for the core that is dominantly reversed polarity with two short normal polarity subchrons.

Remagnetization age and mechanism of Cretaceous sediments in relation to dyke intrusion, Hainan Island: Tectonic implications for South China and the Red River Fault

Jun Meng[1*], Stuart Gilder[1]

1. School of Earth Sciences and Resources, University of Geosciences Beijing, Beijing, Beijing, CHINA

E-mail: jmeng@cugb.edu.cn

Keywords: Remagnetization, Redbed, Paleogeography, South China, Cretaceous

Hainan Island lies near the Red River Fault, a prominent tectonic feature produced by the India-Asia collision. There, we carried out a geochronologic and paleomagnetic study on Cretaceous rocks in order to better understand the kinematic history of the region. U-Pb zircon dating of tuff intercalated in red bed sedimentary rocks yielded a concordant age of 106.6±0.3 Ma; a mafic dyke intruding the red beds yielded a concordant age of 104.6±0.7 Ma. Stepwise demagnetization experiments on 448 sedimentary rock samples and 191 dyke samples isolate solely normal polarities. Paleomagnetic directions of the dykes cluster in two distinct populations in geographic coordinates, indicating that dyke intrusion occurred in two pulses of limited duration (secular variation was not averaged) after tilting of the sediments. Baking of the sediments from the dykes only occurred near the contacts. Together with published data, the mean directions of 104 sites most tightly group at 58.3±3.2% unfolding, indicative of a synfolding remagnetization, which can be constrained to have occurred within a 2 Myr period between sedimentation and dyke intrusion. We suggest that warm (50-100°C) fluid interaction during basin development led to new mineral growth spawning chemical remagnetization. The corresponding paleomagnetic pole at 81.5°N, 145.2°E (A95 = 2.4°) is indistinguishable from the coeval Eurasian reference pole, suggesting the South China Block has remained fixed to Eurasia since 105 Ma. A contour map of paleomagnetic rotations from 115 studies in the region shows that the Red River Fault roughly demarcates rotation magnitudes/signs, suggestive of a major tectonic boundary.

Keywords: Magnetostratigraphy, Ross Sea, Plio-Pleistocene

Earth's climate during the Plio-Pleistocene was characterized by a significant change from warmer-than-present conditions before 3 Ma to a global cooling trend with rhythmic glacial-interglacial cycles. Feedbacks associated with variability of the West Antarctic Ice Sheet have been implicated in amplifying this cooling, but its exact role within this framework remains uncertain due to lack of continuous proximal records. Hole U1524A recently drilled by International Ocean Discovery Program (IODP) Expedition 374 consists of an almost continuous Plio-Pleistocene sedimentary sequence. In this study, we refine the originally noisy shipboard magnetostratigraphy of Hole U1524A by comprehensive analyses of paleo- and rock magnetic data. We demonstrate that drilling overprints can be used to infer the quality of natural remanent magnetization (NRM) at Hole U1524A. It allows a new strategy to identify problematic data when characteristic remanent magnetization directions are unavailable, yielding an improved continuous magnetostratigraphy. Based on the refined age-depth model, we show that the low coercivity NRM component of Hole U1524A captures major climate transitions over the past 3.3 Myr and that its variations in intensity are indicative of changes in terrigenous material transported to the drill site, which is potentially linked to the glacial history of the West Antarctic Ice Sheet advancing and retreating across the Ross Sea continental shelf.

Keywords: OSL dating,10Be exposure dating,glacier-climate modeling,LGM,Lateglacial,southeastern Tibet

This study presents the glacial history and climatic conditions during the Last Glacial Maximum (LGM) and Lateglacial (LG) of the Songlong and Zhuxi valleys in the eastern Nyainqêntanglha Range, southeastern Tibet. Two sets of moraines were identified at the valley mouths, and were dated using cosmogenic 10Be exposure and optically stimulated luminescence (OSL) dating. The ages suggest that two glaciations occurred at ~20-21 and ~14-16 ka, respectively, coinciding with the LGM and LG glacial event. Based on glacier-climate modeling results, temperature drops ranged from 6.3 to 7.8 ℃ during the LGM-LG, with precipitation being 40%-60% of present value. The model results in the model domain are generally consistent with other climate records on the Tibetan Plateau. Glacial advances in monsoon-dominated southeastern Tibet during the LGM-LG were likely driven by low temperatures rather than by high precipitation, which was usually produced by the enhanced Indian summer monsoon during warming periods.

Weakening of continental weathering and cold event in the Late Mesoproterozoic, North China Craton

Nan Peng[1], Hongwei Kuang[1*], Yongqing Liu[1], Xiaoshuai Chen[1], Yuchong Wang[1]
1. Institute of Geology, Chinese Academy of Geological Sciences, Beijing, CHINA
E-mail: kuanghw@126.com

Keywords: cold event, continental weathering, Late Mesoproterozoic, Xiamaling Formation, Longshan Formation, North China Craton

A giant unconformity has long been considered to exist in the Late Mesoproterozoic (Xiamaling Formation and Longshan Formation transition), North China Craton (NCC), but whether this unconformity existed and whether there were other important unrevealed geological events during the transition have not been comprehensively explored. In particular, if there are several hundred million years of depositional discontinuities during the transition, they must have experienced a long exposure process, and physical or chemical weathering information must be recorded in the sediments. So, sedimentary detrital zircon dating is employed to explain whether an unconformable interface exists and geochemical methods such as Li isotope and sensitive geochemical elements in sediments are analysized to study the weathering intensity changes at the interface. Furtherly, the possible driving mechanism and geological significance can be better understood in the evolution of the late Mesoproterozoic North China Craton.

The detrital zircon age spectrum characteristics of the main Neoproterozoic strata from the NCC show that besides the detrital zircons with ages similar to those of Mesoproterozoic sandstones (dominated by > 1600 Ma), the zircons with the age of 1500-1000Ma are found which are not developed in Mesoproterozoic sandstones. However, the detrital zircon age spectrum of the Longshan Formation, which is considered as Neoproterozoic, shows two peaks at 2500 Ma and 1800 Ma, and no zircons less than 1500 Ma are obtained. This means that the Longshan and Xiamaling Formations were integrated deposits, and both belong to the Late Mesoproterozoic.

The abundance of Li shows a decreasing trend from the top of the Xiamaling Formation (mean of 53.2 ppm in Huailai, Hebei; mean of 30.97 ppm in Jixian, Tianjin) to the bottom of the Longshan Formation (mean of 30.8 ppm in Huailai; mean of 24.36 ppm in Jixian), while the δ^7Li value shows a correspondingly increasing trend from the top of the Xiamaling Formation (mean of 1.4‰ in Huailai; mean of 1.75‰ in Jixian) to the bottom of the Longshan Formation (mean of 11.8‰ in Huailai; mean of 7.13‰ in Jixian). The chemical index of alteration (CIA), chemical index of chemical weathering (CIW), and plagioclase index of alteration (PIA) show a decreasing trend from the top of the Xiamaling Formation to the bottom of the Longshan Formation, while the compositional change index (ICV) shows a corresponding increasing trend. In addition, the substitute index of chemical weathering intensity, such as K_2O/Al_2O_3, Na_2O/Al_2O_3, and FeO/Fe_2O_3, presents an increase in value, while the Rb/Sr value is decreased. All above indicate that continental chemical weathering weakened during the sedimentary transition period of the Xiamaling and Longshan Formations, which may be related to global climate cooling and even glacier event in the Late Mesoproterozoic (~1.30-1.00 Ga).

In general, the Longshan Formation is probably a series of shore-shallow sedimentary strata that developed in the global, relatively cold climate of the Late Mesoproterozoic.

3. Department of Geology, University of Vienna, Vienna, AUSTRIA
4. Department of Geography, Royal Holloway University of London, Egham, Surrey, UNITED KINGDOM
E-mail: kuanghw@126.com

Keywords: Luoquan glaciation, characteristics, age constraints, Ediacaran, snowball Earth

The Luoquan Formation unconformably overlaid different systems of the Mesoproterozoic (>1.6 Ga) with large discontinuities of about 1.0 Ga, on which the huge erosional landforms, such as striated pavements of different sizes, various striations, grooves and ridges and P-forms are well preserved, indicating a north to south movement direction of glacier (Le Heron et al., 2018, 2019; Chen et al., 2020). The Luoquan Formation is mainly composed of subglacial massive diamictites and weakly stratified diamictites, periglacial fluvial conglomerate, pebbly sandstone with rhythm layer, and marine laminated siltstone and mudstone with and without dropstone, which constitute a vertical sedimentary succession of subglacial, periglacial and glacial marine facies from continent to sea. In particular, the periglacial sand wedge (cast) structure occurred at the interface between the Luoquan Formation (including Dongpo Formation) and the Xinji Formation at the bottom of Cambrian, which is rare in the Neoproterozoic glacial records in China, indicating the palaeogeographic background of periglacial frozen soil during the Ediacaran-Cambrian transition period and the periglacial landform of the deglaciation during the Luoquan glaciation in the southern margin of North China. Paleontological and zircon dating indicate that the Luoquan glaciation was developed between the Ediacaran-Cambrian transition period or earlier than 574-539 Ma and later than the period of Gaskier glaciation. Represented by the Luoquan diamictite, the Ediacaran glacial sedimentary records span more than 3000 km from Anhui, Henan, Shaanxi on the southern margin of the North China Craton (NCC), Gansu and Ningxia of the west margin of NCC, and the Qilian Mountain and Qaidam (Oulongbuluke) to Quruqtagh of Xinjiang, and even to the central Asia and reaching the Middle East in the Arabian Peninsula. Besides, it has also been widely reported on other continents, such as Europe and North American. Therefore, the Ediacaran glaciation was probably another episodic “snowball Earth” event.

E-mail: kuanghw@126.com

Keywords: Ediacaran, Luoquan Formation, Glacial dynamic evolution, North China Craton

A series of diamictites of late Ediacaran are widespread across Southeast–Central Asia, with the Luoquan Formation particularly well preserved along the southern margin of the North China Craton (NCC). A basal unconformity, comprising abundant striations and p-forms, such as Muschelbruch, steep-sided cavetto interpreted to have been produced subglacially, was cut into the Mesoproterozoic basement, which indicate a near north to south direction of glacier movement. Although the thickness of the Luoquan Formation varies greatly from north to south, the succession of Luoquan Formation at each outcrop evolves from massive or stratified diamictite at the base to laminated fine-siltstone with dropstones upward, and with or without siltstone (i.e., Dongpo Formation) capped on the top. However, special case occurred at Yiyang section in the northwest, which contains two sets of fining upward succession from massive diamictite to laminated pebbly sandstone, and then to dropstone bearing siltstone. Therefore, the Luoquan glacier in the southern NCC showed multiple cycles of dynamic evolution, and the first set of glacial advance-retreat cycle may corresponds to the formation of extensive subglacial bedforms and landscapes.

Cap dolostone indicating the earliest Ediacaran paleogeomorphology of the Yangtze Craton

Yongqing Liu[1*]

1. Energy and Resources Research Center, Institute of Geology, Chinese Academy of Geological Sciences, Beijing, CHINA
E-mail: liu_cags@126.com

Keywords: Ediacaran, Cap dolostone, Paleogeomorphology, Yangtze Craton

The cap dolostone is a type of carbonate with global distribution, significant carbon isotope negative drift and special sedimentary structures in the aftermath of the Snowball Earth. It is traditionally believed that the cap dolostone can be found in wide depositional environments from continental shelves, slopes to basins. However, the research on the cap dolostone blanketing the Marinoan Nantuo Formation in the Yangtze Craton (YC) of South China shows that the cap dolostone is only deposited in the continental shelf or shallow water ramp settings; the so-called "cap dolostone" of deep-water origin such as formed in the slope and basin environments is a misunderstanding. Meanwhile, because the western YC is located at the paleo-uplift area, where the marine transgression in the early Ediacaran cannot reach, the cap dolostone was generally absent. Therefore, at the beginning of Ediacaran, the paleogeomorphology of the YC was characterized by the uplift in the west, and the extensive & flat shallow water (ramp) environment in the middle and east. In particular, the cap dolostone facies changed into deep-water cherts in distally steeper ramp (basin) in the southeast margin of YC.

Late Eocene signals of oncoming Icehouse and changing ocean circulation, Antarctica

Xiaoxia Huang[1*]
1. Geophysics, Institute of Deep Sea Science and Engineering, Sanya, Hainan, CHINA
E-mail: huangxx@idsse.ac.cn

Keywords: Prydz Bay, East Antarctic Ice Sheet, Eocene-Oligocene transition, clinoforms, Mass-transport deposits

The end of the Eocene greenhouse world marked the most dramatic phase in the long-term cooling trend of the Cenozoic time. Here we interpreted seismic data from offshore Prydz Bay, Antarctica, provide new insight on the Paleogene stratigraphic transition from greenhouse to icehouse conditions and ocean circulation changes. Despite the lack of Paleogene sediment cores to provide precise chronology, we identify a prominent Paleogene transitional phase (Greenhouse to Icehouse) preserved in the deep-water sedimentary record by correlating from shelf to the continental slope based on 75,000km of multi/single channel seismic reflection data. The occurrence of mega-Mass Transport Deposits (MTDs) on the slope suggests significant instability and collapse of the upper part of the continental margin during deposition of glacio-fluvial braid-plain sand on the outer shelf (stratigraphic unit III in Ocean Drilling Program Site 1166). A later phase of the transition is represented by the growth of a well-defined set of Latest Eocene continental slope clinoforms. These were constructed largely by sediment delivered to the margin by marine-terminating glaciers on the shelf. The identification of the MTDs and prograding clinoforms helps define the transition interval (late-mid Eocene to Eocene-Oligocene boundary) of ice sheet dynamics, prior to amalgamation of a continent-wide ice sheet. A marked migration of the earlier margin depocenter toward the west and northwest, attested by onset of drift sedimentation, dominated the full glacial phase, strongly suggest a more vigorous ocean circulation as the earth has entered to the icehouse since the E-O boundary.

Keywords: Late Tonian, Sturtian glaciation, Northern Yangtze Craton, Sedimentary sequences, Sedimentary evolution, greenhouse-icehouse transition

Sea-level reconstructions provide us with snowball Earth scenario depicted by global ice sheets and low sea levels. The sea-level falls under the control of the Sturtian glaciation, caused unconformity (sedimentary discontinuity) between the glacial rock series and underlying strata in many cratons such as South Australia, Scotland, and Denmark. However, the Yangtze Craton shows a unique and continuously deposited sedimentary sequence of clastic rocks. In that context, this study explores this process through detailed sedimentological analyzes of six outcrops of Liantuo and Gucheng formations in the Shennongjia area, northern Yangtze Craton. The facies sequences of the Liantuo and Gucheng formations record transition from alluvial fan-braided river to shallow sea, and finally turn to glacial systems: (1) Beginning at ~770 Ma, the rapid subsidence of the northern Yangtze Craton was indicated by conglomerates and sandstones cover, which is interpreted as fan-braided fluvial facies; (2) At 750 Ma, the geological record demonstrates a fluvial to shallow marine facies transition; (3) After 720 Ma, Shennongjia or even the northern Yangtze Craton entered the glaciomarine environment with gradual development of the ice sheet. A model of sedimentary evolution from Late Tonian to the early Cryogenian of the Yangtze Craton is proposed under the constraints of chronology, driven by the tectonic-climate duality, which further deepens and expands our understanding of the climate and environment at the beginning of snowball Earth.

Keywords: Fischer Plots, Sea-level change, Ediacaran, Doushantuo Formation, high-frequency cycles, Sedimentary facies

The rapid rise of glacioeustatic sea-level is the most extreme paleoenvironment alteration in the aftermath of the Snowball Earth. Although geologists conducted a lot of multi-subdiscipline research on this issue previously, there still exist potential for further discussions of the process in detail. The practice for decades years proved that the Fischer plot is a simple and robust tool to illustrate the fluctuations of accommodation patterns v.s. cycles sets or strata depth which could be interpreted as relative sea-level changes (e.g. Goldhammer et al., 1990; Sadler et al., 1993). This research simulates the Fischer plot to unravel the sea-level change in the aftermath of Marinoan glaciation by measuring the lower Ediacaran Doushantuo Formation in Shennongjia, South China. The result shows that 131 five order-cycles and 9 three order-cycles help us propose a two-stage variation of ice melting-forced sea-level change, i.e., (1) early high-frequency and slow to rapid stepwise rising, and (2) followed by stable decreasing in the latter. In addition, the vertical sedimentary facies of the lower Doushantuo Formation display, in ascending order, (1) intertidal carbonate rock, (2) subtidal clastics with turbidite and (3) intertidal lagoon fine clastics, indicating the process of the relative waxing and waning of sea-level. Such interpretation of the Fischer plot and the sedimentary facies' vertical evolution is beneficial to study the high-frequency sea-level change and paleogeographic reconstruction of post-Marinoan deglaciation.

This paper is supported by International Innovation Resources Cooperation Project (Z201100008320007) from Science and Technology committee of Beijing, National Natural Science Foundation of China (42072135) and Geological Survey Project (DD20221649).

The Carbon Cycle and Climate Fluctuations in the Early Permian Kungurian: Evidence from the Putaoling Section in Lower Yangtze Region

Chaogang Fang[1*]
1. Department of Oil and Gas, Nanjing Center, China Geological Survey, Nanjing, Jiangsu, CHINA
E-mail: fangchaogang206@163.com

Keywords: Kungurian, carbon isotope, carbon cycle, atmospheric carbon dioxide concentration, Lower Yangtze Region

The Early Permian Kungurian is in the climate transition period from the Late Paleozoic Ice Room to the Early Mesozoic Super Greenhouse, accompanied by global events such as the increase in atmospheric carbon dioxide concentration, ocean hypoxia, and decline in biodiversity. It is an important window and case study of the synergistic evolution of the global carbon cycle and climate environment. This study couples organic carbon isotopes (δ13Corg) and inorganic carbon isotopes (δ13Ccarb) and calculates Δ13C through stratigraphic, sedimentological and sedimentary geochemical studies of continuous sections of carbonate rocks of Putaoling Section at Chaohu in the Lower Yangzi region of South China, thereby indicating changes in the marine environment, carbon cycle anomalies and the evolution of biodiversity. The data show a simultaneous negative drift (KCIE event) of δ13Ccarb and δ13Corg in the Kungurian S. subsymmertricus dentate belt with a magnitude of about 1‰ and can be compared and related to other marine Kungurian profiles in South China. The simultaneous negative bias of δ13Ccarb and δ13Corg indicates the global carbon cycle anomaly caused by the input of a large number of lighter carbon isotopes in the Kungurian, which may be associated with the large igneous provinces associated with the mantle column on the northern margin of Gondwana and the release of methane hydrates, ultimately leading to higher greenhouse gas concentrations represented by atmospheric CO2 (pCO2). Excessive greenhouse gases rapidly exchange with the ocean and lead to lower ocean pH, potentially inhibiting calcification and cementation of reefs. Increasing seawater temperature will reduce oxygen solubility, making it easier to form an anoxic reducing environment, which may affect biodiversity. The environment of massive death of plankton and anoxic acidification is very conducive to the preservation of organic matter, which is also an important reason for the generally high TOC during this period. Anomalous carbon isotope fluctuations in the upper part of the Kungurian may be associated with global sea-level fall and upwelling currents.

What does a glacial deposit really look like, and what is "normal" in Earth's sedimentary record of glaciation?

Daniel Le Heron[1*]
1. Geology, University of Vienna, Vienna, AUSTRIA
E-mail: daniel.le-heron@univie.ac.at

Keywords: Glaciation, Cryogenian, Late Palaeozoic, Ordovician, Uniformitarianism

When we look at modern, Alpine glacial landscapes, we are struck by the abundance of chaotic and poorly sorted material, bearing large boulders. This material is diamict: unsorted, boulder-bearing material that is fashioned into a variety of familiar glacial landforms called moraines, and sometimes streamlined structures (drumlins). Earth has experienced many glaciations, and has a rich record of diamictites stretching from about 2.2 Ga to the present day. However, even superficial investigation reveals that the records of many glacial periods such as the Cryogenian and Late Ordovician are greatly contrasting. Cryogenian rocks crop out spectacularly in places like South Australia, Namibia, Scotland and the western USA. Glacially striated pavements below these are strikingly rare, in spite of these being associated with a so-called "snowball Earth". Spectacular, thick diamictites are interbedded with abundant dropstone-bearing strata and thus testify to a glacial influence, but not all diamictites are glacial and many record mass failures of slopes in a marine environment. By contrast, there is a high abundance of these features recording subglacial erosion in Late Ordovician and Late Carboniferous records. Huge networks of palaeo-ice streams can be mapped from satellite data, to allow detailed ice sheet reconstruction. The deposits of the Late Ordovician glaciation are predominantly sandstone, supercritical flow deposits are abundant, and most of the subglacial record records shearing of soft-sediment rather than "traditional" scratches on bedrock. Examples of these deposits are in Morocco, Algeria, Libya and Saudi Arabia. The Late Carboniferous record includes palaeo-fjord systems (e.g. in Namibia and Argentina) with polished bedrock surfaces that closely resemble Pleistocene fjord systems. Approaching the glacial record often requires "out of the box" thinking, because the present is not always the key to the past. This begs the question as to which glacial period, if any, is truly representative in terms of a glacial sedimentary record on Earth. So, do we really know what a glacial deposit looks like?

Precambrian red beds: their temporal and spatial distributions and association with glaciations

Huaqing Bai[1], Hongwei Kuang[2*], Yongqing Liu[2], Nan Peng[2], Kening Qi[3,2], Yuchong Wang[4,2], Xiaoshuai Chen[2]
1. Geothermal Department, Chinese Academy of Geological Sciences, Beijing, CHINA

4. School of Geosciences and Surveying Engineering, China University of Mining and Technology (Beijing), Beijing, CHINA
E-mail: kuanghw@126.com

Keywords: Red bed, Precambrian, Distribution, Sedimentary environment, Glaciations, Formation mechanism

Red bed is one of the most important witnesses of significant geological events. Making fully understanding of their sedimentary environments and forming mechanisms provides a great contribution for us to better understand the Earth's history and life evolution through time. Herein we make a statistic of the Precambrian red beds in more than 70 outcrops from nearly 30 countries and areas, including their lithology, sedimentary environment, areal distribution, and age data. 12 red bed sets are recognized with 5 of them considered as globally distributed, and the others are regional or local distributed. Globally distributed ones could act as paleoenvironment indicators, while the local ones are mainly dominated by local sedimentary environment and have little international significance. Lithologically, these red beds include red conglomerate and sandstone deposited in terrestrial (aeolian, alluvial, and fluvial) settings, red siltstone, muds, and carbonates deposited in shallow marine (dominately tidal and glacial marine) settings, and red mudstone, limestone, or dolostone deposited in shallow marine to bathyal transition areas. The terrestrial and shallow marine red beds are the dominating ones, while the red beds in shallow marine to bathyal transition areas are few and mainly concentrated in Ediacaran strata. Chronological coupling of the red beds deposition with the occurrences of glaciations, global eustatic sea-level changes, flourish of photoautotrophs (e.g., cyanobacteria), as well as the $\delta^{13}C$ and $^{87}Sr/^{86}Sr$ isotope indicate that the Paleoproterozoic Rhyacian red bed (Set 1) and Neoproterozoic Cryogenian and Ediacaran red beds (Sets 10-12) are closely related to the Paleoproterozoic and Neoproterozoic glaciations, Great Oxidation Event, and Neoproterozoic Oxygenation Event. The photosynthesizing of cyanobacteria is the most plausible oxygen producing mechanism which can increase and sustain significant levels of O_2 in atmosphere. The occurrence of glaciations decreased the water transmittance and prevented photosynthetic production of O_2 to oxidize Fe^{2+}, acting as a protector for oceanic Fe^{2+} accumulation. While melting of glaciers made the light available again for phototrophs and restarted the photosynthetic O_2 production to form red beds. In general, researches on Precambrian red beds are of great importance in decoding the systematical changes in paleoenvironment and shed light on the analysis of paleoevents like glaciations, and more attention should be given to them.

E-mail: xh0816@ynu.edu.cn

Keywords: Sedimentary Characteristics, Late Paleozoic Ice Age, Lhasa Block

The Late Paleozoic ice age, as the glacial event with the widest influence range and the richest geological record since the Phanerozoic, recorded the complete greenhouse-icehouse-greenhouse climate change process, which is of great significance for us to understand the evolution of earth climate. Although a large number of studies have been carried out on the spatial-temporal evolution and controlling factors of the Late Paleozoic ice age, little is known about the records of the Late Paleozoic ice age in Lhasa block. In view of this, we have conducted a detailed sedimentary study on the Late Paleozoic ice age records in the Shenzha area of the Lhasa block. The Late Paleozoic ice age records of Lhasa block are mainly present at the upper part of Yongzhu Formation and Laga Formation, with the age constraint of Late Carboniferous-Permian. Twenty lithofacies types and eighteen lithofacies associations are recognized, which are arranged into eight sedimentary facies, including tidal flat facies, shore facies, glacial facies, shallow sea shelf facies, ice river facies, ice lake facies, outwash fan facies and carbonate platform facies, among which glacial facies is dominated by ice-rafting deposit, subglacial deposit and subglacial foreland deposit. Vertical sedimentary environment changes indicate the transition from early marine glaciers to late terrestrial glaciers, representing a continuous retreat of glaciers to land, consistent with an overall global warming trend from the Late Carboniferous to the Early Permian. In addition, multiple glacial-interglacial sedimentary sequences of the Laga Formation reflect that the Lhasa block has experienced multiple glacier evolution cycles, which can be compared with Late Paleozoic glacial record in Australian.

Heinrich event 6 recorded in a cave stalagmite from southeast China

Fujie Zhao[1], Min Ren[1*]
1. College of Ocean and Earth Sciences, Xiamen University, Xiamen City, Fujian, CHINA
E-mail: zhaofujiea@163.com

Keywords: speleothem, paleoclimate, Asia monsoon, Heinrich event

A stalagmite from Youqin Cave (southeast China), which is composed predominantly of columnar calcites with no evident diagenetic modifications, captured the Dansgaard-Oeschger Events (DO17 and DO16) and the Heinrich Event (H6) by the abrupt shifts in the δ18O records between 66.2 and 57.2 ka. The millennial-scale climate changes recorded in the stalagmite were tied to the fluctuations in the intensity of the Indian and East Asian monsoons. A comparison with climate records in Greenland ice cores and oceanic sediments suggests that during H6 the strength of the Asian monsoon was reduced. Compared with stalagmites collected from south China and North India, the centennial-scale δ18O variations in the Youqin stalagmite within the H6 are more dramatic than those in the stalagmites further inland. The contrast between stalagmites from different localities implies that during H6 (1) the East Asian monsoon had more influences on southeast China than the Indian monsoon; and (2) the centennial-scale δ18O fluctuations were possibly associated with the El Niño-Southern Oscillations that affected the area. Paleoclimate changes recorded by the stalagmite from Youqin Cave in the East Asian monsoon region provide important information for understanding global climate changes during the last glaciation period.

The subsurface core-based paleosols and lacustrine sedimentary characteristics of the Eocene-Oligocene transition, Dongying Depression, Bohai Bay Basin, East China

Yang LI[1*], Zaixing Jiang[2], Huixi Lin[1]
1. Sinopec Petroleum Exploration and Production Research Institute, Sinopec Petroleum Exploration and Production Research Institute, Beijing, CHINA
2. Energy Resources, China University of Geosciences, Beijing, Beijing, CHINA
E-mail: ly2021.syky@sinopec.com

Keywords: Lacustrine basin, Eocene Oligocene transition, Bohai Bay Basin, East Asia

The Eocene-Oligocene transition (EOT) is an interest in geosciences field, which is characterized by cooling and arid climate feature. That climate varies in terrestrial settings, as reported by sedimentary records worldwide. However, the discussions are limited in the East Asia area since the lack of ideal outcrops in regions, which makes the inadequate knowledge of sedimentary records and monsoon-like climate patterns during the EOT in the East Asia. Thanks to the new subsurface cores collections. This study conduct the first time subsurface core description of paleosols, which were formed during the EOT in lacustrine basin of East China (Dongying Depression, Bohai Bay Basin). Based on petrographic analysis, the paleosols illustrate calcite precipitation nodules, with erosion surfaces and elements leaching making ferro-glaebules and nodules coatings. The calcareous and Fe-Mn horizons are developed, with appears of gleyed horizons. The main types are aridisols and oxisols. The subsequent paleosol named vertisol is characterized by the cracks and slickensides during wet and dry years occurred in seasonally arid paleoclimate. The leaching depth of calcareous horizon was used to estimate precipitation, with results between 105 mm and 178 mm annually, showing arid conditions in lake basin. The paleosols features are recorded in the second member of Shahejie Formation in three distinct wells located in the basin. Integrating the constraints of high resolution astronomical in region, the arid types of paleosols were firmly evaluated forming during the EOT. The palynological characteristics have xerophytic species, such as Labiatae and Ephedripites, separating from the Polypodiaceae and Alnipollenites existed in lower sediments developed in humid period. The geochemical elements support the rising of Mg/Ca and higher contains of Fe/Mn, illustrating arid conditions in terrestrial environments. The sedimentary records of lacustrine basin during the EOT were analyzed based on 15 cored wells, over 100 wells logs and seismic facies. The facies show the delta-lake sedimentary system is characterized by distributary channels developed in delta fronts before the EOT. The later weaken provenance inputs without thick sand deposits reflects the climate changing. The thin sheets and siltstone with calcite nodules appear in cores and within well correlations. The purple and brown-to-red clays were observed, which are similar to gleyed horizons of paleosols, showing seasonally fluctuations within shallow water levels shrinking after humid age. The sand isometric map of the changing time show banks and shoals extend quasi-parallel to the lake shore. The sedimentary features recovery in the upper intervals to some extent, with limited scale of sandbodies developed in delta-lake settings. Besides, the statistical map during the EOT also show the spit-like deposits, which are common in modern lakes influenced by regional prevailing winds. The scientific discussions on monsoon-like climate in the Eocene provide a possible interpretation that the dominant northwest winds during arid time influence sediments, with seasonally southeast humid vapor input the basin as well. The paleosols formed in uplifts within the basin are possible responses to the tectonic extension climax (42-32.8 Ma) in subduction of paleo-pacific ocean and Asian terra, which already left erosion records in regions.

E-mail: thomas.vandyk.2018@live.rhul.ac.uk

Keywords: Glaciation, Ediacaran, Luoquan, North China Craton

When preserved from deep time glaciation, subglacially striated bedrock surfaces allow the interpretation of past ice characteristics that are often elusive from the study of sediments alone. Salient amongst these is the thermal regime, which has a profound influence upon ice behaviour and consequent sediment erosion, transport and deposition. Typically, striated bedrock surfaces are linked to ice at its pressure-temperature melting point, indicating a locally warm-based thermal regime. Conversely, a cold-based thermal regime is defined by ice frozen to the substrate and is linked to minimal erosion. Cold-based erosional forms have been identified in Antarctica but their recognition is next to impossible if imprinted upon a surface previously or subsequently affected by warm-based erosion (e.g. striation). In the ancient record this is especially problematic, as it is typically only through the recognition of characteristic warm-based features that a surface can be confirmed as subglacial at all. Consequently, it is likely that there is an observational bias in the rock record toward warm-based over cold-based ice. This study, through careful geomorphologic analysis of unusually well preserved striated surfaces of the North China Craton from the Ediacaran Period (c. 635 – 540 Ma), presents rare examples that record dominant cold-based and more limited warm-based erosion on the same subglacial surface. It is hoped that this approach may benefit other workers interested in identifying cold-based as well as the more obvious warm-based subglacial conditions from the record of deep time glaciation.

Magnetic Study of Sediments from core ARC7-P24 in Chukchi Sea, Northwest Ice Ocean

Junnan Zhang[1], Huaichun Wu[1*]
1. College of Marine Sciences, China University of Geosciences (Beijing), Beijing, CHINA
E-mail: whcgeo@cugb.edu.cn

Keywords: Arctic Ocean, Magnetic stratigraphy, Environmental Magnetics,element cycle, Beaufort Gyer

Abstract

The unique geographical location and sedimentary environment make the stratigraphic division and comparison of deep-sea sediments in the Arctic Ocean much more difficult than other sea areas(Mei et al.,2015Zhang et al.,2021).Therefore, the geochronological studies of the Arctic Ocean sediments are relatively scarce, which in turn increases the difficulty of conducting core environmental climate studies on a time scale.

In this paper, XRF element scanning, magnetic stratigraphy, and environmental magnetic analysis were performed on the P24-hole columnar samples (water depth 1662 m, column length 285 cm) collected at the Chukchi Sea Station in the Northwest Ice Ocean during China's seventh Arctic scientific expedition.The results of magnetostratigraphy show that the core P24 recorded two geomagnetic drift events in Laschamp and Norwegian-Greenland Sea when the Brunhes positive polarity. Combined with the cycles of Mn and Ca elements in the core, the chronological framework of the MIS5 in the P24 core was established.Environmental magnetic studies have shown that the main magnetic-carrying mineral in the P24 core is magnetite.The change of magnetite content is controlled by the change of provenance input controlled by the intensity of Beaufort Gyer during glacial and interglacial periods. During the interglacial period, the Beaufort Gyer strengthened, and the magnetic-bearing minerals in the icebergs or large ice blocks in the Canadian Arctic Islands were transported to the Chukchi Sea and unloaded to the seabed, resulting in an increase in indicators such as magnetic susceptibility;During the glacial period, the Beaufort Gyer weakened significantly, and the transported magnetic minerals decreased, resulting in a significant decrease in indicators such as magnetic susceptibility.

In conclusion, this study provides a reliable age scale for the core of the P24 hole in the Chukchi Sea of the Northwest Ice Ocean, and provides a new basis for the study of environmental climate change in this region on a time scale.

The late Paleozoic Ice Age Orutanda fjord in Namibia: the importance of gravitational resedimentation filling an overdeepened basin

Eduardo Luiz Menozzo da Rosa[1*], John Isbell[1], Roger Swart[2], Natalie McNall[1], Nicholas Fedorchuk[3]
1. Geosciences, University of Wisconsin-Milwaukee, Milwaukee, Wisconsin, UNITED STATES
2. BlackGold Geosciences, BlackGold Geosciences, Windhoek, Khomas, NAMIBIA
3. Department of Earth Science, Southern Connecticut State University, New Haven, Connecticut, UNITED STATES
E-mail: menozzo2@uwm.edu

Keywords: Dwyka Group, Kaokoveld, glacial, mass wasting, subaqueous density flows

The filling of fjords is complex as it is controlled by glacier dynamics, sediment supply, relative sea-level changes, and topography. The latter makes fjords noticeable as overdeepenings and steep flanking slopes encourage downslope resedimentation of glacially-transported debris through the entire spectrum of gravitational mass movements and sediment density flows. Various paleofjords left sculpted by Gondwanan glaciers during the late Paleozoic Ice Age (LPIA; 362-256 Ma) have been demonstrated, most prevalently in Argentina, Brazil, and Namibia. This work presents the fjord morphology and depositional history of a glacial-deglacial cycle recorded in the Dwyka Group hosted in the Orutanda fjord in northwestern Namibia. Three stages are defined for the fjord evolution: glaciation, early deglaciation, and late deglaciation. The Orutanda fjord is roughly N-S oriented, 19 km long, 3.7 km wide, and has a maximum preserved depth of 470 m. The analysis of cross sections and the longitudinal profile demonstrate an overdeepened basin created after the convergence of a tributary glacier. The glacial trough was eroded during the glaciation stage by a southward advancing, wet-based glacier estimated to be between 90-200 m thick, with ice thickness varying according to the longitudinal position in the fjord. Following the erosion and total occupation of the trough by the glacier, the early deglaciation stage encompasses the progressive retreat of the tidewater glacier, flooding of the fjord, and sedimentation in an overdeepened basin. Proglacial sedimentation is recorded only by laminated mudstones and iceberg-rafted debris. Sedimentation was dominated by intense paraglacial downslope gravitational resedimentation of the glacially-transported debris accumulated in the flanking slopes. This resulted in coalescing debrites-turbidites lobes on the fjord's floor with sediment pathways perpendicular to the fjord axis. Slumps entirely composed of deformed debrites and turbidites indicate that these resedimented facies were prone to renewed downslope mass wasting. During late deglaciation, the Orutanda glacier became land based and the fjord experienced the instalment and progradation of a fjord-head delta. The axial southward progradation of the fjord-head delta is recorded only from slumps and turbidites derived from the failure of the fjord-head delta front and delta plain. The depositional record in the Orutanda fjord showcases a deep-time stratigraphic example of a fjord fill that is composed almost entirely from products of subaqueous gravitational resedimentation. An additional outcome is the successive resedimentation episodes which the glacial debris underwent until their final deposition on the fjord's floor. Recognizing an accurate genesis for glacial facies is fundamental for the recognition of glaciation in the stratigraphic record as well as for more detailed analyses on the reconstruction of former ice margin positions, ice thickness estimations, and the nature of fjords stratigraphic architecture.

A newly discovered Cretaceous erg in the Turpan-Hami Basin, NW China: Climatic and geographic insights into the Cretaceous and future greenhouse world

Dehai Zhang[1*]

1. School of Earth Science, China University of Geosciences (Wuhan), Wuhan, Hubei, CHINA

E-mail: dhzhang@cug.edu.cn

Keywords: erg, greenhouse world, cliamte

Desertification, extending the area of desert and intensifying storms, has already hindered human sustainable development, and it will grow more serious along with the intensification of global warming in the future. Because of the similar geographic configuration and climatic circumstances, the Cretaceous world, known as a key greenhouse period of Earth's history, acts as a relevant model to comprehend the future greenhouse world. Here, we reacquainted the Early Cretaceous terrestrial deposits of the Liushuquan Formation (K1l) and Dahaidao Formation (K1d) in the Hami Basin, NW China. We found that the K1l, originally considered to be aqueous deposits, is composed of > 300 m of successive aeolian deposits and confirmed as representing a typical intermountain erg environment. The Liushuquan paleo-erg was the northernmost early Cretaceous erg discovered in Asia and was regulated by the subtropical high-pressure zones, the uplift of adjacent mountains, and regional topography. Paleoclimate evolution derived from paleogeography, paleoecology, and chemical weathering conditions indicates a marked transition from a hot and arid to a hotter and more humid climate from the early to mid-Cretaceous world, which would be attributed to the continuous rise of atmospheric CO2 concentrations and subsequent drastic shrinking of the Hadley circulation. Considering the Cretaceous climate and geography, we suggest that the climate will be hotter and drier and that the Kumutag desert has the potential to expand in the future greenhouse world.

Significance of turritella dominated assemblage (TDA) within mid-Cretaceous carbonates of Bagh Group, central India: Evidence of sedimentological non-uniformitarianism

PRANTIK MONDAL[1*], Kalyan Halder[2], Biplab Bhattacharya[1]
1. EARTH SCIENCE, INDIAN INSTITUTE OF TECHNOLOGY ROORKEE, HARIDWAR, UTTARAKHAND, INDIA
2. Geology, Presidency University , Kolkata, West Bengal , INDIA
E-mail: prantik_m@es.iitr.ac.in

Keywords: Carbonates, Sedimentological non-uniformitarianism, Cretaceous, Turritella, TDA

The Turritella dominated assemblage (TDA) in modern times are heterogeneous in nature, mostly reported in siliciclastic sediments within a relatively narrow range of environmental conditions. The TDAs are often useful indicators of different ecological parameters like depth, salinity, nutrient flux and temperature in establishing modern environments (Marincovich and Kase,1986; Thewissen et al. 1994; Kollman et al., 2002; Martinez and del Rio, 2002). However, the environmental conditions favorable for such assemblages had changed overtime and are poorly understood. The occurrence of TDA in carbonates is almost absent in modern environments. The modern carbonates are commonly accumulated under the abundance of carbonate producing organisms under low silicilastic supply. Such accumulations occur today in dominantly two environments, warm-low nutrient (WLN- called as tropical; found in low-latitudes) and cool-high nutrient (CHN- temperate, nontropical; found in high-latitudes) conditions. The accumulation of carbonates in warm-high nutrient (WHN) conditions, which is rare to absent in the present world, is observed from the Cretaceous successions, when the ocean chemistry was significantly different from present oceanic conditions.

The present work is the report of a TDA from the mid-Cretaceous Nodular limestone Formation, Bagh Group, central India. The Nodular Limestone is divided into six facies, which are litho-bioclastic wackestone-packstone facies, bioclastic lime-mudstone facies, mudstone facies, lithoclastic wackestone facies, TDA bearing mudstone facies and bioclastic wackestone facies. The TDA bearing lithounit varies in thickness between 10 and 15 cm with abundant turritelline fossils, which are well preserved as molds and casts within the horizon. Based on previous studies on TDAs and sparse data on carbonate dominated TDAs, it was assumed that turritellines are found predominantly in siliciclastic sediments of Cretaceous and Cenozoic, as the stratigraphic distribution and record of TDAs in carbonates are limited in the past as well as in the present (Beauchamp, 1984; Cooley, 1985; McCartan et al., 1985; Allmon, 1988; Allmon and Dockery, 1992; Spizuco and Allmon, 1992; Allmon and Knight, 1993; Allmon, 1996; Allmon, 2004; Allmon, 2007; Allmon and Cohen, 2008). The assemblage described here, adds a significant amount of knowledge about the occurrence and depositional environment, which favoured growth of turritellines within the mid-Cretaceous carbonates. The present assemblage would contribute to the understanding of palaeoecological and paleoenvironmental interactions of TDAs within carbonates by acknowledging the limiting factors like temperature, oxygen, depth, salinity and substrate using geochemical and paleo-redox proxies. Moreover, indicators of variable sediment supply with respect to sea level fluctuations were also explored as one of the possible explanations for the formation of these condensed turritelline dominated sections.

It is evident that the principle of sedimentological uniformitarianism does not hold for TDAs, as the ecological and environmental distribution and occurrence of TDAs from the past Cretaceous period to recent time had changed. The temporal change in the sedimentological association of TDAs cannot be neglected and may coincide with the global climatic change from greenhouse to icehouse conditions during the Oligocene epoch (Allmon and Knight, 1993; Prothero et al., 2003; Allmon, 2007).

Keywords: ENSO, Early Cretaceous, varve, climate simulation, northeast China

The El Niño-Southern Oscillation (ENSO) is the dominant mode of interannual climate fluctuation and generates teleconnections impacting global climate variability today. Its behavior in past greenhouse climates provides a useful perspective for understanding future ENSO under global warming. Despite evidence of active ENSO since the Late Cretaceous, whether ENSO operated at earlier times is unknown. Here we present evidence from annually-resolved lacustrine sediments in northeast China, showing signals of interannual precipitation variability 120 million years ago, with major frequency bands of 2.0-2.7 and 3.5-4.0 years. A coupled climate simulation of the Early Cretaceous generates ENSO with similar periodicities in tropical Pacific sea-surface temperatures and atmospheric teleconnection to northeast China precipitation. The simulated Early Cretaceous ENSO is higher in frequency and amplitude than ENSO of the modern climate. Our geological and modeling evidence suggests that ENSO, stronger than in the present-day, operated in the Early Cretaceous greenhouse climate.

Evolution of atmospheric circulation across the Cretaceous–Paleogene (K–Pg) boundary interval in low-latitude East Asia

Mingming Ma[1*], Xiuming Liu[1]
1. Department of geography science, Fujian Normal University, Fuzhou, Fujian, CHINA
E-mail: mamingming159@163.com

Keywords: Global monsoon, Atmospheric circulation, K–Pg, Low-latitude East Asia, Terrestrial records

The Cretaceous–Paleogene (K–Pg) boundary interval is an important time interval for deep-time paleoclimatic research, and most records of this interval are derived from marine sections. In this study, we conduct high-resolution magnetic and geochemical analyses in a terrestrial sedimentary succession from the Nanxiong Basin (Southeast China). We combine this data with previous work to compare these results with global marine and other terrestrial records. We find that the magnetic and geochemical parameters record a sequence of global climatic changes across the K–Pg boundary interval. Moreover, during the Maastrichtian cold “greenhouse” time interval, the climate changes in the studied area are consistent with the benthic foraminiferal $\delta^{18}O$ record from the North Atlantic, and we observe no correlation between the $\delta^{13}Ccarb$ and $\delta^{18}Ocarb$; in contrast, during the Danian “greenhouse” time interval, the climate changes in the studied area are consistent with the benthic foraminiferal $\delta^{18}O$ records from both the Pacific and the North Atlantic, and we observe a positive correlation between $\delta^{13}Ccarb$ and $\delta^{18}Ocarb$. We suggest that the observed changes are likely linked to the transformation of atmospheric circulation in low-latitude East Asia. These new insights have implications for “global monsoon” research and understanding the causes of the mass extinction.

Organic matter enrichment driven by global warming prior to and at the base of OAE 1a in southern Tibet, eastern Tethys

Ying Nie[1], Xiugen Fu[1*]
1. School of Geoscience and Technology, Southwest Petroleum University, Chengdu, Sichuan, CHINA
E-mail: fuxiugen@126.com

Keywords: Lower Aptian, OAE 1a, Global warming events, Depositional environment, Organic matter accumulation

Global warming events in geological history are usually accompanied by the widely distributed source rock deposition. However, the mechanism of organic matter (OM) enrichment under global warming remains unclear. The Lower Aptian (Early Cretaceous), especially the Oceanic Anoxic Event 1a (OAE 1a) interval was an episode of global warming, and OM-rich sediments also showed a wide distribution in this time. During this interval, OM-rich rocks were formed in southern Tibet, which could provide a chance to reveal the mechanism of OM accumulation under global warming. Here, we present geochemical and mineralogical date to investigate paleoenvironmental conditions and the mechanism of OM enrichment prior to and at the base of OAE 1a in the Gucuo area of southern Tibet, eastern Tethys. Several geochemical proxies (MoEF, UEF, and Th/U) reflect changing redox conditions took place prior to and at the base of OAE 1a. Oxygen contents in the water mass tend to decrease prior to OAE 1a (may from oxic to suboxic conditions). At the onset of OAE 1a, a brief anoxic waterbody prevailed. After that, oxygen contents gradually increase (may from suboxic to oxic conditions). Productivity-related Ba/Al and Babio are indicative of a high biotic productivity during the sedimentation. The low values of B/Ga reveal a freshwater to brackish water condition, suggesting massive freshwater injection occurred prior to and at the base of OAE1a. Both of the CIAcorr values and Ga/Rb–K2O/Al2O3 and SiO2–Al2O3+K2O+Na2O bivariate diagrams reflect a warm-humid climate existed prior to and at the base of OAE1a. Combined with previous researches, a warm-humid climate in the study area was controlled by global warming during this interval. For one thing, a warming climate promoted the prosperity of aquatic organisms; for another thing, enhanced runoff and massive freshwater infusion under a warming climate enhanced fluvial delivery of nutrients to ocean, which would raise bioproductivity of surficial water. A high biotic productivity created massive OM, which contributed to OM accumulation. This study underscores that a high bioproductivity driven by global warming plays an essential role during the OM-rich sediments deposition.

Intensive peatland wildfires during the Aptian-Albian oceanic anoxic event (OAE1b): Evidence from borehole SK-2 in the Songliao Basin, NE China

Keywords: Lower Cretaceous, OAE1b, Peatland, Wildfire, Coals

The Cretaceous has been considered a “high-fire” world accompanied by widespread by-products of combustion in the rock record. The mid-Cretaceous oceanic anoxic event 1b (OAE1b) is marked by one of the major perturbations in the global carbon cycle characterized by deposition of organic-rich sediments in both marine and terrestrial settings. However, our understanding is still limited on changes in wildfire activity during OAE1b period. Here, we carried out a comprehensive analysis, including organic carbon isotope ($\delta^{13}C_{org}$), total organic carbon (TOC), coal petrology, trace elements, and pyrolytic polycyclic aromatic hydrocarbons (pyroPAHs), of coal seams in the middle Aptian to early Albian Shahezi Formation from borehole SK-2 of Songliao Basin, NE China. Two negative $\delta^{13}C_{org}$ excursions in the Shahezi Formation can be corresponded with the Jacob/113 and Kilian sub-events of OAE1b. Moreover, the intensive peatland wildfires have been identified during the sub-event periods of OAE1b based on the co-occurrence of high abundance of charcoal and pyroPAHs at that time. In addition, Sr/Ba, Sr/Cu and Sr/Rb ratios demonstrate that enhanced peatland wildfires were controlled by dryer climate conditions owing to episodic northward migration of arid zones in East Asia related to rising global temperature during the sub-events of OAE1b. The climate-driven extensive wildfire activity in the mid-latitude terrestrial ecosystems can be a contributing factor for OAE1b through increased flux of nutrients fueled primary producers in the lake and marine environments leading to more speculative anoxia allowing the deposition of organic-rich sediments. Our results provide essential understanding of the importance of wildfires in driving mechanism of OAEs in Earth’s history.

Keywords: Early Cretaceous, Lacustrine sediments, Liupanshan Basin, Organic matter enrichment, Aliphatic biomarkers

Understanding the burial of organic matter in terrestrial sediments is improtant for reveal the carbon cycle in the Early Cretaceous. Here, total organic carbon (TOC) content, C/N ratio, n-alkane distribution, and δ13C composition of individual hydrocarbons of outcrop samples were employed to reveal the origin and preservation of high abundance of organic matter in the Madongshan Formation of Huoshizhai section in the Liupanshan Basin. Results show that the variations in TOC value of those samples in the studied profile can be divided into three stages. Stage I, TOC value is less than 1.45%. Short-chain n-alkanes are enriched in those samples, the δ13C value of n-C14 to n-C19 varies in a more wide range and is heavier than medium-chain n-alkanes (n-C20 to n-C24) and high carbon numbered n-alkanes >C24, and the C/N ratio ranges from 10 to 20. Stage II, TOC value measurably increases to the maximum value of 5.86%. The n-alkane distributions are mainly composed of two peaks of low (n-C18, n-C19) and medium (n-C23) carbon numbered n-alkanes, and some samples are characterized by the signal peak of n-C23. The δ13C value of medium molecular weight varies in a relatively narrow range and is clearly more negative than that of the low and high carbon numbered n-alkanes, and the C/N ratio is between 20 to 50. Stage III, TOC value tends to decrease. The percent of high molecular weight increase significantly in the n-alkane distributions, and presenting a clear odd-over-even carbon number predominance in those alkanes. Meanwhile, the δ13C composition of the high molecular weight odd and even n-alkanes in most samples have a saw-toothed carbon isotopic shape, and the C/N ratio decrease significantly and with an average value around 20. Those characteristics indicate that the predominant source of organic matter in the Madongshan Formation changes from aquatic algae to terrestrial plants. In addition, the high advantage of phytane and the detection of gammacerane in the whole samples may propose that those samples deposited in a salinity stratified water column associated with anoxic bottom waters.

Toarcian Ocean Anoxic Event in the eastern Tethys

Xiugen Fu[1*], Jingxian Deng[1], Ying Nie[1]
1. Geoscience and Technology, Southwest Petroleum University, Chengdu, Sichuan, CHINA
E-mail: fuxiugen@126.com

Keywords: Toarcian Oceanic anoxic event, carbonate and organic carbon isotopes, Total organic carbon, Qiangtang Basin, Eastern Tethys

The Early Toarcian "Oceanic Anoxic Event" (T-OAE) is a very significant paleoenvironmental perturbation of the Mesozoic that coincided with marked disruptions to both the climate system and marine ecosystems. This event is associated with widespread burial of marine carbon and a large negative carbon-isotope excursion (CIE) in carbonates, organic matter, and fossil wood. These features have been attributed to a large-scale injection of isotopically light carbon into the ocean-atmosphere system, possibly from the release of volcanogenic CO2 from the emplacement of the Karoo-Ferrar Large Igneous Province (LIP) in southern Gondwana and/or from dissociation of methane hydrates. The T-OAE has been well documented in the western Tethyan and Boreal realms. Only a few studies on the T-OAE have been reported from the northwest, central, and northeast Panthalassic Ocean. Therefore, the global expression of the T-OAE needs to be established through analysis of Early Toarcian rocks in other paleogeographic locations. In the eastern Tethys, Our studies present high-resolution carbon-isotope data, bulk geochemistry, and mineral characterization from various setting in the Qiangtang Basin. The Toarcian carbon-isotope excursion has been observed in the Biluoco section, Sewa section, Wenquan section, and northern Qiangtang depression (well QTKT-1). These data suggest that the T-OAE was extensive in the Qiangtang Basin. The Toarcian carbon-isotope profiles from the Qiangtang Basin, eastern Tethys are compatible with those in contemporaneous strata in the western Tethyan and Boreal realms, supporting the global expression of the T-OAE.

Terrestrial carbon cycle and atmospheric CO2 concentration: Insights for prelusion and aftermath of the Chicxulub impact and Deccan eruption

Jingyu Wang[1], Xianghui Li[1*], James Barnet[1], Yin Wang[1], Chenyu Zheng[1]
1. School of Earth Science and engineering, Nanjing University, Nanjing, Jiangsu, CHINA
E-mail: seanlee@nju.edu.cn

Keywords: carbon cycle, atmospheric CO2, Deccan Trap,Chicxulub impact, paleoclimate, Cretaceous-Paleogene boundary

The end-Cretaceous mass extinction has traditionally been attributed to the coeval catastrophic events of the Chicxulub asteroid impact and Deccan large igneous province volcanism. To decipher the driver and examine the climate conditions across the Cretaceous-Paleogene boundary (KPB), we conducted carbon isotope analyses of pedogenic carbonates in the Sichuan and Nanxiong basins, South China, in order to reconstruct atmospheric CO_2 concentrations (pCO_2) spanning 76–62 Ma. Combined with data from the Songliao Basin (north-east China) and Tornillo Basin (USA), $\delta^{13}C$ data and pCO_2 display high-frequency and high-amplitude fluctuations. Kernel smoothed results show a slight decreasing tendency with some early pre-KPB fluctuations and major post-KPB oscillations. In the 67–64 Ma interval, multiple breakpoints of $\delta^{13}C$ and pCO_2 are recognized in four stages, which represent rapid transient climate and carbon cycle events. Two breakpoints at 66.6 Ma and 66.2 Ma, along with breakpoints after the KPB (66.03 Ma), are not consistent with the onset of Deccan Traps volcanism (~66.3-66.4 Ma) and post-KPB duration (~66.0−65.6 Ma), implying the Deccan Traps degassing may not have played a major role in climate change around the KPB. The turnover breakpoint at ~65.90−66.0 Ma is coincident with the Chicxulub impact, supporting major transient climate and carbon cycle change associated with bolide impact, although the role of the Chicxulub impact on longer term climate and carbon cycle change after the KPB is uncertain. A gradual increase in $\delta^{13}C$ and pCO^2 from ~65.4 Ma may represent the onset of recovery of the terrestrial ecosystem. By comparing to the marine system, we propose that most of the major carbon cycle and climate changes do not correlate with the onset and cessation of Deccan Traps volcanism or the Chicxulub impact. We also suggest that ecosystem recovery within the terrestrial realm was a more difficult and erratic process compared to the marine ecosystem in the aftermath of the KPB.

Association of eolian facies and alluvial facies indicating widespread intermountain ergs in the Late Cretaceous South China

Chenyu Zheng[1], Xianghui Li[1*], Jingyu Wang[1]
1. Earth and Planet Sciences, Nanjing University, School of Earth sciences and Engineering, Nanjing, Jiangsu, CHINA
E-mail: seanlee@nju.edu.cn

Keywords: Alluvial-aeolian system, Late Cretaceous, Intermountain erg, South China

The Cretaceous is a period under typical greenhouse. In past, variable Cretaceous climate and the Late Cretaceous cooling have been verified by huge evidence from marine sediments and biota. And more and more terrestrial materials have been discovered and reported to support the hypothesis. Of them, the climate-sensitive eolian sandstones have been found and reported in the Cretaceous terrestrial sequences in South China. In these new findings, eolian sandstones were described and discussed on eolian facies and paleowind direction, few are involved in the association of the coarse alluvial facies.

In our recent investigation, we noted that some eolian facies are often associated with alluvial facies in the Late Cretaceous terrestrial sequences in South China. We then carried out field observation plus lithological texture identification under microscope. Results show that: sandstones are generally fine-to-medium grained (mean φ=2.53-3.59) and well-sorted, with a dominant composition of quartz, arranged in massive cross-bedded tabular bodies. The dip directions of foresets are usually NE. In SEM photos, the subrounded to rounded quartz grains displaying surface textures such as dish-shaped impact scars. The well- sorted sandstones commonly covered or interlayered cobbles and pebbles which juxtaposed singly in lineation, or interbedded with coarse sand matrix supported pebble to cobble conglomerates under slightly eroded surfaces. Locally, clast supported conglomerates deeply scoured into the well-sorted sandstones.

We interpreted the sandstone and conglomerate assemblages as two lithofacies and multiple sublithofacies. The lithofaceis are aeolian facies subdivided as aeolian dunes, interdunes, aeolian sandsheets and gobi deposits due to deflation, and alluvial deposits subdivided as ephemeral channels, pebble to cobble sheetfloods and debris flow deposits. Above features indicate that the sandstones are eolian and conglomerates are arid alluvial in origin. Taking into the spatial range of these eolian and arid alluvial facies with shape and size of the basins that occupy the facies association, we propose that the eolian facies associated with alluvial facies in the Late Cretaceous sequences are widespread intermountain ergs in South China, and they could not be the general desert in a relatively large and continuous distribution. The multiple alternative of eolian and arid alluvial facies indicates a (semi-) arid climate sustained in the middle Late Cretaceous in South China.

Keywords: Os isotope, volcanism, Cenomanian-Turonian boundary, Tibet

Oceanic anoxic event 2 (OAE2) occurred across the Cenomanian-Turonian boundary during the Cretaceous hot greenhouse climate and represents a large abrupt oceanographic- atmospheric event in a greenhouse world. The initiation of OAE2 has attracted extensive attentions and is generally believed to be associated with submarine volcanism. Although proxy records from the Northern Hemisphere show a large osmium isotope excursion indicative of volcanism apparently preceding the carbon isotope excursion (CIE) of OAE2, the timing and mechanism of the global initiation of OAE2 remain elusive in part due to the lack of detailed osmium-isotope proxy records across the OAE2 intervals in the Southern Hemisphere. Here we report a high-resolution initial osmium isotope (187Os/188Osi, Osi) and δ13Corg record from a highly expanded OAE2 interval in southern Tibet, China that was deposited in the northern margin of India Plate in eastern Tethys in the Southern Hemisphere. The Osi record documents three distinct Osi shifts toward unradiogenic compositions with increasing amplitudes at ~95.1 Ma, ~94.8 Ma, and ~94.5 Ma, respectively, indicating episodic, intensifying volcanism with the highest intensity episode at 94.5 Ma. In addition, the large Osi negative excursion at ~94.5 Ma is followed by an 200 kyr Osi minimum interval concomitant with a cooling interval as revealed by an overall broad minimum interval of the difference of the paired δ13Ccarb and δ13Corg. This cooling interval is broadly synchronous with the Plenus Cold Event (PCE) recorded in the Northern Hemisphere. Furthermore, the large Osi negative excursion paradoxically lags the onset of OAE2 by 50 kyr at the Tibetan section. Comparison with and re-examination of the expanded OAE2 record of the Yezo Group (Japan) and those from the western interior seaway (WIS) in North America reveal the regional difference in the phasing relationship between the large Osi excursions and the CIEs of OAE2. Intriguingly, the large Osi excursions occurred during a near synchronous global transgression at ~94.5 Ma that increased the connectivity of global oceans. Taken together, these results suggest that enhanced ocean connectivity was essential to spreading the perturbation of submarine volcanism to world oceans to trigger the global onset of OAE2 at ~94.5 Ma.

3. Geological Survey of Canada, Calgary Natural Resources Canada, Calgary, Alberta, CANADA

E-mail: lzhang@cugb.edu.cn

Keywords: Deccan Traps volcanism, End-Cretaceous mass extinction, Hg chemostratigraphy, Hg isotope, Northern China

The Cretaceous-Paleogene (K-Pg) boundary mass extinction is commonly attributed to the Chicxulub impact and/or the Deccan Traps (DT) volcanism, but the underlying trigger remains uncertain. The lack of detailed identification of the DT eruptive pluses impedes the full assessment of their relationship to the K-Pg boundary mass extinction. Here we present the first mercury (Hg) chemostratigraphy records on the paleo Asian plate, coupled with climatic and biotic data, to constrain the effects of the DT on the Late Cretaceous climate change and mass extinction. In northern China, a total Hg (THg) spike follows warming caused by the DT volcanism and corresponds to the significant species losses. Our study suggests that this most intense pulse of the DT (~50 kyr duration) occurred just before the K-Pg boundary and suggests that it contributed to the end-Cretaceous mass extinction in northern China.

A new prospect to study paleoenvironment of the Late Cretaceous red beds

Jinniu Chen[1,2], Chao Li[1,2], Xuegang Mao[3*]
1. School of Ocean and Earth Science, Tongji University, Shanghai, CHINA
2. State Key Laboratory of Marine Geology, Tongji University, Shanghai, CHINA
3. College of Geographical Science, Fujian Normal University, Fuzhou, Fujian, CHINA
E-mail: maoxuegang1@163.com

Keywords: Red beds, Late Cretaceous, Paleoenvironment, Paleosols

The Cretaceous red beds in southeastern China are conventionally regarded as lacustrine-fluvial sediments in basin, while their paleoenvironmental implication is still in debate. In present study, the late Cretaceous paleoenvironment documented by red beds (Liancheng and Guanzhaishan section) in the western Fujian province were investigated based on environmental magnetism, grain size, geochemistry of the paleosols. This study shows that: (i) The red beds in the western Fujian, mostly in form of interbedded siltstone with gravels, are dominated by fine silt particles with minor clay and sand. The dominant magnetic carrier in red beds is hematite, which attributes to low magnetic susceptibility in the two sections. (ii) The weathering degree, reflected by chemical index of alteration (CIA), is moderate as those formed in warm and humid climate. In addition, the rare earth elements (REE) of red beds show enriched light rare earth element (LREE), depleted heavy rare earth elements (HREE), positive Ce anomaly and negative Eu anomaly, which resembles that of average upper continental crust (UCC), thus indicating thoroughly mixing sediments. (iii) Although paleosols were recognized in the red beds, in particularly GZS section, these paleosols were weakly developed with no apparent B horizon (e. g. Bk and Bt) in paleosols profile. The conflict between moderate chemical weathering degree and weak pedogenesis infers that the red bed sediments had experienced to an extent chemical weathering in source area before deposition. The red sediments were hardly chemically weathered after deposition. It should be noted that only the red beds are not enough to diagnose paleoenvironment variations, while the paleosols must also be taken it into account, which can provide an alternative prospect in studying Cretaceous red beds. (iv) The late Cretaceous paleoenvironment in western Fujian was suspected to be arid and semiarid. The hematite in red beds were mainly derived from source area, indicating dry oxidizing environment, rather than aqueous condition.

Sedimentology and carbon isotope record of an Oxfordian carbonate ramp system, Lower Saxony Basin, Germany

Deyan zhang[1*], Francois-Nicolas Krencker[1], Stefan Huck[1], Ulrich Heimhofer[1]
1. Institute of Geology, Leibniz University Hannover, Hannover, Neddersassen, GERMANY
E-mail: zhang@geowi.uni-hannover.de

Keywords: Oxfordian, Lower Saxony Basin, Chemostratigraphy

During the Oxfordian, the Lower Saxony Basin was covered by a shallow epicontinental sea, in which a thick succession of alternating marine limestones and marls was deposited. Due to the scarcity of biostratigraphic markers and numerous sedimentary gaps, the stratigraphic dating is still uncertain and hampers further studies on a basin-wide scale.

The Bisperode section located south of Hannover, Germany, contains a ~125 m thick succession of limestone and marl of the Korallenoolith Formation (middle–upper Oxfordian). The succession features 7 superordinate facies types, composed of 13 different microfacies types. A total of fifteen small-scale and nine medium-scale sequences are identified as transgressive-regressive cycles. The depositional model is interpreted to represent a patch reef-bearing ramp that shifted to an ooid-dominated carbonate ramp.

Chemostratigraphy has been verified as a reliable means of contrasting and calibrating biostratigraphic schemes on local and global scales. A high-resolution carbon isotope record was obtained from 257 bulk rock samples (at a spacing of ~50 cm). For comparison, an additional 164 drilled powder samples were obtained in the lower part of (7.0 to 48.5 m) the section (at a spacing of ~25 cm). Values from the bulk rock sample show the same trend as those of the drilled powder. Carbon isotope values vary between -0.1 and +3.1 ‰ and show some distinct long-term variations across the section, although, different depositional environments display facies dependent carbon isotope ratios. The new chemostratigraphic data enable correlation with the previous carbon isotope records (Konrad core, Eulenflucht core, and Steinbergen section). Based on this, a composite high-resolution carbon isotope stratigraphic record for Oxfordian successions in the Lower Saxony Basin can be established. Bulk geochemistry parameters of mineral data provide additional information and complement the sedimentological data.

Mid-latitude precipitation in East Asia influenced by a fluctuating greenhouse climate during the latest Cretaceous through the earliest Paleogene

Jiquan Chen[1*]

1. School of Earth Sciences and Resources, China University of Geosciences, Beijing, Beijing , Beijing, CHINA

E-mail: jqchen@cugb.edu.cn

Keywords: Cretaceous, Songliao Basin, greenhouse climate, precipitation, East Asia, paleosol

Deep-time records from greenhouse climate periods (e.g., the Late Cretaceous) provide a reference point for understanding how high atmospheric CO2 concentrations influence precipitation in the mid-latitude Northern Hemisphere (e.g., East Asia). In this study, we quantitatively reconstruct mean annual precipitation (MAP) in East Asia during the latest Cretaceous through the earliest Paleogene (~76-65.5 Ma), based on a well-studied paleosol sequence from the Sifangtai and Mingshui Formations from the SK-1n scientific borehole in the Songliao Basin, northeastern China. We use several proxies, depth to the calcic horizon (DTC) and two elemental geochemistry proxies in the paleosol B horizon (CIA-K, CALMAG), which all show clear changes in the MAP associated with warming and cooling events. In the warming period (e.g., at ~69.5-68.5 Ma), an increase in the land-sea thermal contrast led to an expanded, enhanced, poleward-shifted thermal low-pressure system over the East Asian continent, which triggered an enhanced hydrological cycle and increasing MAP in the Songliao Basin. During the cooling period (e.g., at ~72.5-69.5 Ma and ~68.5-66.5 Ma), weakened East Asian monsoon and strengthened equatorward-shifted westerlies allowed for colder and arid air masses to encroach upon the Songliao Basin, which led to decreased MAP. Changes in MAP across the K-Pg boundary coincide with climate fluctuations and catastrophic geological events. Furthermore, our work compares three warming intervals in deep-time (middle Maastrichtian, late Maastrichtian and earliest Paleogene) with Shared Socio-economic Pathway scenarios used by the IPCC for the end of the 21st century, and indicate MAP increases in East Asia with ongoing anthropogenic CO2 emissions.

The Cretaceous (early Albian to early Campanian) biostratigraphy and paleotemperature reconstruction of the eastern Tethys: Calcareous nannofossil evidences from southern Tibet, China

E-mail: xichen@cugb.edu.cn

Keywords: Cretaceous, Eastern Tethys, Southern Tibet, Calcareous nannofossils, Biostratigraphy, Paleoclimate

Studies of geochemical proxies, e.g., carbonate $\delta^{18}O$ and TEX_{86} have documented that the Earth's climate significantly changed during the Cretaceous Period. However, the knowledge about the sea surface temperature (SST) history of the eastern Tethys was limited owing to the diagenetic alteration of carbonate and organic biomarkers. Based on calcareous nannofossil records of the Nirang section, this paper studies the biostratigraphy and SST evolution of the Cretaceous in the Tethys Himalayas of southern Tibet. There are 131 species identified from the studied succession. Twelve bioevents were recognized, allowing us to assign an early Albian to early Campanian age (CC8 to CC18 biozones) of the section. Meanwhile, a disconformity within 81-71Ma was identified in the early Campanian–early Maastrichtian. The SST evolution was analyzed by calcareous nannofossils Modified Temperature Index (MTI). The MTI results reveal that the long-term SST changes in the Tethys Himalayas of southern Tibet experienced a progressively warming from early Albian to early Turonian followed by rapid cooling in middle Turonian, and a warmth persisted interval till early Campanian. Short-term warming and cooling intervals, e.g., rapid warming in early Albian and latest Albian, cooling in the late Albian, peak warmth at Cenomanian–Turonian transition, and cooling in the middle Turonian are recorded in the study area too. The SST history of eastern Tethys can be well correlated to neighboring Exmouth Plateau and southern high latitude deep- sea sites. However, the compilation of TEX_{86} data indicates a substantial cooling during the Coniacian to Campanian. We suggest that the north drift of the Indian continent towards the equator is likely responsible for sustained warmth in the Tethys Himalayas during late Turonian to early Campanian, although the paleoclimate could be cooling.

A high-resolution record of paleoenvironmental changes across the Pliensbachian-Toarcian boundary from Yorkshire, UK

Yuqing Zhu[1], David Bryan Kemp[1*]
1. School of Earth Sciences, China University of Geosciences Wuhan, Wuhan, HuBei, CHINA
E-mail: davidkemp@cug.edu.cn

Keywords: Mercury, Organic carbon-isotope, Carbon cycle, Pliensbachian-Toarcian, Sea level

The Toarcian Oceanic Anoxic Event (T-OAE; ~183 Ma ago) in the Early Jurassic Period was one of the largest perturbations to the climate system of the past 250 Ma. It is recorded in sedimentary rocks as a pronounced negative carbon-isotope excursion (CIE) in the major biospheric reservoirs of carbon, suggesting a major release of 12C-enriched carbon to the ocean-atmosphere system. Across the Pliensbachian-Toarcian boundary (PTB), a smaller negative CIE has been recorded from many sections worldwide. Like the later T-OAE, the PTB event was associated with seawater warming and biotic extinction. Both events were likely temporally coincident with Karoo-Ferrar Large Igneous Province emplacement. Consequently, carbon effusion related to large-scale volcanism has been suggested as a causal driver of the PTB event and T-OAE. Nevertheless, the precise nature and global significance of the PTB event is unclear. Here, we present new high-resolution sedimentological and geochemical data from bulk organic-rich rocks spanning the late Pliensbachian to early Toarcian from Yorkshire (UK). We show that the negative CIE (magnitude of ~4‰) across the PTB was followed by a hitherto unrecognized and smaller negative CIE (magnitude of ~2‰) in the Dactylioceras tenuicostatum ammonite Zone. Both perturbations coincide with evidence for sea-level fall and elevated organic carbon and mercury concentrations. In addition, the tenuicostatum CIE was coeval with storm deposits and evidence for seawater deoxygenation. Our preliminary research indicates that both events were superimposed on a complex pattern of sea-level change. Changes in the flux of terrestrial organic matter related to sea level change may have been the cause of the observed mercury anomalies, rather than volcanism. The cause and significance of the tenuicostatum CIE remains unclear, but our study adds new detail for understanding the pattern of paleoenvironmental change during this interval of the Early Jurassic.

High-resolution sedimentation rate determined by cyclostratigraphy in an Aptian pre-salt lacustrine carbonate system, offshore Brazil

Xiao-Fa Yang[1*]
1. Research Institute of Petroleum Exploration & Development, PetroChina, Beijing, CHINA
E-mail: ouyangxiaofa@petrochina.com.cn

Keywords: sedimentation rate, cyclostratigraphy, lacustrine carbonate system, Brazil

The discovery of large-scale oilfields in the offshore Basins has revived interest in the exploration of the Aptian pre-salt carbonate systems in the Brazilian southeastern continental margin. Aptian lacustrine carbonate systems are characterized by special texture and mineral composition whose distribution and correlation have been broadly discussed in the last decade. Power spectral, Fourier transform, and correlation coefficient analyses of the gamma-ray logging data from an exploration borehole reveal strong astronomical signals of long eccentricity, short eccentricity, and obliquity cycles during Early Cretaceous. On the basis of the long eccentricity (405 kyr) tuning 4.5 astronomical time scales results, the carbonate systems above the basalt strata covers a 1.8 Ma period from 113.0 Ma to 114.8 Ma. The high-resolution sedimentation rates of the carbonate strata vary from 9.5 cm/kyr to 12.09 cm/kyr. This result is in good agreement with the paleontological ostracod biozones ages and the basalt Ar-Ar ages. This case study supports the cyclostratigraphic interpretation of a Cretaceous magnetic susceptibility series and provides new insights into changes of the depositional setting in an Aptian pre-salt lacustrine carbonate system.

Climate simulation supports ENSO activity from the Late Cretaceous California

Jianming Qin[1], Yuan Gao[1*], Jian Zhang[2], Chengshan Wang[1]
1. School of Earth Sciences and Resources, China University of Geosciences Beijing, Beijing, CHINA
2. School of Physics, Peking University, Beijing, CHINA
E-mail: yuangao@cugb.edu.cn

Keywords: Climate Simulation, Greenhouse Climate, ENSO, Terrigenous Laminae

Using climate simulation, we provide a new explanation of teleconnections between late Cretaceous El Niño – Southern Oscillation (ENSO) variability and participation proxy data from annually-resolved terrigenous laminae of Marca Shale, California persented by Davies et al. (2011). Our coupled climate simulation (first published by Zhang et al. (2019)) of the Late Cretaceous generates ENSO with similar periodicities in tropical Pacific sea-surface temperatures (SST) and atmospheric teleconnection to California precipitation. We think the teleconneection between tropical Pacific SST and participation of California is similar with them in Holocene(Du et al., 2020), when tropical Pacific SST changed the Aleutian Low and the Sub-tropical High, caused a longitudinal moving of Westerlies, then influenced the participation of California. Our evidence suggests that ENSO operated in the Late Cretaceous greenhouse climate.

Reconstruction of Quantitative Lithofacies Palaeogeography Based on Latent Class Analysis from Observed Samples

Yupeng Li[1*]
1. Beijing Research Center of EXPEC ARC, Saudi Aramco, Beijing, CHINA
E-mail: yupeng.ua@live.com

Keywords: data–driven, latent structural analysis, quantitative palaeogeography

The conventional quantitative lithofacies palaeogeography mapping method is summarized as single factor analysis and multiple factor comprehensive. It has been widely accepted and very often used in the compilation of lithofacies palaeogeography maps. However, the procedure requires high experiences and the final map can't avoid certain degree of bias based on the experience of the geologist performing the multi-factor comprehensive mapping. This stems from the fact that there is no mathematical principle involved to achieve the single factor superposition. Therefore, it is necessary to deploy a mathematical relationship when performing the lithological palaeogeography map comprehension to achieve a superior data–driven approach and avoid any possible objective bias.

This study proposes a quantitative lithofacies palaeogeography analysis method based on latent class analysis that can provide a solid mathematical theory for the traditional lithofacies palaeogeography mapping procedure. Latent class analysis is a class of latent structural analysis methods proposed in the 1950s by Lazarsfeld and Henry and improved by Goodman (Lazarsfeld and Henry, 1968; Goodman, 1974). The proposed workflow can be divided into the following four integrated steps:

First step is to design of the questions before a questionnaire survey in sociological research, which is the basis for all subsequent analysis work. The lithofacies paleogeography analysis identifies the possible investigative factors for the specific research target area, such as the formation thickness, certain lithology content, etc. Each factor will be looked at as a manifest variable in later latent analysis.

Second step is to count the outcomes of all the observation locations or samples to get the spatial distribution characteristics of each manifest variable. All questions must be answered at each observation location that means all factors should be investigated from each sample. Only in this way can the spatial correlation of each factor (manifest variable) be built in the same probability statistics space.

In third step, it is to transform the manifest variables to latent variables. Using the latent classes to integrate multiple manifest variables will change the data analysis space from a higher statistic dimension into a lower one. This will reveal geological features embedded in multiple manifest variables.

The final step is lithofacies palaeogeography mapping. The latent class analysis model obtained in the previous step is used to explain each observation location sample outcome.

One case study presented in this study shows that the latent class analysis will make the superposition of multiple factors automatically, and the final obtained map reflects the distribution characteristics from the observations. The synthesis procedure based on a rigorous mathematical principle presents an improvement on the classic single factor analysis and multiple factor comprehensive method by extracting and characterizing the geological patterns embedded in all the observations.Thus, the conventional single factor analysis and multifactor integration method is now transformed with probability theory based latent analysis theory.

Provenance of Lower Jurassic sediments in the South China Continental Margin: Evidence from U-Pb ages of detrital zircons

Jintao Kong[1], Zhongjie Xu[1*]
1. College of Earth Sciences, Jilin University, Changchun, Jilin Province, CHINA
E-mail: zhongjiexu@jlu.edu.cn

Keywords: Chi-square test, Detrital Zircon geochronology, South China Craton, Source to sink

In the Early Jurassic, a large-scale transgression occurred on the South China Continental Margin (SCCM), affected by the initiation of Paleo-Pacific subduction. This transgression significantly influenced the source areas and transport mode of Lower Jurassic sediments in the SCCM. This study presented 640 new detrital zircon ages to discuss the Early Jurassic source to sink system in the SCCM. The Chi-square test and multidimensional scaling (MDS) indicated that the major sinks can be divided into the western, central, and eastern SCCM. The Yunkai Terrane and Hainan Island were primary source areas for the western SCCM. The Wuyi Terrane and Nanling Tectonic Belt provided abundant detrital materials for the eastern SCCM. It should be noted that the central SCCM was a vast shallow sea in the Early Jurassic due to the large-scale transgression. Thus, the coastal currents and drowned pre-Jurassic river valleys controlled sediment delivery to the central SCCM. Overall, the Lower Jurassic sediments distribution system in the SCCM was significantly affected by Paleo-Pacific subduction.

Provenance of flysch and molasse separated by basal ~360Ma unconformity from Chinese Tianshan area: Constraints on the Silurian to Mississippian tectono-paleogeographic evolution in the southwestern Central Asian Orogenic Belt

Meng Zhang[1*], Guocan Wang[1], Xionghua Zhang[1], Ruilu Guo[2], Wei Wang[2]
1. School of Earth Science, China University of Geosciences (Wuhan, Wuhan, Hubei , CHINA
2. Insistute of Institute of Geological Survey, Institute of Advanced Studies, China University of Geosciences (Wuhan), Wuhan, Hubei , CHINA
E-mail: cugzhangmeng@163.com

Keywords: provenance, flysch and molasse, tectono-paleogeographic evolution, southwestern Central Asian Orogenic Belt

Tectono-paleogeographic reconstruction in the tectonic switching eras of the Central Asian Orogenic Belt (CAOB) could decipher its multiple accretionary process during Paleozoic. In the Dananhu-Harlik Arc, Yili-Central Tianshan Arc and the North Tianshan Complex between two arcs from the southwestern CAOB, the Latest Devonian to Early Carboniferous molasse or volcanic rocks unconformably overlie on the pre-Late Devonian flysch, volcanic rocks, metamorphic rocks and ophiolitic rocks. In this contribution, we focused on the provenance evolution from each side of the Ordovician to Early Devonian Dacaotan Ophiolite located in the northern North Tianshan Complex. In the north side of the Dacaotan Ophiolite, three Silurian to Middle Devonian flysch samples contain no or minor Precambrian age scatters, and respectively yield the major age ranges of 550-420Ma, 550-390Ma and 400-370Ma. The εHf(t) values of zircons with 370-480Ma ages in these samples yield values of 4.65 to 15.71. In contrast, in the south side of the Dacaotan Ophiolite, the ~420Ma flysch sample yield the age ranges of 420-500Ma, 850-1000Ma and 1200-1800Ma and the εHf(t) values of Paleozoic zircons ranging from -9.86 to 1.18, and the ~380Ma flysch samples contain the similar age ranges and the dominantly negative εHf(t) values (Chen et al., 2019). However, the Latest Devonian to Mississippian molasse in the two arcs and North Tianshan Complex commonly contains the 330-400 age ranges (Zhang et al., 2013; Liu et al., 2014). In the Dananhu-Harlik Arc, the detrital zircons with 400-330Ma ages have εHf(t) values that range between -9.92 to 15.36 (Li et al., 2020), whereas in the south side of the Dacaotan Ophiolite, the 400-330Ma zircons yield εHf(t) values ranging from 11.75 to 14.35. These new evidences and reviews suggest that the Dananhu-Harlik and Yili-Central Tianshan Arcs are two discrete arcs during the Silurian to Middle Devonian, and they were mutually amalgamated along the Dacaotan Suture in the Latest Devonian, leading to the formation of basal ~360Ma unconformity in the two arcs and the North Tianshan Complex, and the mutual transportation of crustal material across the suture of two arcs. Moreover, our other contribution shows that the similarity value of Middle Devonian rugosa coral fauna is predominantly higher than the Early Devonian rugosa coral fauna between these two arcs, suggesting that the Dananhu-Harlik Arc gradually moved closer to the Yili-Central Tianshan Arc during the Early to Middle Devonian. Comprehensively combining with the data about the ophiolites, magmatism, structural deformation, provenance, and paleobiogeography from the southwestern CAOB, we speculate that the bidirectional roll-back subduction of the North Tianshan Ocean led to the extension of the Kalamaili and South Tianshan back-arc oceanic basins and the convergence of the Dananhu-Harlik and Yili-Central Tianshan Arcs. After the arc-arc amalgamation, the ocean basins connected with the sutured North Tianshan Ocean and back-arc basins continuingly subducted until the Permian, leading to the formation of the Carboniferous to Permian intra-arc basin with immature oceanic crust in the composite arc.

Keywords: deep sea, detrital zircon, Gulf of Mexico, Miocene, sediment mixing

Sediment routing from hinterland to the deep sea is complicated because it involves evolution of river drainage from source areas to coastal plains and sediment mixing on the shelf and slope by marine currents. Previous regional paleogeographic mapping in the Gulf of Mexico (GOM) has observed a >150 km offset between the middle Miocene paleo-Tennessee fluvial axis and the associated deep-sea fan depositional axis, indicating a complicated sediment pathway. We integrate new and published detrital zircon (DZ) U-Pb age data from fluvial, shelf and deep-sea deposits to examine the complex Miocene sediment routing system in the northern GOM. These data suggest an increase in sediment load derived from western North America (increased Western Cordillera terranes; <300 Ma zircon age component) from the early to middle Miocene in the deep-water Green Canyon protraction area. The early Miocene Green Canyon area received sediments mainly from fluvial axes located directly updip: the paleo-Mississippi River (44%–56%; characterized by Yavapai-Mazatzal, Mid-Continent and Western Cordillera sourced 1800–1600 Ma, 1500–1300 Ma and <300 Ma, respectively, and Grenville-Appalachian sourced 1300–950 Ma and 500–300 Ma age components) and smaller rivers and tributaries draining the Appalachian Mountains (e.g. paleo-Tennessee River, 18%–43%; mainly Grenville-Appalachian sourced 1300–9500 Ma and 500–300 Ma age components). In contrast, the middle Miocene Green Canyon deep-sea fan shows a strong DZ signal from the paleo-Red River (38%; increased <300 Ma zircon age component), which requires input of additional sediment sources from west of the paleo-Mississippi system. In addition, the paleo-Tennessee River, which was a major middle-Miocene sediment source for the central-eastern GOM due to uplift and increased erosion of the Appalachian Mountains, is underrepresented (34%; decreased 1300–950 Ma zircon age component) in the middle Miocene Green Canyon fan. We suggest that two mechanisms combined to produce the increased middle Miocene input from western sediment sources and restriction of locally up-dip Tennessee River sources: (1) regional drainage changes involving middle Miocene capture of the paleo-Red River and its tributaries by the paleo-Mississippi River, which at the same time lost some of its eastern tributaries owing to expansion of the paleo-Tennessee and (2) eastward (clockwise) marine transport of western-sourced sediment along the shelf or slope, which deflected the paleo-Tennessee signal >150 km eastward to feed the deep-sea fan further east, perhaps reflecting intensification of a precursor to the GOM Loop Current.

Paleogeography is the merger of sediment and volcanic facies, depositional settings, tectonic plate movements, topography, climate patterns and ecosystems through time. The construction of paleogeographic maps on tectonic plate reconstruction models requires a team effort to compile databases, data-sharing standards and computer projection methods. Two goals of the Paleogeography working group of the International Union of Geological Sciences (IUGS) program for Deep-Time Digital Earth (DDE) are: (1) to interlink on-line national lexicons for all sedimentary and volcanic formations, and develop on-line ones for nations that currently lack these; (2) to target specific regions and intervals for testing/showcasing paleogeography output from the merger of these databases.

Following those goals, we developed new cloud-based lexicons and applied interactive visualization techniques to regions in East Asia. This has been a successful collaboration among computer-engineers, plate-modelers and stratigraphers in India (ONGC), China (Chengdu Univ. Tech., and Chinese Acad. Geol. Sci.), USA (Purdue Univ., and Paleomap Project), Australia (GPlates visualization team) and Vietnam (Vietnam Nat. Univ.). Independent online lexicons with map-based and stratigraphic-based user-interfaces have been developed for all Proterozoic to Quaternary formations on the Indian Plate (over 800), the majority of the Devonian through Neogene of China, (ca. 1700 as of April 2022), and partially for Thailand and Vietnam. A multi-database search system returns all geologic formations of a desired date or geologic stage from these 4 independent databases. With one-click, a user can plot the regional extent of one or of all of those regional formations on different plate reconstruction models of that desired age. In the future, the fillings of the formation polygons will be either appropriate lithologic facies patterns or color-coding of interpreted depositional environments

Provenances of Shuangyingshan Clastic Rocks in Beishan Orogen and Implications for Continental Evolution

Ning Huo[1], Qianqian Guo[1*], Yichao Chen[1]
1. School of Earth and Planetary Sciences, University of Chinese Academy of Sciences, Beijing, CHINA
E-mail: guoqqyj@163.com

Keywords: Central Asian orogenic belt, Beishan, Clastic rocks, Continental evolution

The formation and evolution of the continental crust is an essential part of solid earth science research. The accretionary orogenic belt is a critical area for the growth of the continental crust. Yet, the estimation of the actual content of the new crust is often affected by the different anatomical ideas of the orogenic belt. The growth mechanism of accretionary orogenic belts, especially the key question of whether the accretionary orogenic belt is a collage of micro-continents or an accretionary wedge accretionary arc-type growth, is still controversial. This research studied the clastic rocks in the Shuangyingshan area of Beishan, which is located on the southern margin of the Central Asian orogenic belt, and came up with the following findings:

(1) The detrital zircon LA-ICP-MS U-Pb chronology results show that the maximum deposition age of the four clastic rock samples collected from the YingMaotuo, Shajing, and Zelumu is 503Ma, 443Ma, 431Ma, and 539Ma. The maximum deposition age of Shuangyingshan clastic rocks in Beishan is Early Silurian. This result is against the so-called Beishan Precambrian complex.

(2) Microscopic observations of clastic rocks show that they are mainly composed of mineral debris such as quartz, feldspar, and detritus, indicating an inmatured source, probably the fore-arc accretionary complexes.

(3) Whole-rock major and trace element analysis shows that the clastic rocks are characterized by high Si, Al, Na+K, and low Mg. The La/Sc, Th/Sc, La/Co, Th/Co, and Th/Cr values of the studied samples point well to the felsic source region. The εHf(t) values of the clastic samples indicate that a large amount of juvenile crust is involved.

(4) The distribution spectrum of the detrital zircons of the Tarim Craton is entirely different from the Shuangyingshan area in Beishan, which indicates that the clastic rocks in the Shuangyingshan area cannot be supplied by a hypostatic microcontinent from the Tarim Craton.

This result supports the idea that the crust of the Beishan orogenic belt is growing in the form of successive accretionary wedges and accretionary arcs, rather than in the form of a simple collage of continents.

Keywords: interglacial intensity, sorting coefficient, Ili loess, mid-Brunhes transition, Northern Hemisphere ice volume

Quantifying the spatiotemporal characteristics of interglacial periods enhances our understanding of the current warm period and improves predictions of future climate change. However, the intensity of precipitation during interglacial periods varied across Asia, especially between interglacials that occurred before and after the mid-Brunhes transition (MBT, around 430 ka). In this study, we present a high-resolution eolian dust record documenting the past 900,000 years, which was retrieved from the thickest loess borehole sequence (202.49 m) in the Ili Basin, Central Asia and conduct modelling study. We propose that the sorting coefficient of Ili loess is a more sensitive proxy for wind intensity than commonly used mean grain size, and the sorting coefficient is further used to reflect Northern Hemisphere ice volume (NHIV). Supported by numerical modeling experiments and additional multiple lines of evidence, we suggest that increased NHIV during post-MBT interglacials relative to pre-MBT interglacials caused heterogeneous precipitation intensity during interglacials over Asia.

Keywords: Climate paleogeography, Knowledge system, Paleoclimate classification, Deep-Time Digital Earth program

The climate paleogeography, especially the climate classifications, helps to interpret the global and regional climate changes and intuitively compare the climate conditions in different regions. However, the application of climate classification in deep time (i.e., climate paleogeography) is prohibited due to the usually qualitatively constrained paleoclimate and the inconsistent descriptions and semantic heterogeneity of the climate types. In this study, a climate paleogeography knowledge system is established under the framework of the Deep-Time Digital Earth program (DDE). The hierarchical knowledge system consists of five paleoclimate classifications based on various strategies. The classifications are described and their strengths and weaknesses are fully evaluated in four aspects: "simplicity, applicability, quantifiability, and comparability". We also reconstruct the global climate distributions in the Late Cretaceous according to these classifications. The results are compared and the relationships among these climate types in different classifications are evaluated. Our study unifies scientific concepts from different paleoclimate classifications, which provides important theoretical basis for the application of paleoclimate classifications in deep time.

E-mail: alexandre.pohl@u-bourgogne.fr

Keywords: Cambrian, paleogeography, climate, model-data comparison, general circulation model

The Proterozoic/Phanerozoic transition was characterised by major changes in Earth's biosphere and step-changes in the nature of Earth's chemical cycles. Unfortunately, loose constraints on the palaeogeographic and climatic context hamper interpretation of the co-evolution of the biosphere and the physical environment over this interval. Cambrian palaeogeographies proposed in the literature can be highly variable. For example, different configurations have positioned Gondwana either spanning the full range of southern palaeolatitudes, or rotated 90° and occupying only tropical palaeolatitudes. Quantitative palaeoclimate data are becoming available for the early Cambrian Period, though these data remain scarce and do not yet present a coherent global picture. A more geographically extensive dataset is required to evaluate climatic hypotheses on a global scale. Here, we couple lithological indicators of palaeoclimate with general circulation model simulations to assess the (dis)agreement between data and model predictions of early Cambrian climate under contrasting palaeogeographies. The concordance between geological data and model simulations is scored to assess the relative merits of each palaeogeographic reconstruction. This study highlights the potential of coupling numerical climate models and qualitative palaeoclimate data to refine our understanding of the Cambrian world, and provide climatic and geographic context for the rise of animal-rich ecosystems.

Keywords: paleogeography, digital twin, tectonics, geodynamics

The geological record, despite the spatial and temporal gaps and biases, provides the crucial time capsules that help us reconstruct the past state of Earth in deep time. Although a wide range of efforts are underway to construct a present-day Digital Twin of Earth (important for geo-hazards, etc.), fewer efforts have been focused on establishing a “Deep-time Digital Earth”. Here we describe the framework for a deep-time digital twin of our planet that captures processes from deep mantle flow to surface tectonics, eustasy and flexure, landscape evolution, and climate. These models require a range of geological data constraints and have the benefit of being able to “fill gaps” both in spatial and temporal domains, where regional data coverage is appropriate, while also providing an opportunity to evaluate uncertainties and competing geological interpretations.

The new generation of deep-time digital Earth models incorporate stratigraphic, igneous, metamorphic, and paleontological constraints for the tectonic and paleogeographic evolution of our planet for the Phanerozoic (with emerging models covering even older timeframes). Importantly, keeping track of data inputs and time-evolving data coverage is key to understanding uncertainty and targeting regions for additional data collection where the geological record may be under-sampled. We demonstrate how plate tectonic reconstructions in the community (py)GPlates (www.gplates.org) framework can be used to drive mantle flow models, and explore rigid and deforming plate evolution. These components of the solid Earth system can be linked to ocean-atmosphere climate simulations, as well as landscape evolution models (such as pyBadlands) to also explore the influence of eustasy, flexure, climate and even aspects of the biosphere (such as reef systems), all of which were previously prohibitive to consider in a self-consistent deep-time tectonic and paleogeographic context.

Given the cost of collecting and analysing geological data, these models are an important value-adding step that enables us to extract additional knowledge from previously disparate data collections. The “deep-time digital twins” of our planet also provide unprecedented opportunities for transdisciplinary discoveries ranging from basic Earth science to evolutionary biology, resource exploration, and understanding changes in planetary habitability.

A Reconstruction of palaeodrainage patterns for South-East Gondwana basins of peninsular India in the Palaeozoic-Mesozoic period

Sankar Kumar Nahak[1], Santanu Banerjee[1*]
1. Department of Earth Sciences, IIT Bombay, Mumbai, Maharashtra, INDIA
E-mail: santanu@iitb.ac.in

Keywords: Palaeo-drainage, Detrital zircon, Geochronology, Palaeo-reconstruction, Gondwana, Mesozoic

Gondwana Supergroup is defined by continental rift-basin deposits, with minor marine inputs, formed between the late Carbonaceous and lower Cretaceous. Excellent outcrops of Gondwana sediments are exposed along three river valleys along the eastern margin of the Indian continent: Damodar Valley, Son-Mahanadi Valley, and Pranhita-Godavari Valley. These south-east Gondwana sedimentary strata reflect the reversal of the present drainage pattern of the basins (Damodar, Satpura, Son-Mahanadi, and Pranhita-Godavari basin) in the Mesozoic. The reversal of drainage patterns is related to the upliftment of plumes related to hotspot reactivity and plate reorganization. The present-day drainage pattern follows these same Permian grabens, but in the opposite direction. However, the exact timing of the drainage reversal during the Mesozoic is yet to be constrained.

The proposed study will focus on tracing provenance, tectonic settings, transport history, and for time stratigraphic correlation and sedimentary environment. The vertical differences of heavy mineral assemblages in sandstone will be examined for understanding the evolution process and the uplift-denudation process of the provenance area. Sandstones are mixtures of mineral grains and rock fragments coming from naturally disaggregated products of erosion of all types of rocks. Hence, the study of sandstones plays a vital role in searching the sources of sediments and reconstruction of tectonics. The petrographic study of sandstone will provide information about the lithologic composition, weathering, sediment recycling, and distance from the depositional site. The QFR plot will be made by using Gazzi-Dickinson point-counting method. The provenance and the tectonic setting of the sandstone will be interpreted by using QFR modal analysis techniques, and it can also differentiate between the textural and mineralogical maturity.

Detrital zircon U-Pb geochronology will be used for distinguishing provenance histories, age spectrum, correlating stratigraphic units, and crustal evolution. By using the Laser-ablation–inductively coupled plasma–mass spectrometry (LA-ICP-MS) it is proposed to estimate, U-Pb crystallization ages and Hf isotope ratios from detrital zircon of the Mesozoic sandstone. This combination of U-Pb ages and Hf isotopic compositions of single-grain detrital zircons makes it possible to determine, through each grain, not only the age but the nature and source of the host magma. By studying all sources of data from Gondwana basins of peninsular India, we will be able to correlate the sediment dispersal pattern, stratigraphic correlation, and crustal evolution of other Gondwana basins of the world.

E-mail: ymgong@cug.edu.cn

Keywords: Cyclostratigraphy, orbital forcing, F–F mass extinction, sea level changes, Kellwasser events

One of the five great mass extinctions of the Phanerozoic is the Frasnian–Famennian (F–F) mass extinction, for which the causes have not yet been identified. In this study, cyclostratigraphic analysis of two F–F transition sections was carried out in South China: the Yangdi section, a marine slope facies, and the Lali section, a marine basin facies. Paleoclimate proxy data collected at high resolution along these sections include magnetic susceptibility and X-ray fluorescence geochemistry. Time series analysis and modeling of the proxy data reveal that frequencies comparable to those of the Earth's long and short orbital eccentricity, obliquity, and precession index characterize the two successions. Metronomic 405-kyr long orbital eccentricity cycles identified along the two sections were used to construct a floating astronomical time scale across the F–F transition, revealing that 1000 kyr separates the Lower and Upper Kellwasser horizons (LKH and UKH), and ~1600 kyr separates the maximum values of the LKH and UKH δ13C excursions. The estimated duration of the UKH is 150 kyr, during which the first, second, and third extinctions of the F–F biotic crisis lasted 120 kyr, 20 kyr, and 10 kyr, respectively. Sedimentary noise models of the magnetic susceptibility and Ca concentration time series indicate that changes in sedimentary noise correspond to sea level variations. Modeling suggests that the long orbital eccentricity cycles controlled sea surface temperatures, and that third-order eustatic changes were forced by the combined orbital eccentricity and obliquity variations. Finally, we propose an "astronomical climate change" model as a defining mechanism of the F–F biotic crisis.

Eocene hyperthermal events in the terrestrial system: Geochronological and astrochronological constraints in the Fushun Basin, NE China

Tingting Yu[1*]
1. , Jilin University, , , CHINA
E-mail: 963721074@qq.com

Keywords: Eocene,Astronomical orbital,Hyperthermal events,Organic matter enrichment,Terrestrial system

Frequent hyperthermal events during the Eocene (55-47 Ma), primarily characterised by carbon isotope excursions (CIEs), have been identified from marine records worldwide. However, only a few excursions have been recognised and described in continental deposits, thereby limiting the understanding of the effect of global warming on terrestrial systems. Thick, dark, organic-rich mudstone containing complete astronomical age information was deposited during the Palaeogene in the Fushun Basin. Based on U–Pb zircon dating and Milankovitch cycle analysis, the astronomical time scale (ATS) of the Fushun Basin was established. Based on the high-resolution chronostratigraphic framework, combined with the negative migration characteristics of organic carbon isotopes (δ13CTOC), three hyperthermal events were identified: Eocene Thermal Maximum 2 (ETM2), Eocene Thermal Maximum (ETM3) and long-term Early Eocene Climatic Optimum (EECO). In particular, several periods of short-term hyperthermal events were identified in the EECO period: L, M, N, O, P, Q, R, S, T, U, V, W, C22nH3, C22nH4, C22nH5, C21rH1, C21rH2, C21rH3, C21rH4, C21rH5, C21nH1 and C21nH2. The records of sea and land hyperthermal events show that the records corresponding to land basins are timelier and more sensitive.

3. School of Earth and Space Sciences, Peking University, Beijing, CHINA
4. Department of Atmospheric, Oceanic and Earth Sciences, George Mason University, Fairfax, Virginia, UNITED STATES
E-mail: yaox@lzu.edu.cn

Keywords: Orbital eccentricity metronomes, cyclostratigraphic-calibrated GPTS, astronomical origin, Miocene red-green mudstones, northeastern Tibet

Studies of lacustrine cyclostratigraphy in northeastern Tibet have made great strides in reconstructing the regional precipitation and aridification, and disentangling paleoclimate signals arising from the uplift of the Tibetan Plateau during the Miocene Epoch. A major success has been the recognition of Milankovitch forcing in the cyclostratigraphy reaching back through the Cenozoic. However, this cyclostratigraphy needs detailed calibration between the orbital metronomes and the Geomagnetic Polarity Time Scale (GPTS) to improve the accuracy and precision of age models. The orbital eccentricity metronome (405-kyr cycle) is typically applied to develop an age calibration between cyclostratigraphy and the GPTS. However, 405-kyr cycles have been difficult to detect in Cenozoic cyclostratigraphy of northeastern Tibet. Here we present an analysis of Miocene red-green mudstone sections by considering lithological color rank series. We formulate binary color rankings for the red-green mudstone rhythms based on published lithology logs from 8 Ma to 22 Ma. Time-frequency analysis of the color rank series highlights predominant 405-kyr cycles, which were previously unnoticed in other paleoclimate proxies. Our results include a calibration between 405-kyr-tuned cyclostratigraphy and the GPTS, identifying the orbital eccentricity (405-kyr) metronome from E19 to E53 in the reconstructed color rank time series. The red and green mudstone layers correspond respectively to the maxima and minima of long orbital eccentricity (405-kyr) cycles. The red mudstones formed in floodplain environments corresponding to warm-humid climate, whereas green mudstones formed in high-energy marginal lake environments corresponding to cold-dry climate. We propose that intensified precipitation during maximum orbital eccentricity resulted in higher fluvial detrital input, leading to red mud deposition in the basin, whereas less precipitation during minimum orbital eccentricity resulted in lower detrital input, leading to green mud deposition in the basin.

Accurate time scale recovery by estimating variable carbonate accumulation rates in oceanic sedimentary sequences

Jonathan Hammer[1], Linda Alide Hinnov[1*]
1. Atmospheric, Oceanic, and Earth Sciences, George Mason University, Fairfax, Virginia, UNITED STATES
E-mail: lhinnov@gmu.edu

Keywords: cyclostratigraphy, time scale, sedimentation rate

We present a two-component model for sediment accumulation rate and time scale recovery for oceanic sedimentary sequences. In this model, one component, typically the insoluble fraction, accumulates at a constant rate, and the other component, typically the carbonate fraction, varies. Using empirical weight percent of the variable component, an algorithmic solution is derived that determines the relationship between stratigraphic position and time. Artificial examples demonstrate that when the model assumptions are accurate the algorithm provides a near-exact solution. Algorithm performance is explored under a wide range of model assumptions. Finally, the algorithm is applied to well known oceanic sedimentary sequence datasets from the Late Quaternary icehouse and mid-Cretaceous greenhouse. We compare results with previous, independently determined time scales for the sequences. We discuss the potential application of this algorithm for a wide variety of sedimentary sequences.

Organic carbon burial is paced by a ~173 kyr obliquity cycle in the middle to high latitudes

He Huang[1*]

1. School of Earth science and Resource, China University of Geosciences (Beijing), Beijing, CHINA

E-mail: huang1006@cugb.edu.cn

Keywords: orbital cycle, nonlinear response, carbon burial, mid-high latitude

Earth's climate system is complex and inherently nonlinear, which can induce some extraneous cycles in paleoclimatic proxies at orbital time scales. The paleoenvironmental consequences of these extraneous cycles are debated owing to their complex origin. Here, we compile high-resolution datasets of total organic carbon (TOC) and stable carbon isotope (13Corg) datasets to investigate organic carbon burial processes in middle to high latitudes. Our results document a robust cyclicity of ~173 thousand years (ka) in both TOC and 13Corg. The ~173-ka obliquity–related forcing signal was amplified by internal climate feedbacks of the carbon cycle under different geographic and climate conditions, which control a series of sensitive climatic processes. In addition, our new and compiled records from multiple proxies confirm the presence of the obliquity amplitude modulation (AM) cycle during the Mesozoic and Cenozoic and indicate the usefulness of the ~173-ka cycle as geochronometer and for paleoclimatic interpretation.

E-mail: Kongxiangxin@126.com

Keywords: East Asian monsoon, Eocene climate, Astronomical time scale, Orbital signal, Salt rhythm

East Asia experienced complex climate changes during the Eocene, among which the origin and development of the monsoon pattern is of great importance. Due to the lack of the constraints of a complete time frame and research of the sedimentary records, the evolution process of the East Asian climate is still unclear. In this study, the Eocene strata of continental sequence in the Qianjiang depression of the Jianghan Basin, in central China, were evaluated to explore the Eocene climate evolution characteristics in East Asia. A complete high-precision Eocene astronomical time scale from 55.34 Ma to 33.9 Ma was established. The study showed that the dominant orbital signals in the sedimentary records changed from eccentricity in the early–middle Eocene to obliquity in the middle–late Eocene. The enhancement of obliquity signal corresponded to the lithological change in the Qianjiang Depression which responded to the global cooling; moreover, we found that obliquity signal in the sedimentary records could indicate the emergence of the East Asian monsoon. We considered that the development of the salt layer may be the result of the monsoon effect, which can be further used as the indicator for the monsoon. Therefore, the initial appearance of salt layers may be related to the formation of the monsoon, and the large set of salt rhythmites deposits dominated by obliquity signal can indicate the stability of the East Asian monsoon. Using the floating astronomical time scale, we concluded that the East Asian monsoon first formed 46.65–43.71 Ma and stabilized 43.71 Ma. The complete time history of the evolution of the East Asian monsoon, the conjoint development characteristics of salt rhythmites and obliquity signal in this study can be a new perspective and basis for future studies on the East Asian monsoon.

Orbital forcing of late-Early Devonian storm events on a mixed carbonate-siliciclastic shelf, Longmenshan area, Sichuan Province, China

Zhengan Chen[1], Fengjie Li[1*]
1. Institute of Sedimentary Geology, Chengdu University of Technology, Chengdu, Sichuan, CHINA
E-mail: lifengjie72@163.com

Keywords: Hybrid deposits,Tempestite,Milankovitch,cyclicity,Emsian,Eifelian

The Yangmaba Formation of latest Early Devonian in the Longmenshan area of Sichuan Province, China, is a shelf facies consisting of clay-rich, of siliciclastic sand-rich, of carbonate-dominated and of hybrid mixed clastic-carbonate deposits. Storm deposits vary in their thickness, in their composition and in their abundance-per-meter within these mixed carbonate-siliciclastic deposits. Meter-scale statistics of the relative storm frequency (events-per-meter) and magnitude (bed thickness) were compiled in two coeval sections through each of the hybrid facies in the lower Yangmaba Formation, which spans approximately the entire Polygnathus patulus conodont zone of the uppermost Emsian Stage. Low-pass filtering, spectral analysis and Acycle interpretation of these tempestite statistics yield 3 ½ main oscillations in each section, with an average wavelength of ca. 23 m. These long-wavelength trends are semi-coincident with interpreted long-term variations in sea level, where shallower depths allowed a greater influence by storms. Superimposed on the long-wavelength cycles are medium-wavelength cycles of 5.5 to 6.3 m. The estimated ca. 1.5 Myr time-span of this conodont zone of the lower Yangmaba Formation and the approximate 1:4 ratios of these wavelengths indicate that frequency and intensity of major storms and the recording of tempestites in the sedimentary record were modulated by ca. 100-kyr and 95-kyr short-eccentricity orbital-climate oscillations superimposed on a main 405-kyr long-eccentricity cycle. These eccentricity-climate cycles governed storm intensity and regional sea level on this margin of the tropical Yangtze Platform of South China.

Milankovitch forcing exerts a major control on climate that is recorded in the sedimentary rock record. However, its influence on hyperpycnal flow sedimentation is largely unknown. Hyperpycnites, sediments resulting from hyperpycnal flow, which is related to climate by flood frequency and magnitude, may be valuable tools for deciphering Earth's paleoclimate. Their origin and distinctive layering have been explained by various mechanisms, including initial phase of slope re-adjustment, intermittent tectonically or gravity-driven surface deformation, sea-level fluctuations, and variations in sediment supply. Their potential link to paleoclimate variations remains unexplored. Here we use cyclostratigraphic analysis combined with high precision U-Pb dating to investigate the potential influence of Milankovitch forcing on their deposition. A continuous drill core of the 125-million-year-old Early Cretaceous Laiyang Formation (eastern China) reveals well-defined cyclic hyperpycnal flow patterns. The radioisotopic dating constrains the formation's sedimentation rate to 86 m Myr−1 and links the observed cycles to precession index, obliquity and orbital eccentricity cycles. We conclude that Milankovitch cycles exerted a primary control on hyperpycnal flow sedimentation.

Corresponding author (daisher@lzu.edu.cn)

Cyclostratigraphy is to establish a high-precision astronomical chronometer by identifying Milankovitch cycle signals in the sedimentary strata. The high-resolution astronomical chronometer of the Paleozoic has not been fully established, which is known as the "frontier" of cyclostratigraphy. The study of Ordovician cyclostratigraphy in South China has been basically completed, but the study of North China is still relatively few. The southwest margin of Ordos Basin is a relatively well-developed Ordovician strata in North China. In Qishan section of Baoji City, Shaanxi Province, the Ordovician strata is well-developed, completely exposed and relatively lightly affected by tectonic geological processes. It is an ideal section for researching Ordovician cyclostratigraphy.

This paper studies the cyclostratigraphy of Qishan section, mainly researching the cycle period of Pingliang Formation of Upper Ordovician. Through field survey and measurement, the 600m thick Pingliang Formation of Qishan section is determined, and 3715 samples are collected at the top (36m thick) and bottom (30.3m thick) of the section Pingliang Formation at an interval of 2-10cm for magnetic susceptibility measurement. Time series analysis shows that the magnetic susceptibility has cycle period of 2.34m, 1.65m, 0.58m, 0.35m and 0.3m at the top of the top section, corresponding to the short eccentricity, obliquity and precession. After depth-time conversion, the astronomical cycles of 135kyr, 86kyr, 31kyr, 19kyr and 17kyr are identified, including 16 short eccentricity cycles, and the calculated floating astronomical chronometer lasts about 2.16Ma. Here are 1.88m, 1.25m, 0.47m, 0.28m and 0.23m thick cycle period in the bottom section. After depth-time conversion, 133kyr, 87kyr, 36kyr, 20kyr and 17ky rastronomical cycles are identified, and there are also 16 short eccentricity cycles, and the floating astronomical age scale is 2.128Ma.

Key words: Ordos Basin; Pingliang Formation; Magnetic susceptibility; Cyclostratigraphy

Milankovitch cycles of Quaternary strata and its indications for paleoenvironmental variations in the Qiongdongnan Basin, South China Sea

Tingna Zuo[1], Ren Wang[1*]
1. School of Earth Resources, China University of Geosciences (Wuhan), Wuhan, Hubei, CHINA
E-mail: 760231842@qq.com

Keywords: Qiongdongnan Basin, Milankovitch cycles, Quaternary, clay minerals, Paleoenvironmental variations

Milankovitch cycles affected paleoclimate, paleoenvironment, sea-level changes and the onset/termination of glacial/interglacial periods. The effects of astronomical cycles have been used to calculate paleo-water depth, obtain sediment supply rate, determine geological interface age and divide sedimentary sequences. The Qiongdongnan Basin (QDNB) is rich in oil and gas resources, but few studies have been done on astronomical cycles and paleoclimate in the QDNB. The Quaternary strata in QDNB are mainly fine-grained mudstone deposits and its sediments have stored significant information on sea-level changes and paleoenvironmental variations. Taking the Ledong Formation in QDNB as the research object, an integrated analysis of sedimentological data, well-logging, borehole dating data, clay minerals and major/ trace element composition provided a detailed description of the sea-level changes and paleoenvironmental variations. At first, the data from the Well-08 drilled through Quaternary strata in the QDNB has enabled the reconstruction of the evolution of sea level and environment. The signals of Milankovitch cycles in Quaternary strata were identified, and the results of the spectral analysis show that the fine sensitive component records the periodic change information of the Earth's orbital parameters (~405-, 100-, 33-, and 20-kyr). Additionally, the variation of clay mineral and major element compositions, like the ratio of Sr/Cu in this area shows an obvious glacial-interglacial cycle, which reveals that the paleoenvironment in the QDNB has undergone three periods since the Quaternary: late glacial period, early interglacial period and interglacial period. Besides, cold and dry conditions are usually characterized as an increase in the productivity and input of terrestrial increase during glacial periods combined with low sea level, clay minerals and major/ trace element composition. Conversely, during the interglacial period, sea level rises. At a highstand, terrigenous sediments supply is reduced, the clay minerals showed an increasing trend of kaolinite and a corresponding decrease of illite, which reflected the humid and hot environment. The results of this study show that the Milankovitch cycles, sea-level changes and clay mineral compositions changes of Quaternary strata in QDNB are highly consistent, which is of great significance to study the variations of paleoclimate and paleoenvironment in the basin.

Astronomical forcing of the paleoclimate and paleoenvironment on lacustrine magnetic records of the Lower K1sh formation in the Early Cretaceous Songliao basin, northeastern China

Shujing Zhang[1], Huaichun Wu[1*]
1. School of the Ocean Sciences, China University of Geosciences (Beijing), Beijing, CHINA
E-mail: whcgeo@cugb.edu.cn

Keywords: SK-2 borehole, lacustrine, Early Cretaceous, cyclostratigraphy, paleoclimate

Continuous cores of the lower Cretaceous in Songliao Basin, northeastern China, have been drilled out by the International Continental Drilling Project of SK-2 borehole, providing unprecedented geological materials for investigations of the early Cretaceous continental paleoenvironment and paleoclimate. In this study, we systematically studied the lacustrine successions of the lower Shahezi Formation (K1sh) in depth 4542-5694 m using the techniques of environmental magnetism, microscopic imaging, geochemical stratigraphy and cyclostratigraphy. Magnetic analysis reveals that there is an inverse correlation between magnetic susceptibility (MS) and lithology, where mudstones hold the largest values, and sandstones hold the smallest. The main magnetism carriers in the lower K1sh are pseudo-single-domain (PSD) and/or multi-domain (MD) ferromagnetic minerals, whilst the mainly dominant minerals of MS are paramagnetic and ferromagnetic minerals. To further explore the genesis of the environmental and climatic variations, MS was utilized as an alternative proxy to proceed with cyclostratigraphic analysis. Sedimentary cycles of 113.04 m, 34.11 m, 13.34 m and 6.00m are significant in power spectrum, which are in ratio highly accordant with long eccentricity (405 kyr), short eccentricity (124 kyr), obliquity (47 kyr), and precession (21 kyr) cycles in Early Cretaceous, proving the considerable impact of astronomical cyclicity on sedimentary rhythmicity. Long eccentricity controlled sedimentary facies, short eccentricity and precession are regarded to have mutually shaped the lake level oscillations. It should be noted that semi-precession periods identified from MS and the U sequence is most likely to directly drive the sand-mudstone alternations with the seasonal discrepancies of summer insolation. Finally, by tuning the inferred long and short eccentricity cycles to 405 kyr and 124 kyr orbital eccentricity theoretical curves, we established floating astronomical time scales (FATS) of 3356.99 kyr and 3248.80 kyr respectively, both of which fall into the range of the published U-Pb ages. Sedimentation rate was estimated ranging from 27.50 cm/kyr to 28.91cm/kyr, confirming the rapid deposition characterized within the fault lacustrine basin. In summary, our study acquired experimentally detailed magnetic characteristics of the early Cretaceous terrestrial sediments, shed new light on the astronomically forced configurations of paleoclimate on these magnetic properties, and provided a preliminary geochronological constraint for further marine-terrestrial comparison towards coeval strata.

Orbitally forced organic matter accumulation recorded in an Early Permian mid-latitude palaeolake

Wentao Huang[1,2], Huaichun Wu[1,2*], Qiang Fang[1,2]
1. School of Ocean Sciences, China University of GeosciencesBeijing, Beijing, CHINA
2. State Key Laboratory of Biogeology and Environmental Geology, China University of Geosciences, Beijing, Beijing, CHINA
E-mail: whcgeo@cugb.edu.cn

Keywords: Organic matter accumulation, Cyclostratigraphy, Milankovitch cycles, Lucaogou Formation, Junggar Basin

Organic matter (OM) sequestration acts as a significant sink of the CO_2 in Earth's carbon cycle and is tightly associated to the climate and depositional environments. The contemporaneous changes in primary productivity, preservation conditions, and sedimentation rate in the OM enrichment have been intensively discussed. However, the dominant factors in different depositional settings and the orbitally-forced variations in the lacustrine OM accumulation remain poorly constrained. Here, we investigate the depositional environment and OM accumulation in response to the astronomical forcing recorded in the Lucaogou Formation in southern Junggar Basin, northwestern China. Sedimentological and cyclostratigraphic studies show that both shallow lake and semi-deep to deep lake deposits recorded significant Milankovitch signals including long eccentricity (405 kyr), short eccentricity (~90.9 kyr), obliquity (34.5–37.4 kyr), and precession cycles (22.8 kyr, 22.7 kyr, 21.3 kyr, and 17.3 kyr). A linkage among the lithofacies, natural gamma ray (NGR), and total organic carbon (TOC) content suggests that the depositional environment and OM accumulation were in pace with the astronomically forced hydrological cycle and lake-level changes during the Lucaogou Formation depositional period. This complicated interaction was likely resulted from the teleconnection between changes in ice volume and monsoonal intensity on Milankovitch time scale. In addition, OM sequestration is a dynamically cumulative process of supply and degradation. The anti-phase and in-phase relationships between TOC and NGR content from the restricted mudflat towards shallow lake and towards deep lake respectively suggested OM accumulation efficiency was low in the active shallow water, likely resulted from the enhanced degradation. Finally, we propose a depositional model for the OM sequestration in Lucaogou Formation and suggest that detailed sedimentological studies are essential for the cyclostratigraphic analysis.

Using cyclostratigraphic evidence to define the unconformity caused by the Mesoproterozoic Qinyu Uplift in the North China Craton

Dan Lyu[1], Yan Deng[1,2], Huajian Wang[1*]

1. Petroleum Geology Experimental Research Center, Research Institute of Petroleum Exploration and Development, Beijing, China, Beijing, CHINA

2. School of Earth and Space Sciences, , Peking University, Beijing 100871, China, Beijing, CHINA

E-mail: wanghuajian@petrochina.com.cn

Keywords: Milankovitch cycles, North China Craton, Mesoproterozoic, The Qinyu Uplift, Geological unconformity, Weathering crust

In the Yanliao Basin of the North China Craton, the Mesoproterozoic Xiamaling Formation contacted unconformably with the underlying Tieling Formation. This unconformity was caused by the Qinyu Uplift. Underneath this unconformity, the Tieling Formation experienced variably weathering with more extensive erosion of carbonates in the west than in the northeast of the basin. To constrain the timing of the Qinyu Uplift and the duration of subsequent unconformity, cyclostratigraphic analysis was conducted on the Tieling carbonate rocks. Referencing the periodicities of the eccentricity, obliquity and precession obtained from the Mesoproterozoic Xiamaling and Hongshuizhuang Formations, Milankovitch cycles during the Tieling Formation were recognized. A bentonite located at the middle of the Tieling Formation was recognized from the core at the Beizhangzi section, and was considered to be contemporaneous with those found at the Jixian and Liujiagou sections, which had a consistent age of 1441 Ma. Then a deposition rate from the bentonite layer to the top interface of the Tieling Formation was calculated to be 1.65 ± 0.22 cm /kyr, and the duration time were ca. 9 million years. So the minimum age of the Tieling Formation was ca. 1432 Ma. Combined with our new 207Pb/206Pb weighted average age of 1418 ± 14 Ma obtained from the bottom of the Xiamaling Formation, the Qinyu Uplift was constrained to occur between 1432 Ma and 1418 Ma, older than the previously suggested age of 1400 Ma. The duration of this unconformity was suggested to be no less 14 million years, and might be longer in the western part.

Cyclostratigraphic constraints on the negative carbon isotope excursion from the upper Doushantuo Formation, South China

Tao Zhong[1*]
1. Institute of science, China University of Geosciences(Beijing), Beijing, CHINA
E-mail: zhongtao0311@163.com

Keywords: the Doushantuo Formation, Cyclostratigraphy, the Shuram Excursion, duration

The Ediacaran strata record a most remarkable $\delta^{13}C$ negative carbon isotope excursion of carbonate globally in geological history, named the Shuram Excursion (SE) (Fike et al., 2006). The driving mechanism of the evolution of metazoan life by this disturbance of the global carbon cycle has always been one of the Ediacaran research hotspots. However, due to the lack of chronological constraints, the origin of the SE is still obscure and this driving mechanism is thus unclear (Bristow and Kenedy, 2008). A few astrochronologic studies provide constrains for the duration of SE, mostly over 7 .7 Myr (Minguez and Kodama, 2017; Gong et al., 2020; Sui et al., 2019). Recently Li et al. (2022) reported a 6.1 ± 0.2 Myr duration from the Zhengjiatang section that preserves a complete SE, which is perhaps the best estimate so far. In contrast, stratigraphic hiatus/unconformity may exist within the reported SE in other successions globally, which causes an over-estimation.

To better understand the duration and origin of the SE, we carried out cyclostratigraphic studies on the SE of the Doushantuo Formation from the Nanxiangerwan section, not far away from the Zhengjiatang section. In this study, magnetic susceptibility (MS) is used as the palaeoclimate index. Rock magnetism and mineralogical analysis indicated that the MS was mainly contributed by the terrigenous inputs, which were controlled by climate changes. The spectral results by the multi-taper method (MTM) of the MS sequence of the upper Doushantuo Formation from the Nanxiangerwan section showed that the complete Milankovitch periods were recorded. After tuning to the target 405-kyr-period sequence, a floating astronomical scale was established. Then the duration of the SE was established as ~ 6.5 Myr. This is consistent with the latest Re-Os age constraints with a < 6.7 ± 5.6 Myr duration for the SE (Rooney et al., 2020), the 6.1 ± 0.2 Myr duration from the Zhengjiatang section (Li et al., 2022) and is similar to those estimated from North America, Australia and Oman. Therefore, this infers the global isochronism of the SE, perhaps with an origin of the (heterogeneous) oxidation of the global ocean.

Biomarker evidence for deforestation and an obscuring short eccentricity (100 kyr) across the Triassic-Jurassic boundary in the high-palae-latitude Junggar Basin, NW China

Linhao Fang[1*], Xiaoyu Zhang[1]
1. Geosciences Department, China University of Petroleum (Beijing), Beijing, CHINA
E-mail: linhao.fang@cup.edu.cn

Keywords: biomarker, Triassic-Jurassic boundary, mass extinction, wildfire and deforestation, floating astronomical scale, obscuring short eccentricity

One of the five largest mass extinctions, the end-Triassic mass extinction (ETME) in 201.6 million years ago, occurred near to the Triassic-Jurassic boundary (TJB) (Hillebrandt, et al., 2013). Dramatic declines of marine and terrestrial ecosystems were approximately synchronous with the eruption of the Central Atlantic Magmatic Province (CAMP). The loss of marine biodiversity is linked to an extreme global warming, while the reasons for floral destruction on the land ecosystems remain in debate. Here, biomarker records of higher plants are reported from the terrestrial high-palae-latitude Junggar Basin, NW China. The strata around the ETME interval are marked by sharp increases in the abundances of cadalene, retene, pimanthrene and furans, which are synchronous with "fern spikes". These results are interpreted as ruins of land vegetation and an enhanced burial of higher plants, which are consistent with palynological evidence of the loss of floral diversity. Based on an integrated stratigraphic correlation, an increased burial of higher plants, wildfires and CAMP volcanisms are synchronous both in the Haojiagou section and other classic TJB sections globally. We propose that widespread deforestation may be due to the CAMP-derived acid rains and then massive rapid death of vegetation provides moisture-free fuels for wildfires, rather than an initially enhanced wildfires lead into the deforestation.

Moreover, a floating astronomical scale is established for the Haojiagou section based on magnetic susceptibility data, and compared with previous study on Lith Index (Sha et al., 2015), combined with Laskar astronomical cycle model (La2010) of this period, the astronomical chronological characteristics of this section were discussed and a short eccentricity 100 kyr was identified. The results show that the ETME-TJB duration is 291 kyr with magnetic susceptibility constraint and 288 kyr with Lith Index constraint. However. in the moving window spectrum analysis results, an obscuring short eccentricity (100 kyr) occurs in the ETME-TJB period and the obliquity signal is enhanced. According to La2010, no astronomical orbital anomalies during interval of 201.6Ma to 201.3Ma indicate that the obscuring eccentricity is not determined by astronomical cycles, but probably related to the environmental fluctuations on Earth surface systems

Paleoceanography of the equatorial Pacific over the past 5 Myr: High resolution benthic foraminiferal δ18O and δ13C records at ODP Site 807

Hua Feng[1], Jun Tian[1*]
1. State Key Laboratory of Marine Geology, Tongji University, Shanghai, CHINA
E-mail: tianjun@tongji.edu.cn

Keywords: Western equatorial Pacific, Pliocene-Pleistocene, stable isotope

The western equatorial Pacific is pivotal to precisely understand the global climate change and its evolution over geological time. However, continuous paleoceanographic records with high time resolution and accurate age model over the last 5 Myr are few in this important ocean region. Here, we present a high time resolution (2-3 kyr) benthic foraminiferal d18O and d13C record from Ocean Drilling Program Site 807 in the western equatorial Pacific and establish an accurate age model for the past 5.025 Myr. Comparison of the benthic d13C records from the west and east equatorial Pacific, and the North and South Pacific reveals that organic matter oxidation is the most important factor determining the deep water d13C value along the flow path of the deep Pacific circulation over the past 5 Myr. From 4.0 Ma to 2.7 Ma, a rapid decrease in benthic d13C gradients (Dd13CW-E) between the west (Hole 807A) and east (ODP Site 849 and IODP Site U1338) equatorial Pacific potentially resulted from strong ventilation in the North Pacific during the warm Pliocene. The subsequent gentle decrease in benthic d13C gradients might indicate stratification in the North Pacific and reduction of biogenic flux with the intensification of the Northern Hemisphere Glaciation (NHG) at 2.7 Ma. Both the Dd18OW-E and Dd13CW-E are strongly paced by 405 kyr long eccentricity cycles and 41 kyr obliquity cycle, revealing the complex interplay of both high and low latitude climatic processes on deep Pacific circulation changes.

Milankovitch paleoclimatic, tectonic, and sedimentary signals in late Permian-Early Triassic fluvial-lacustrine records, Bogda Mountains, NW China

Wentao Zhang[1*], Wan Yang[1]
1. GGPE, Missouri University of Science and Technology, Rolla, Missouri, UNITED STATES
E-mail: wznfd@mst.edu

Keywords: non-marine records, Milankovitch signals, late Permian-Early Triassic

Non-marine cyclostratigraphic records are a manifestation of repetitive changes of ancient continental environmental, paleoclimatic, tectonic, and ecosystem conditions. Stratigraphic sections in Bogda Mountains, the greater Turpan-Junggar intracontinental basin, NW China, provide detailed records of the late Permian-Early Triassic terrestrial paleoenvironmental and paleoclimatic evolution at the paleo-mid-latitude of NE Pangea.

In this study, lithology and interpreted depositional environments are used in quantitative analysis because the environmental shifts occurred probably mainly in response to climatic changes. The section was measured at a cm-dm scale to document the lithology, sedimentary texture and structure, fossils, and stratal geometry. The stratigraphic thickness of the South Taodonggou section is 283 m. Many previous studies used astronomical tuning methods to estimate and reduce the distorting effects of long-term variable sedimentation rates of sedimentary records. However, the short-term sedimentation rate variation of different lithofacies should also be considered. The gamma analysis of Kominz and Bond (1990) estimates the facies-dependent thickness-time conversion factors (gammas) to convert and tune the thickness series into time series before spectral analysis. Multi-taper method (MTM) power spectral analysis and evolutive MTM are used to characterize the frequency content of the gamma-untuned and tuned series.

There are four types of high-order cycles (HCs): meandering stream, lacustrine deltaic, and lakeplain-littoral (subgroups 1 and 2). To obtain consistent gammas for each lithofacies, gamma analysis is conducted for each type of HCs. The gamma results suggest that environmental lithofacies in the South Taodonggou section have approximately constant time-thickness relations. Six normalization schemes are experimented. The spectra of the gamma-untuned and six gamma-tuned series of the South Taodonggou section have several statistically significant peaks which are compared with the line spectrum of Milankovitch climatic cycles at 244-249 Ma (Berger et al., 1992; Hinnov, 2000). Five peaks above or close to the 99% confident limit in the spectra of gamma-tuned series 3 all match with the line spectrum. Thus, the spectra of gamma-tuned series 3 is chosen for calibration with Milankovitch climatic cycles. The peak at frequency 0.0127 is assigned to the long-obliquity of a period of 40.5 kyr. The short-eccentricity peaks are at periods of 117.4 and 86 kyr, the long-obliquity at 40.5 kyr, the long-precession index at 20.7 and 19.9 kyr. Two low-amplitude peaks may also match with the Milankovitch peaks. They are the long (29.6 kyr) and short-obliquity (24.3 kyr) cycles. The good match of the spectrum of the third gamma-tuned series with that of Milankovitch cycles, suggesting that the cyclic sedimentation of the South Taodonggou section was significantly influenced by Milankovitch climatic forcing. The stratigraphic completeness of the South Taodonggou section is estimated to be 27% as the ratio between depositional duration and total duration.

Keywords: Toarcian-Oceanic-Anoxic-Event, Sichuan Basin, Astronomical forcing

The Toarcian Oceanic Anoxic Event (T-OAE) is characterized by one of the largest carbon cycle perturbations of the Mesozoic, with associated climatic and environmental change, most notably the widespread development of anoxia in marginal marine basins. On land, an enhanced hydrological cycle led to the development of major lakes, or significantly elevated lake levels, in continental basins in China, such as in the Sichuan, Tarim and Junggar basins. Stratified lake watercolumns and the development of anoxic–euxinic lake bottom water conditions initiated a negative feedback mechanism in Earth's climate system through increased lacustrine (lake) carbon burial.

The sheer size of these lakes possibly allowed for lacustrine carbon burial to have a significant impact on Earth's carbon cycling at that time.

Here, we show new geochemical data from the Sichuan Basin and show that lake levels rose at the onset of the T-OAE. Importantly however, lake levels were likely not stable, but rather fluctuated on astronomical time-scales, possibly in response to periodic changes in the hydrological cycle (and monsoon intensity) and the transport of moisture into continental interiors. Furthermore, the lacustrine climate records spanning the T-OAE provide crucial continental constraints on the duration of the T-OAE, which remains heavily debated based on marine climate archives.

Keywords: late Paleozoic icehouse, carbon burial, climate change, coal forest, obliquity forcing

The demise of late Paleozoic icehouse is Earth's first icehouse-to-greenhouse transition in an extensively vegetated world. In this paper, an astronomically forced teleconnection on a global scale is made to delineate a dynamic carbon sequestration history and its impact on icehouse termination. After a loss of coal forests in tropical Euramerica, floral survival became linked with 1.28 Myr obliquity cycles between low-latitude North China and high-latitude Gondwana from ~299.2–295.5 Ma. The expansion of coal forests enhanced carbon burial that increased O2 and lowered CO2 levels in the atmosphere, elevating atmospheric O2/CO2 to the point of crossing a threshold and triggering the collapse of coal forests at ~295 Ma. Following the sharply decline of coal forests, the lack of efficient carbon sinks on land, in combination with the reduced weatherability in the arid continent interiors, was unable to consume the excess CO2 from vegetation fires, leading to the termination of the late Paleozoic icehouse at ~295 Ma. A deep-time example is provided here on how a vegetated icehouse crossed a threshold, entering into a greenhouse without anthropogenic impacts.

Keywords: groundwater, lake level, sea level, astronomical forcing, Late Triassic

Two different hypotheses, glacioeustasy and groundwater aquifer eustasy, have been proposed to explain short-term, high-amplitude sea-level oscillations during past greenhouse-dominated intervals. However, the veracity of aquifer eustasy on long-term, high amplitude sea level has never been rigorously tested. We test these competing hypotheses using an objective approach of sedimentary noise modeling for the lake-level reconstruction. Statistical tuning and astronomical calibration of paleoclimate and paleoenvironment proxies (depth rank, rock color, gamma ray, and sonic velocity) from the lacustrine Newark Basin enable the construction of a 31.55-Myr long astronomical time scale (ATS) for the Late Triassic that is comparable to classic Newark ATS previously presented. Using this timescale, sedimentary noise modeling in the lacustrine Newark Basin is carried out through the Late Triassic. Lake level fluctuations reconstructed by sedimentary noise modeling and principal component analysis reveal that million-year scale lake-level variations were linked to astronomical forcing with periods of ~3.3 Myr, ~1.8 Myr, and ~1.2 Myr. Our results demonstrate that astronomical forcing, as a driver of groundwater dynamics, may have an impact on global sea-level changes in the Late Triassic. This study thus emphasizes the importance of high-resolution, objective reconstruction of sea- and lake-levels for further testing the hypotheses of glacioeustasy and aquifer eustasy under a warming condition.

Downhole gamma ray data to reconstruct an age-depth model of the lacustrine deposits of Chalco basin, Central Mexico

Mehrdad Sardar Abadi[1*], Christian Zeeden[1], Arne Ulfers[1], Thomas Wonik[1]
1. Rock Physics & Borehole Geophysics, Leibniz Institute for Applied Geophysics, Hannover, Lower Saxony, GERMANY
E-mail: mehrdad.sardarabadi@gmail.com

Keywords: Quaternary, Tropical North America, Borehole Logging, Magnetic Susceptibility

Understanding the evolution of lower latitude climate from the most recent glacial periods of the latest Pleistocene to post glacial warmth in the continental tropical regions has been obstructed by a lack of long and continuous time series. Here we examine sediments from Lake Chalco, located in the Valley of Mexico, central Mexico (19°30'N, 99°W). The basin represents a hydrological closed system surrounded by the Trans-Mexican Volcanic Belt aging from the Oligocene to the present. We use borehole logging to conduct a cyclostratigraphic analysis of the Lake Chalco sediments, and incorporate other available dating information. More than 400 m of sediments are logged for several geophysical properties including magnetic susceptibility and spectral gamma radiation.

Gamma radiation can be used to identify elemental isotopes in the geological record, which is used for stratigraphic correlation and paleoclimatic investigations. Among the lake deposit of Chalco sub-basin, 388 total tephra layers (≥1 mm in thickness) were reported from the core description. Tephra layers with specific gamma ray signatures, presenting a challenge for extracting the primary signals caused by environmental and climatic agents. Here, we apply a tailored protocol to identify tephra layers embedded in other sediments using high-resolution gamma ray spectroscopy. This facilitates dividing the overall sediment column into representative horizons of tephra and non-tephra.

After extracting the non-volcanic primary signal, we apply a suite of evolutive cyclostratigraphic methods to the Lake Chalco logging data, with a focus on gamma ray data. The high-resolution results suggest that the Lake Chalco sediments contain several rhythmic alterations with a quasi-cyclic pattern comparable with the Pleistocene benthic stack. This allow us to calculate a ~500-kyr time span for the sediment deposition in Lake Chalco. By using cyclostratigraphic analysis on data captured by geophysical downhole logging, we demonstrate the potentially broad applicability of this method for downhole logging data and provide further insight into the sedimentation history of Lake Chalco.

E-mail: xichen@cugb.edu.cn

Keywords: Albian, OAEs, Cyclostratigraphy, Carbon cycle, Terrigenous input, Southern Tibet

The Albian age is characterized by frequent short-lived perturbations of the global carbon cycle, including a series of Oceanic Anoxic Events (OAEs). Carbon isotope Excursions (CIEs) document these OAEs in detail. A strong influence of orbital forcing on oceanographic and climatic conditions in the Albian has been documented, but the relationship between orbital changes and the carbon cycle is still unclear. The Albian CIEs are well recorded globally, except in the eastern Tethys. The major forcing mechanisms of Mesozoic carbon cycling have long remained a conundrum. Here, we present bulk carbon ($\delta^{13}C_{carb}$) and oxygen ($\delta^{18}O_{carb}$) isotope data, magnetic susceptibility (MS), and total organic carbon (TOC) data from the Nirang Section in the Tethyan Himalaya of southern Tibet, China. The $\delta^{13}C_{carb}$ record for the first time documents the long-term secular variations in $\delta^{13}C$ during the Albian in the Tethyan Himalaya. The $\delta^{13}C$ curve obtained in Nirang can be correlated well with reference sections in other basins. OAE1b and 1c were identified as troughs in $\delta^{13}C$ profile in the lowermost and upper part of the section. Cyclostratigraphic analysis of MS, $\delta^{13}C_{carb}$ and TOC content from the Nirang section reveals the imprint of the orbital cycles of eccentricity (~100 kyr and ~405 kyr) and a long-term amplitude modulation of either obliquity or eccentricity (1.2 Myr). A detected ~1.1 Myr periodicity is the most significant cycle, providing strong evidence for astronomically paced climate change in the eastern Tethys during the Albian. The band-pass filters of the ~1.1 Myr periodicity in MS and TOC display a close correspondence, suggesting that the productivity and/or preservation potential of organic matter was likely controlled by orbitally forced changes in terrigenous input. Increasing $\delta^{13}C$ values correspond to higher values of MS and TOC content and vice versa, indicating that the $\delta^{13}C$ values of the eastern Tethys during the Albian were influenced by the intensity of the terrigenous flux and the subsequent burial of organic matter paced by orbital change. This work implies that cyclic changes in carbon reservoirs in the low latitudes during the Albian were controlled by seasonal variations in terrigenous input driven by the influence of orbital cycles on regional hydrological processes.

Orbital forcing of carbon sink and hydrologic cycle during the Middle Triassic greenhouse climate in China

Runjian Chu[1], Huaichun Wu[1*]
1. School of ocean sciences, China University of Geosciences (Beijing), Beijing, CHINA
E-mail: whcgeo@cugb.edu.cn

Keywords: Middle Triassic, Milankovitch Cycles, Grand Cycles, Tethys, organic-rich

Exploring the relationship between continental organic-rich deposits and orbital forcing of climate is critical for understanding the roles of orbital forcing played in the Triassic. The Middle Triassic Yanchang Formation (FM) serves as the major source rock in the Ordos Basin, the largest petroliferous basin in China, and provides a unique record for improving our understanding of continental paleoclimate and ecological system in the Triassic hothouse world. Here, three wells (F-75, D-81 and Y-1) of the Yanchang FM in the Ordo Basin are evaluated for paleoclimate change from astronomical forcing. We establish a high-resolution age framework for the Yanchang FM derived from integrated, high-precision U-Pb zircon geochronology using chemical abrasion-isotope dilution-thermal ionization mass spectrometry (CA-ID-TIMS) on interstratified ash beds and cyclostratigraphy based on centimeter-scale multiple proxies for paleoclimate, including magnetic susceptibility (MS), gamma-ray spectral (GRS), X-ray fluorescence (XRF). We procure insights into the dominants of redox cycles in the lacustrine organic-rich shales and detrital input cycles in the deltaic sediments by deciphering the imprint of astronomical cycles on multiple proxies for paleoclimate. The redox cycles in organic-rich shales are largely driven by monsoonal dynamics of Tethys on the bands of precession and eccentricity. The major organic-forming intervals of the Yanchang FM, Zhangjiatan Shale and Lijiapan Shale, spanned ca. 241.1–240.9 Ma and 244.4–243.6 Ma, respectively, which coincided with the periodic humid intervals during the Middle Triassic. These periodic events are compared with Middle Triassic records of global sea level, temperature, biotic evolution and biogenic silica (BSi) flux suggests that the long-eccentricity (~3.3 Ma) forcing was involved in the repeated climatic and biotic upheavals that took place throughout the Middle Triassic. Moreover, the regional lake-level changes inferred from sequence stratigraphy and sedimentary noise modelling are anti-phased with the contemporaneous global sea-level changes. This supports the hypothesis that long-obliquity (~1.2 Ma) astronomically forced water mass exchange between land and ocean reservoirs during the Middle Triassic.

Keywords: downhole logging, cyclostratigraphy, time series analysis

Extensive borehole logging datasets have been gathered for commercial and scientific purposes, but studies exploring their potential through applying time series analysis remain sparse. Typically, fast available logging data are relatively complete and may contain valuable paleoenvironmental information related to orbital forcing. There is, however, complexity in cyclostratigraphy and time series analyses being the reason why scientists often avoid these valuable tools. Here, we summarize the most relevant properties of borehole logging data and pitfalls in the context of time series analysis and cyclostratigraphy. In comparison to interpretation of data from core- or outcrop analysis, it is important to be aware of potential issues such as the effect of variation in borehole diameter and the influences of drilling fluids, and that presented logs may consist of merged results logged in several depth sections.

2. Shandong Provincial Key Laboratory of Deep Oil & gas, China University of Petroleum (East China), Qingdao, Shandong, CHINA
E-mail: xushang0222@163.com

Keywords: Terrestrial basin, Cyclostratigraphy, Early Eocene Climatic Optimum (EECO), Astronomical forcing

The Eocene is a transitional period from bipolar ice-free conditions (greenhouse climate) to bipolar ice sheets (icehouse climate), representing an important period in the Earth's history. It is enigmatic and interesting due to critical thermal events that occurred during the global cooling, such as the Early Eocene Climatic Optimum (EECO) and the Middle Eocene Climatic Optimum (MECO), which have been documented in the marine sediments but are still rarely reported in terrestrial basins. A continuous terrestrial succession of the Eocene Xingouzui Formation in the Jianghan Basin was investigated to understand the terrestrial sedimentary responses to astronomically forced climate changes, especially the Early Eocene Climatic Optimum (EECO). In this work, high-resolution gamma-ray (GR) logs were utilized for the cyclostratigraphy analysis of the Xingouzui Formation. Time series analysis reveals evidence for 405-kyr eccentricity cycles in the GR series, which is supported by statistical modeling of optimal sedimentation rates. An astronomical time scale (ATS) is constructed by tuning the GR data to this 405-kyr eccentricity cycle. This accurate timescale is critical for understanding the processes controlling organic carbon burial as well as paleoclimatic and paleoenvironmental background conditions. The results show that the terrestrial paleoclimate record is consistent with a time frame based on marine records, and highlights the major role of the EECO event in shaping East Asian paleoenvironments. A carbonate and evaporite mineral-rich interval developed in the Xingouzui Formation is closely associated with the EECO recorded in the deep-sea oxygen isotopes record, which is a continental record during warming. We further discuss the role of astronomically forced climate changes in controlling the depositional processes of lacustrine fine-grained sedimentary rocks during the EECO event. The results indicate strong astronomical forcing of the cyclic variations in organic matter abundance, mineral content, and lithofacies. The alternating cycle of dry/wet climate in the Early Eocene in the Jianghan Basin is driven by the eccentricity cycles. The Xingouzui Formation is the main target layer of shale oil exploration in the Jianghan Basin; therefore, our study is conducive to the comprehensive prediction of favorable shale oil layers.

Mesoproterozoic earth orbital period and the evolution of the earth-moon system

Xiaomei Wang[1], Shuichang Zhang[1*], Huajian Wang[1]
1. Key Lab of Organic Geochemistry, RIPED, Beijing, CHINA
E-mail: sczhang@petrochina.com.cn

Keywords: earth orbit parameters, Mesoproterozoic strata, Milankovitch signal, North China

The periodic variation of earth orbit parameters results in a multi-scale rhythm of sediment by controlling the surface climate and sea level changes. The identification of sediment cycle period can also be used to calculate the orbital parameters of geological history and to establish astronomical chronology scales with a resolution of 100,000 or even 10,000 years. There is relatively good tronomical time tuning for the Cenozoic strata and Mesozoic strata (Hinnov, 2018), while there are not so much evidences for Paleozoic studies, even scarce for Precambrian. North China holds the most continuous Mesoproterozoic strata (Wang et al., 2017). The deposition time from Changchanggou Formation to Xiamaling Formation is 1.65~1.35 billion year in the Yanliao Basin, and the stratum has good rhythmic characteristics, covering nearly 8000m, providing an excellent case for the study of Mesoproterozoic astronomical chronology. The periodic astronomical cycle of Milankovitch signal of eccentricity, obliquity and precession is identified from the studies of Hongshuizhuang, Tieling and Xiamaling formation, confirming the earliest Milankovitch cycle and its controlling on the climate changes. The long eccentricity is 405kyr, short eccentricity is 128kyr, obliquity and precession is 28kyr and 14kyr by the spectral analysis of magnetic susceptibility, greyscale data, Cu/Al, Si, Zi/Al, and Ti/Al for Xiamaling Formation sedimentation, recording all of the major periods expected from the orbital forcing of solar insolation on Earth like today and much of the Phanerozoic Eon (Zhang et al., 2015). The Tieling formation records the same long eccentricity of 405kyr, eccentricity from 86~130kyr, and the obliquity of 22.5kyr (Lyu et al., 2021), and Hongshuizhuang formation holds a same long and short eccentricity, obliquity of 20-28.5kyr and precession of 14-16kyr (Cheng et al., 2020). Meyers and Malinverno (2018) got dominant climatic precession cycles of 14 kyr and eccentricity cycles of 131 kyr by using a Bayesian inversion approach to quantitatively link astronomical theory with Xiamaling geologic data, almost similar with data of Zhang et al (2015). So the short eccentricity is short than the modern of 100kyr, and the obliquity and precession obtained from the Mesoproterozoic were obviously smaller than modern of 42 kyr and 23 kyr, which might reflect the closer distance between the earth and the moon and the shorter daytime (Meyers and Malinverno, 2018). Anyway, the Mesoproterozoic climate changes cause the same organic matter burial heterogeneity with Phanerozoic by affecting seawater circulation, seasonal/trade wind intensity and terrigenous input. The discovery of the earth orbit parameters from the North China provide critical constraints for further modifying astronomical solutions for the early Earth and restoring the length of the daytime, and changes the idea of 21-hour resonance in atmospheric thermal tidal forcing during 18-8Ga (Bartlett and Stevenson,2016).

Astronomically forced warming events and organic carbon burial

Chunju Huang[1*], Zhixiang Wang[1]
1. School of Earth Sciences, China University of Geosciences (Wuhan), Wuhan, Hubei, CHINA
E-mail: huangcj@cug.edu.cn

Keywords: astronomical, warming events, organic carbon burial, climate changes

Stratigraphic records are essential for deciphering past climate variability and understanding causality of climate events in Earth history. Some geological records during warming events such as the ocean anoxic events (OAEs), Early Eocene Climatic Optimum (EECO), and Middle Eocene Climate Optimum (MECO) reveal a close relationship between increased surface temperatures and enhanced organic carbon burial in sedimentary basins driven at orbital eccentricity time scales. There are some evidences reveal that the organic carbon burial occurred at the minima of the 405 kyr and ~2.4 Myr long eccentricity cycles and ~1.2 Myr long obliquity cycle with global cooling and decline of atmospheric CO2. However, how the orbitally forced climate changes and driven the carbon cycle variations and what is the mechanisms of the organic carbon burial and source rock formation that remain poorly understood. Here, we present an example of EECO and MECO events recorded at North China oil-bearing basins that reveal the relationship between the astronomically forced climate changes and source rock formation, feedback of carbon cycle on climate changes.

Keywords: Cenomanian, Eagle Ford, source rocks

Modelling source rock petroleum potential requires an understanding of organic matter content, type and geographic extent. These parameters are generally constrained by abundant well and core data in heavily explored and developed basins. However, in frontier basins with sparse data, or in the search of source rock sweet spots in unconventional tight oil and gas plays, prediction of source rock character and extent away from data points is critical. To predict multi-scaled vertical and horizontal source rock heterogeneities (deci-meter to micro-meter) away from well control, we need to understand the impact of the primary forcing mechanisms for source rock formation and preservation.

We present an integrated multidisciplinary study from a continuously cored section of the entire Eagle Ford Group (Boquillas Formation) from the Shell Iona-1 and other research boreholes and surface sections (Texas, USA). The Eagle Ford Group is a prolific source rock along the US Gulf Coast and Gulf of Mexico and was deposited during the Cenomanian to Turonian Stages of the Late Cretaceous, a Greenhouse Climate state period characterized by extreme warmth. The sedimentary succession is characterized by sub-meter scale limestone–marlstone couplets which preserve unambiguous primary environmental signals. Integrated sedimentological, paleobiological and geochemical analyses support greater water-mass ventilation and current activity promoting increased silica/carbonate productivity during the deposition of limestone beds compared to deposition of marlstone beds which reflect greater organic matter productivity and preservation. Astrochronological analysis indicates that these environmental variations occur on multiple orbital timescales. In particular, we propose that obliquity and precession forcing on the latitudinal distribution of solar insolation are consistent with the observed lithological and environmental variations in this mid-latitude epicontinental sea setting. We also present a conceptual model that illustrates the geographic variation in orbital expression on sedimentary successions and associated impact on organic matter type and quality prediction.

As part of the multi-scaled understanding of source rock deposition, we also analyzed exceptionally well-preserved, millimeter-scale laminations from the organic-rich marlstone beds of the lower Eagle Ford. Sedimentological, geochemical, and micropaleontological data indicate that individual pairs of light-dark laminae record alternations in the extent of water-column mixing and oxygenation with sub-orbital periodicities (80–100 yr, 200–230 yr, 350–500 yr, 1650 yr, 4843 yr and 10,784 yr periodicities). The centennial to millennial variations are reminiscent of those found in Holocene total solar irradiance variability, and the 10,784 yr anoxia cycle may be a manifestation of semi-precession-influenced Tethyan oxygen minimum zone waters entering the seaway.

This multi-scaled integrated approach highlights the impact of astronomically forced global and regional climate change on source rock formation and preservation and guides a quantitative approach to modelling petroleum potential and hydrocarbon generation across orbital timescales.

Paleoenvironmental Trends, Cycles and Events at the Onset of Cretaceous Oceanic Anoxic Event 2 Recorded at Demerara Rise, Equatorial Atlantic Ocean

Linda Alide Hinnov[1*], M'bark Baddouh[1], Sean Karoly[1]
1. Atmospheric, Oceanic, and Earth Sciences, George Mason University, Fairfax, Virginia, UNITED STATES
E-mail: lhinnov@gmu.edu

Keywords: Ocean oxygenation, organic-rich laminated black shale, source rock, XRF core scan, photolog, Cenomanian-Turonian boundary

Oceanic Anoxic Event 2 (OAE2) that took place across the Cenomanian-Turonian transition (~94 Ma) is marked by high rates of carbon burial in the oceans and a positive marine carbon isotope excursion, and has been associated with Large Igneous Province volcanism, super-greenhouse conditions, and widespread oceanic anoxia. To investigate paleoenvironmental conditions at the onset of OAE2, high-resolution XRF and color line core scanning was undertaken on the OAE2 black shales from ODP Site 1261, Demerara Rise, western equatorial Atlantic Ocean. Analysis of a composite grayscale scan of the original Site 1261 core photographs detected Milankovitch cycles throughout the OAE2 interval, indicating an average accumulation rate of 1.071 cm/kyr. Eight elements, Ca, S, Si, Fe, K, Ti, Al, and P were scanned at 100-micron resolution (but are stratigraphically smoothed due to the 200-micron wide XRF aperture), and color attributes R, B, G, a*, b*, and l* were logged at 70-micron resolution. A thin volcanic ash marks the start of the carbon isotope excursion and onset of OAE2. The elements are related to detrital influx, primary productivity, nutrient supply and redox conditions (anoxia/euxinia), and reveal strongly changing relationships with the onset of OAE2. The color line scans corroborate XRF elemental cm-scale variations, and with their higher resolution capture significant sub-mm-scale variability, bringing very high-frequency (decadal-centennial scale) paleoenvironmental dynamics of the OAE2 western Atlantic margin into sharp focus. These deposits are a major source rock for recently discovered reservoirs in offshore Guyana and Suriname.

E-mail: nwichern@uni-muenster.de

Keywords: Late Devonian, Kellwasser Crisis, astronomical forcing, anoxic black shales, Rhenish Massif, XRF

The Late Devonian (ca. 379–359 Ma) was characterised by a series of widespread marine anoxic events, documented in the rock record by black shales and limestones. The greatest of these, the Kellwasser Crisis at the Frasnian-Famennian boundary, was associated with one of the "Big five" Phanerozoic mass extinctions. Despite decades of research, it remains controversial what triggered the Kellwasser Crisis and why the Late Devonian ocean was particularly sensitive to widespread anoxia. De Vleeschouwer et al. (2017) hypothesised that the exact timing of tipping the Devonian system into oceanic anoxia could have been related to a particular sequence of astronomical forcing configurations. First, a long-term eccentricity minimum (or "node") creates relatively stable climate conditions for several tens of thousands of years, during which thick continental regoliths are formed. Then, a rapid increase in eccentricity intensifies climate variability and triggers the release of nutrients from the continents into the oceans. To test this hypothesis, we have generated high-resolution elemental records of the Winsenberg roadcut (eastern Rhenish Massif, Germany), employing a number of different X-Ray Fluoresence (XRF) methods. The Winsenberg section is 12 m thick and reflects a deeper outer shelf environment just southeast of the Brilon Reef Complex. It features well-expressed Lower and Upper Kellwasser black shales/limestones (LKW and UKW) that are 150 and 80 cm thick, respectively. While rhythmically bedded carbonates crop out in between the two Kellwasser intervals, the 72-cm thick Usseln Limestone occurs directly below the LKW. This limestone bed contains strongly-expressed cm-scale rhythmical variations in carbonate content and can be traced through much of the Rhenish Massif (Gereke, 2007). Lithologic cyclicity is smaller in scale but also more evident in the Usseln Limestone, compared to the stratigraphic interval in between the two Kellwasser shales. This distinction dictates a difference in XRF analytical approach: while the interval between the LKW and UKW was analysed at a cm-scale using a portable XRF analyser, the Usseln Limestone was XRF-imaged at mm-scale resolution using µXRF elemental mapping. These combined methods allow for a detailed investigation of Winsenberg's environmental response throughout the Kellwasser Crisis, on both astronomical and millennial timescales. On astronomical timescales, the stable 405-kyr eccentricity 'metronome' cycle defines an astrochronological framework that is largely in line with other globally-distributed astrochronologies. The Winsenberg floating chronology will form the basis for testing the eccentricity minimum hypothesis, which is a work in progress. The µXRF images of the Usseln Limestone are combined with petrographic thin-section analysis to show that diagenetic processes did not superimpose the primary rhythm of millennial-scale climate variability. Our results indicate that the Late Devonian Earth system was highly variable on short timescales immediately prior to the Kellwasser Crisis, and the Usseln Limestone provides a unique sedimentary archive to analyse the imprint of these rapid climatic fluctuations in the rock record.

Milankovitch cycles to detect the relation between the abundance of nummulites and the Middle Eocene peak warming: Cyclostratigraphy of the carbonate oil reservoir, Siouf member, in central Tunisia

Jihede Haj Messaoud[1*]
1. ANPERC, King Abdullah University of Science and Technology, Jeddah, SAUDI ARABIA
E-mail: jihede.hajmessaoud@kaust.edu.sa

Keywords: Astrochronology, Petroleum geology, δ13C and δ18O isotopes, Parasequences, Integrated stratigraphy, Paleoclimate change.

The middle Eocene witnessed several episodes of rapid warming, leading to changes in the sedimentary facies and microfossils content. These changes culminated during the Middle Eocene Climatic Optimum (MECO), an episode of global warming that led to the widespread deposition of nummulitic limestone of the Reneiche / Siouf member (Mb.) in central and NE Tunisia. The Siouf Mb. is a lateral equivalent to the Reneiche Mb., both are the leading oil reservoirs in central Tunisia, Kerkennah, and the Gulf of Gabes. This early Bartonian nummulitic limestone member has yielded exceedingly well-developed oil reservoir proprieties. However, the potential links between the occurrences of these exceptionally developed nummulites and the MECO remain poorly investigated. We have used a multi-proxy approach (Sedimentology, biostratigraphy, stable isotopes, and cyclostratigraphy) to place our findings in a well-defined temporal context. We constrain the factors that led to the fast change toward a short-lived nummulitic limestone shelf. The MECO interval is unambiguously identified here at the Reneiche / Siouf Mb. by the biostratigraphic age (lower SBZ17 and E12) and a 3‰ negative δ18O excursion in the shallow-water carbonate platform.
We interpret the coincidence between the MECO and the Reneiche/Siouf Mb. as an indication for a link between the re-appearance of nummulites and the intense warming event. Nummulites appear in low abundance during the Lower Reneiche Limestone unit (LRL, Bey et al., 2015) from 40.52 to 40.18 Ma, then show transient increase reaching maximum abundance at the Upper Reneiche Limestone unit (URL, 40.11 to 40 Ma). Our data show that the abundance peak of nummulites and the negative values of δ18O in the URL post-dated the Middle Eocene third-order maximum flooding surface by 350 kyr, took place during the MECO peak warming from 40.07 to 40 Ma. Our results indicate that the development of the nummulitic limestone oil reservoir is directly related to the onset of the MECO warming event rather than to the sea level. Mesotrophic environment and arid to semi-arid climate during the MECO with a correspondingly high eustatic sea level favored the deposition of the Siouf / Reineche Mb. in central and NE Tunisia from 40.54 Ma to 39.8 Ma.

Keywords: Eocene, PETM, EECO, palynology, carbon isotopes, thermal event

Long-term effects of present global warming on ecosystems on timescales beyond those covered by the human record are mostly a matter of speculation. However, the reaction of ecosystems to global warming on different timescales can be inferred from detailed studies of long-term greenhouse periods and short-term warming events repeatedly known from the geologic past. The Early Eocene Climatic Optimum (EECO) and its superposed short-term warming events such as the Paleocene-Eocene Thermal Maximum (PETM) represent the last greenhouse period before today. It is especially suited for comparisons to the presently developing greenhouse since fauna and flora already reached an evolutionary state similar to today.

The Paleogene succession of the former Helmstedt Lignite Mining District in northern Germany is situated in an estuary at the southern edge of the proto-North Sea. It includes the late Paleocene to lower Eocene Schöningen Formation and the middle Eocene Helmstedt Formation, thus uniquely covering the entire Paleogene greenhouse phase and its gentle demise. Due to the interaction between changes in sea level, salt withdrawal in the subsurface and climate-related changes in runoff from the hinterland the area was subject to frequent changes between marine and terrestrial conditions, repeatedly leading to peat formation. The more than 200 m thick succession with about 13 lignite seams of up to 15 m thickness offers the rare opportunity to study late Paleocene–middle Eocene near-coastal sedimentary systems and to trace the long-term changes and short-term perturbations of the climate on the diversity and composition of plant communities across 10 million years by using pollen and spores as proxies. Changes in vegetation concur with strong differences in petrologic composition of the lignite seams between the two formations, especially with regard to charcoal content. In the Schöningen Formation fusain layers and dispersed fusain are common whereas the lignites of the Helmstedt Formation are nearly devoid of fusain. In both formations the lignite seams are separated by more or less marine interbeds in the lower part while they are associated mainly with fluvial sediments in the upper part.

Bulk organic carbon isotopic data from the Schöningen Formation show different negative carbon isotope excursions reflecting massive short-term carbon cycle perturbations, which can be related to long- and short-term hyperthermals of the early Eocene such as the EECO and the PETM. Palynological analysis proved that shifts in $\delta^{13}C_{TOC}$ values are correlated with changes in the peat forming wetland vegetation. Rapidly changing palynofloras at the PETM may be attributed to the thermal event. However, also during times outside hyperthermals strong changes in the palynofloras occur, which may be related to changing hydrologic conditions, nutrient resources and effects of peat aggradation that influenced the mire forest.

E-mail: jinxin2012cdut@163.com

Keywords: Stable isotope, Nitrogen cycle, Chemocline, Black shale, Ordos Basin

Marine nitrogen cycle perturbations during the Jenkyns Event (Toarcian Oceanic Anoxic Event, ~183 Ma) have been documented by nitrogen isotope ($\delta^{15}N$) signals. These signals emphasize the impact of seawater redox changes on the biogeochemical nitrogen cycle. However, to date there have been no studies on the lacustrine nitrogen cycle during the Jenkyns Event. In this study, we report the first $\delta^{15}N_{bulk}$ data from the Anya section of the Ordos Basin, North China and establish a model of the lacustrine nitrogen cycle through the Jenkyns Event. Based on the co-variation of $\delta^{15}N_{bulk}$ values with independent proxies for redox change (C_{org}/P ratios and $\delta^{34}S_{py}$) from this study and previous work, three phases of Anya deposition are identified: (1) Prior to, and during the early part of the Jenkyns Event, a positive excursion in $\delta^{15}N_{bulk}$ values (~+3.9 to +7.4‰) across a black shale interval occurred. This positive excursion indicates that nitrogen loss (via partial denitrification and/or anammox) was dominant. (2) A negative excursion in $\delta^{15}N_{bulk}$ (~+7.4 to +2.5‰) correlates with a negative $\delta^{13}C_{org}$ excursion that demarcates the main phase of the Jenkyns Event. This negative excursion can be attributed to the predominance of nitrogen fixation (nitrification and nitrate assimilation) within oxygen-rich water, where chemocline collapse promoted upwelling of ^{15}N-enriched ammonium. However, ^{15}N-enriched ammonium is more likely to be oxidized in oxygen-rich water and then incorporated into the pool of dissolved inorganic nitrogen (DIN). Additionally, an increased input of land plants (Type III kerogen) and a change in the hypolimnion's redox conditions (anoxic to dysoxic-oxic) suggest that chemocline collapse was most likely related to an enhanced hydrological cycle during the Jenkyns Event. (3) Following the chemocline collapse, a positive excursion in $\delta^{15}N_{bulk}$ (~+2.5 to +6.4‰) occurs in the later Jenkyns Event and its recovery phase, implying that nitrogen loss was once again prevalent. However, a dysoxic-oxic hypolimnion may have been formed as a result of lake level falls during lake regression, which may explain the subsequent stabilization of $\delta^{15}N_{bulk}$. This study suggests that chemocline collapse may play a significant role in the biogeochemical nitrogen cycle in lacustrine systems, and contributes to our understanding of the terrestrial response to the Jenkyns Event.

Keywords: Paleocene-Eocene thermal maximum, Polecat Bench, smectite, paleoclimatology, continental weathering

The Paleocene-Eocene Thermal Maximum (PETM), ~ 56 million years ago, is a geologically short-term greenhouse gas-induced global warming event. The drawdown mechanisms and rates of the high CO_2 concentrations in the atmosphere-ocean system during the event remain enigmatic. Continental chemical weathering is thought to be an important process removing CO_2 from the atmosphere, although the rates of weathering and drawdown change remain unknown. World-wide, enhanced physical weathering is observed during the event, while evidence for enhanced chemical weathering remains scarce. Here, we test chemical weathering and physical weathering changes in the PETM interval in a proximal continental setting using high-resolution clay mineralogy measurements in floodplain strata. The records from the Bighorn basin, Wyoming, a Laramide foreland basin, reveal a 30-kyr lagged increase of smectites during the body of the PETM that is prolonged for at least 50-kyr after the event. Altogether, this increase can only be explained as the result of an increase of physical weathering and erosion of smectite-rich Cretaceous bentonites in the catchments. The lagged response after the PETM onset most likely relates to the time it takes before the signal fully propagates through the catchments and upstream, basinal channel and floodplain sediments.

We observe significant grain-size sorting smectites with smectites enriched in coarse-grained sediments. However, sedimentation rates and average grain sizes remain similar in the PETM. Therefore, the smectite increase cannot be explained by grain size sorting. In-situ pedogenesis after deposition at the study site was insignificantly different in the PETM from pre-PETM soils, also not being able to explain the observed trends.

Global warming during the PETM could have generated enhanced climate seasonality with contrasting precipitation regimes during the different seasons. This may have led to drier summers causing lower vegetation covers reducing cohesiveness of catchment laterites and basinal soils. More frequent rainstorms then likely intensified the denudation of smectite-rich sediments, which at the same enhanced sediment recycling within the source-to-sink system. The prolonged nature of the smectite enhanced after the PETM event may again relate to post-PETM signal propagation times, which are even lower than after the onset of the PETM due to lower recycling rates after the event. Our result suggest that chemical weathering rates are not significantly altered during transient hyperthermal events of less than 200 kyr or are overruled by physical weathering and erosion changes. Our data therefore suggest that chemical weathering changes might not play as a strong additional role as negative feedback mechanism to reduce greenhouse-gas warming.

E-mail: cristinasq92@gmail.com

Keywords: Early Aptian Oceanic Anoxic Event, Subbetic basin, accelerated environmental changes, inorganic and organic proxies, local palaeogeography, global anoxic conditions

The early Aptian Oceanic Anoxic Event (OAE 1a) represents a major perturbation in the global carbon cycle associated with a light-carbon input into the climate system, from volcanogenic (Ontong-Java Plateau) and/or methanogenic sources, originating significant environmental, biotic and sedimentary changes. The global signature of this event is a negative followed by a positive carbon stable isotope excursion (CIE), which correlates with the widespread massive accumulation of organic matter in all major ocean basins. Besides the global environmental perturbation that characterizes the OAE 1a, local factors are a key aspect to take into account when discussing the global signals on marine successions. Here, we combine new biomarker and elemental data with published high-resolution C-isotope stratigraphy, TOC content and biostratigraphy from an early Aptian pelagic succession in the western Tethys, La Frontera section (Subbetic basin, SE Spain), in order to provide new insights into the relative roles of variations in terrestrial inputs, primary productivity and degree of oxygenation of marine waters during and after the OAE 1a. This section is further compared with a published equivalent record from a nearby succession deposited on a slightly different palaeogeographic context (Carbonero section), in order to discuss the local vs. global controls on the geochemical signal.

In La Frontera section, analyses of the distribution of selected biomarkers (n-alkanes, acyclic isoprenoids, steranes and hopanes) together with the record of redox-sensitive trace elements, has revealed three intervals of accelerated environmental change that correlate with those previously observed in the Carbonero section. These episodes occurred during intervals of rapid change in the C-isotope values. In La Frontera section, the first episode, which coincides with the negative C-isotope excursion at the onset of the OAE 1a (isotope segment C3), is characterized by a weak deoxygenation and environmental stress. The second episode, which took place at the end of the positive shift globally assigned to the C4 segment, represents the major environmental and biotic perturbation of the succession, with development of anoxia/dysoxia and increased continental inputs and productivity. The third interval of rapid perturbations during the OAE 1a occurred in the lower part of C6 segment, in this case showing a moderate increase in marine productivity, weak development of anoxia/dysoxia and no evidences of increased continental inputs. Despite the correlation of these episodes with those observed in the Carbonero section, interesting differences can be noticed regarding the magnitude of these perturbations. At Carbonero, the three intervals have similar intensity in the geochemical signal, whereas at La Frontera the second episode (C4) shows a signal clearly stronger than the others. These differences can be explained by the effect of the local palaeogeography, with variations in subsidence rates that originated more restricted water circulation at the Carbonero section. However, the major episode of accelerated environmental change recorded at the end of C4 segment in both sites would indicate that this interval represents intensified global anoxic conditions. Interestingly, organic and inorganic proxies in both localities show that environmental perturbations persisted after the OAE 1a, indicating a protracted environmental perturbation in the Subbetic basin.

Glauconite authigenesis during the warm climatic events of Paleogene: Case studies from shallow marine sections of Western India

Tathagata Roy Choudhury[1], Santanu Banerjee[1*]
1. Earth Sciences, Indian Institute of Technology, Bombay, Mumbai, Maharashtra, INDIA
E-mail: santanu@iitb.ac.in

Keywords: Paleogene, hyperthermal events, glauconite, oxygen-depleted shelf, rectilinear benthic foraminifera, transgressive deposits

This study explores authigenic mineralization associated with Paleogene warm climatic intervals within passive continental margin sediments in western India, represented by continental to marginal marine to shallow open marine sedimentary packages. These sedimentary packages are punctuated by -cm to -m thick glauconitic shale units, ubiquitous in transgressive shallow marine deposits of Cambay, Kutch, Jaisalmer, and Barmer basins. The Paleogene sediments, having extremely precise biostratigraphic age constraints, represents one of the warmest periods in the Cenozoic era. High-resolution biostratigraphic data, integrated with carbon isotope signatures, demarcate the Paleogene hyperthermal events and reveal an exceptionally high abundance of glauconite corresponding to the warming events. Although most of these glauconites are confined within the upper Paleocene-lower Eocene sediments, glauconite deposits also occur within the middle Eocene and upper Oligocene sediments. In all of these basins, glauconitic shales alternate with limestone/marl and/or grey shale unit representing an open shallow marine depositional setting. Green shale shows fine silt to fine sand-sized glauconite pellets, associated with glauconite infillings within the pores of bioclasts, randomly dispersed in a clayey matrix. The geochemical composition of glauconite varies widely, encompassing the entire maturity spectrum of glauconite minerals. The K_2O content of the glauconite pellets varies from 4 to 8 wt%, while the infillings variety is invariably poorer in K_2O. The glauconites within the upper Paleocene-lower Eocene sediments manifest high Al_2O_3 content (> 10 wt%) while the glauconites within the middle Eocene and lower Oligocene show considerably low Al_2O_3 (< 8 wt%). Despite the highly variable maturity and the Al_2O_3 content, these glauconites are rich in Fe_2O_3(total), exceeding 20 wt% in most of the cases. The glauconitic shales show minor bioturbation and are rich in rectilinear benthic foraminifera, indicative of the oxygen-depleted bottom-water conditions. The unusual composition of upper Paleocene-lower Eocene glauconites relates to their formation within kaolinite substrates during the extremely warm climatic interval. Contrary to this, during the middle Eocene and Late Oligocene, the waning phase of Paleogene warm climatic conditions, glauconite formed by the initial authigenic precipitation of Fe-smectite/ Fe-Al-smectite and its subsequent maturation. The warm climatic condition enhanced the precipitation and runoff, which supplied enhanced nutrients including K, Fe, Al, Si, and Mg into the shallow marine environment, facilitating prolific organic growth and enriching the seawater with cations. The decomposition of organic matter might have resulted in an oxygen-depleted bottom water condition, which was suitable for the mobility and fixation of iron into the glauconite structure. The glauconite formed abundantly during hyperthermal events because of the convergence of favorable factors such as rapid transgression, reduced sedimentation rate, warm seawater condition, enhanced continental weathering, and enhanced supply of nutrients favoring dysoxic shallow shelves.

Keywords: PETM, Central Asia, fluvial style, braided, meandering

The lower Paleogene sedimentary record of the uraniferous Chu-Sarysu Basin preserves a complex succession of coarse fluvial channel-belt deposits interstratified with finer floodplain and delta-plain strata that were deposited on a large subtropical coastal plain at the eastern margin of the Turan Platform. Two laterally extensive, ~25 m-thick sandstone bodies floored by prominent erosion surfaces are recorded below and above the Paleocene–Eocene boundary, respectively, and reflect laterally amalgamated channel fills partitioned by local abandonment mudstone facies. Sedimentary analysis indicates that sandstone bodies consist of multi-storey channel fills exhibiting a variety of architectural elements. The lower sandstone body comprises fining-upward grain-size trends and an abundance of rippled, organic-rich levee deposits characteristic of meandering-channel fills. In contrast, the upper sandstone body is dominated by stacked tabular cross-sets of coarser lithologies suggestive of braided-river deposits. This abrupt geomorphic change from meandering to braided fluvial style suggests a widespread increase in river discharge on the coastal plain arguably controlled by allogenic forcing. Base-level changes linked to a fluctuating water table are unlikely during greenhouse conditions of the early Paleogene, whereas the south Kazakh domain of the Turan Platform had been peneplained and uniformly subsiding since the Late Cretaceous. It is herein proposed that Paleocene–Eocene fluvial systems in the Chu-Sarysu Basin predominantly responded to intensified rainfall and runoff associated with extreme global warming. This study comes within a growing body of sedimentological evidence indicating that the PETM induced increased atmospheric humidity and an enhanced hydrological cycle. These rapid climatic changes led to increased channel-discharge regimes and sediment fluxes that are reflected in coeval sedimentary records worldwide and, for the first time, showcased in coastal-plain deposits of central Asia.

This dataset was collected within the framework of a reservoir and Uranium mineralisation modelling study on Paleogene deposits of the Chu-Sarysu Basin, logistically and financially supported by KATCO JV LLP.

Cretaceous Oceanic Anoxic Events in Turkey: Collaboration of oceanic, climatic and tectonic changes

Ismail Omer Yilmaz[1*]
1. Geological Engineering, Middle East Technical University, Ankara, Cankaya, TURKEY
E-mail: ioyilmaz@metu.edu.tr

Keywords: Cretaceous OAE, Black Shales, Pontides, Taurides, Arabian Platform, Turkey

Occurrences of black shale deposits in Mid-Barremian, Aptian, Cenomanian/Turonian stages in different basins in Turkey are recorded as Cretaceous oceanic anoxic events. The Mid-Barremian black shales (MBE) have been recorded within turbidite succession in deep marine setting in central Sakarya zone of Pontides (Yilmaz et al., 2012). 2 ‰ shifts in carbon isotope curve is recorded in parallel with European basins, but with low TOC value. The Aptian black shales (OAE1a) are recorded in pelagic carbonate slope environments in central Sakarya zone of Pontides and represented by a negative carbon isotope shift with 2 ‰, and TOC around 2% (Yilmaz et al, 2004; Hu et al, 2012). In Sakarya zone of Pontides, OAE2 is recorded in pelagic slope carbonates (Yilmaz et al, 2010) with carbon isotope curve more than 1 ‰ positive shift and >2 % TOC. Another OAE2 was recorded in Antalya Nappes of Taurides without carbon isotope curve but TOC >20% (Yurtsever et al. 2003, Bozcu et al. 2011).

Platform equivalents of OAE 2 have been recorded on the Arabian Platform carbonates in SE Turkey (Mulayim et al., 2019; 2020). In the north of Arabian Platform, there is a sudden change from upper Cenomanian shallow water platform carbonates to lower Turonian hemipelagic shales/clayey limestones with high organic carbon content. Stable isotope content of the transition is well recorded with change around +1,9 ‰, and the temperature difference is calculated around 2,2 °C (Yılmaz et al, 2020). Interesting point of the OAE 2 on Arabian Platform is to follow a drowning phase and covered by black shales in lower Turonian.

The OAE1a and OAE2 levels recorded in Turkey can easily be correlated with European examples and mainly controlled by sea level and tectonics in large-scale and climate and oceanographic changes in small-scale. The most extensive distribution of the OAE records in Turkey belong to OAE1a and OAE2, and display potential for source rocks for hydrocarbon exploration.

A sulfur-isotope record of long-term oceanic anoxia in the Toarcian and possible protracted cease of gypsum deposition

Zhong Han[1*]

1. Institute of Sedimentary Geology, Chengdu University of Technology, Chengdu, Sichuan, CHINA
E-mail: hanzhong19@cdut.edu.cn

Keywords: Toarcian Oceanic Anoxic Event, Sulfur isotopes, Long-term anoxia, Stepwise deoxygenation, Tibetan Himalaya

The early Toarcian of the Early Jurassic saw a long-term positive carbon-isotope excursion (CIE) abruptly interrupted by a significant negative shift, associated with rapid global warming and an oceanic anoxic event (T-OAE, 183 Ma). However, the detailed processes and mechanisms behind ocean deoxygenation are unclear. Here, we present high-resolution carbonate-associated sulfate-sulfur isotope data (δ34SCAS), from the Tibetan Himalaya, spanning the Toarcian interval. The δ34SCAS record shows a large positive shift from ~+20‰ to ~+40‰ which persists to nearly the end of the Toarcian. This confirms that the oceans were spatially heterogeneous with respect to their sulfate-sulfur isotope composition and suggests major pyrite burial associated with widespread development of anoxic/euxinic bottom waters during the early Toarcian. Box modelling results and sedimentary evidence suggest that large amounts of pyrite burial likely occurred in the near-equatorial deep-sea floor of the Panthalassa/Tethys. Additionally, the high-resolution δ34S data presented here provide strong evidence for two major phases of the early Toarcian ocean deoxygenation and this process was likely terminated around the end of the T-OAE nCIE. Box modelling also indicates that the persistent positive δ34S of seawater in the aftermath of the event was likely maintained by a long term downwards shift in the relative proportion of gypsum burial. This was likely driven by the forcing of seawater to below gypsum saturation point driven by a combination of massive evaporite burial of sulfate prior to the event and increased pyrite burial during it.

Mercury evidence for combustion of organic-rich sediments during the end-Triassic crisis

Jun Shen[1*]

1. State Key Laboratory of Geological Processes and Mineral Resources, China University of Geosciences , Wuhan, Hubei, CHINA

E-mail: shenjun@cug.edu.cn

Keywords: Mercury isotope, Jurassic, pelagic sediments, extinction

The sources of isotopically light carbon released during the end-Triassic mass extinction remain in debate. Here, we use mercury (Hg) concentrations and isotopes from a pelagic Triassic–Jurassic boundary section (Katsuyama, Japan) to track changes in Hg cycling. Because of its location in the central Panthalassa, far from terrigenous runoff, Hg enrichments at Katsuyama record atmospheric Hg deposition. These enrichments are characterized by negative mass independent fractionation (MIF) of odd Hg isotopes, providing evidence of their derivation from terrestrial organic-rich sediments ($\Delta^{199}Hg < 0‰$) rather than from deep-Earth volcanic gases ($\Delta^{199}Hg \sim 0‰$). Our data thus provide evidence that combustion of sedimentary organic matter by igneous intrusions and/or wildfires played a significant role in the environmental perturbations accompanying the event. This process has a modern analog in anthropogenic combustion of fossil fuels from crustal reservoirs.

The first record of OAE2 and high resolution integrated stratigraphy of the Cenomonian-Turonian succession, Sulaiman Range, Pakistan

Muhammad Hanif[1*], Mahnoor Sabba[1], Ismail Omer Yilmaz[2], Mohibullah Mohibullah[3]
1. National Centre of Excellence in Geology, University of Peshawar, Peshawar, Khyber Pakhtunkhwa, PAKISTAN
2. Department of Geological Engineering, Middle East Technical University, Turkey, TURKEY
3. Department of Geology, University of Balochistan, Quetta, PAKISTAN
E-mail: hanif.nceg@gmail.com

Keywords: Pakistan, Cretaceous, calcareous nannoplankton, Goru Formation, OAE2, planktonic foraminifera

High-resolution planktonic foraminiferal and calcareous nannoplankton biostratigraphy is provided for the pelagic succession of the Goru Formation from Murree Brewery Section of the Sulaiman Range, Pakistan. The Goru Formation in the studied section spans over the Middle Albian (Biticinella breggiensis; CC8 Zone) to Late Turonian stages (Marginotruncana sigali; CC12 Zone). Lithologically, the Goru Formation is predominantly composed of the carbonate-rich mudstones and a 0.5m black shale interval representing OAE2 followed by red colored marl/limestones (potentially Cretaceous Oceanic Red Beds, CORBS). Biostratigraphically, The Cenomanian/Turonian (C/T) boundary is identified based on the First Appearance Datum (FAD) of calcareous nannoplankton Quadrum gartneri and the FAD of the planktic foraminifera Helvetoglobotruncana helvetica. The Carbon and oxygen isotopic analysis on the carbonate fraction is also presented. A prominent negative δ13C isotopic excursion of 6 ‰ occurs at the bottom of the black shale interval, this is followed by a positive isotopic excursion of 5.8‰ representing the Cenomanian-Turonian boundary (CTB) immediately above the black shale interval. A change to more negative δ18O values from the uppermost Cenomanian into the lowermost Turonian may be the result of warming. Similar to other Tethyan sections, the onset of the OAE2 predates the CTB in Murree Brewery Section as recorded in many European sections. A major turnover in the deep-dwelling planktonic foraminifera (Rotaliporas) occurred during the Cenomanian-Turonian boundary Interval. The single-keeled Rotaliporas was succeeded by the double-keeled Globotruncanids. Three dissolution resistant calcareous nannoplankton taxa are dominant i.e. Watznaueria barnesae, Eiffellithus turriseiffelii, Eprolithus floralis within the studied interval. High species richness and high abundance of the tropical species Watznaueria barnesae, suggest warm tropical waters. The two abundant species, tropical W. barnesae and cool water E. floralis alternate in abundance in the early and middle Turonian, suggesting changing climatic conditions.

E-mail: huxm@nju.edu.cn

Keywords: Paleogene hyperthermal, Carbonate microfacies, Calciturbidite, Condensed glauco-phosphorite, SW Iran, Neo-Tethyan ocean

Early Paleogene hyperthermal episodes including the Paleocene-Eocene Thermal Maximum (PETM) have long been viewed as analogues of the Anthropocene global warming. Few studies, however, have analyzed the environmental consequences of such climatic anomalies in deep-water turbidite-rich successions. This integrated sedimentological, biostratigraphic, and stable-isotope study of the Paleogene Pabdeh Formation, deposited along the Arabian continental margin of southwestern Iran, allowed us to document the geological response of hyperthermal events in deep Neo-Tethyan Ocean. The late Thanetian event (Pre-Onset Excursion or long-term late Paleocene climatic perturbation), the Early Eocene Climate Optimum, and the Middle Eocene Thermal Maximum were successfully identified within the Pabdeh Formation. The PETM event could not be documented because the Paleocene/Eocene boundary corresponds to a prolonged non-depositional hiatus marked by a glauco-phosphorite interval. Based on high-resolution microfacies analysis, three different processes in a carbonate slope to basin-margin environment were distinguished including pelagic settling, upwelling-condensation-reworking, and storm-induced turbiditic deposition. Detailed sedimentological analysis revealed an anomalous abundance of storm-induced proximal to distal turbidites represented by packstones with deep-water and reworked shallow-water bioclasts occurring during the hyperthermal intervals. A close causal link between climate warming and tropical storms during the early Paleogene hyperthermal events is thus envisaged. As a principal mechanism, we propose that rapid warming in response to massive carbon release triggered pronounced sedimentological changes along low-latitude tropical margins, leading to generation of storm-induced calciturbidite and re-deposition in the deep sea during hothouse stages.

Biogeochemical responses to global warming during the Paleocene-Eocene Thermal Maximum in the eastern Tethys

Qingting Wu[1], Ying Cui[1*]
1. Earth and Environmental Studies, Montclair State University, Passaic, New Jersey, UNITED STATES
E-mail: cuiy@montclair.edu

Keywords: PETM, North Atlantic Igneous Province, eastern Tethys

The Paleocene-Eocene Thermal Maximum (PETM; 56 Ma) represents a rapid and sustained climate perturbation event that coincides with the emplacement of the North Atlantic Igneous Province (NAIP). Although proxies for chemical weathering, biological productivity, and oceanic deoxygenation are commonly used in the deep oceans, the role of the eastern Tethys, a subtropical shallow marine environment, in regulating the carbon cycle dynamics and climate feedbacks is poorly understood. Here we present geochemical data from the Tarim Basin, northwestern China to assess the environmental responses of the eastern Tethys to the PETM. An increase in chemical weathering proxies (chemical index of alteration, chemical index of weathering, modified chemical index of alteration, and plagioclase index of alteration) indicates enhanced terrestrial input shortly after the PETM onset, possibly due to an intensified chemical and physical weathering. The PETM onset is also characterized by an increase in Mo and V concentrations, indicating an expansion of oceanic anoxia. At the same time, primary productivity appears to increase abruptly, presumably due to an increased riverine flux of nutrients (Ni, Fe, and P) that stimulated marine productivity. The ecosystem stress imposed by elevated nutrient fluxes and anoxia expansion is likely amplified by simultaneously intensified chemical and physical weathering, highlighting the importance of integrating geochemical proxies in tracking the environmental responses to climate changes.

Keywords: PETM, Mercury, shallow-water carbonates, Dinarides, NAIP

The Paleocene-Eocene Thermal Maximum (PETM; ~ 56 Ma) was an interval of extreme transient climate change, associated with global warming and a massive perturbation of the global carbon cycle (e.g., Zachos et al., 2003). This latter is testified by a sharp Negative Carbon Isotope Excursion (N-CIE) in the global marine and terrestrial $d^{13}C$ records, linked to the injection of large volumes of isotopically light carbon into the ocean-atmosphere system. The source of such ^{13}C-depleted carbon is still a matter of debate. The emplacement of the North Atlantic Igneous Province (NAIP) with the release of huge amounts of CO_2 is suspected to be one of the factors that may have caused such a relevant change in the composition of the atmosphere/ocean carbon reservoirs and the associated abrupt climate perturbation. Research is increasingly exploring mercury (Hg) anomalies as tracers of volcanism during the Paleocene-Eocene interval mostly in deep-water and subordinately in shallow-water settings (e.g., Tremblin et al., 2022 and references therein), arguing about their possible relationship to the NAIP emplacement and its impact on the PETM onset and duration.

The aim of this contribution is to present an integrated study of sedimentology, stratigraphy (bio and chemo), and geochemistry of the deposits belonging to the Adriatic Carbonate Platform cropping out in the Classical Karst area of Friuli Region (NE Italy), encompassing the PETM event. In particular, here we show paired new carbon- and oxygen-isotope data combined with Hg concentrations and TOC analyses from two shallow-water marine carbonate sections across the Paleocene-Eocene boundary.

The two investigated sections were deposited during the migration of the foreland basin related to the Dinaric orogeny and are today exposed in the Classical Karst area near Trieste (Italy) for about 50 and 300 meters, respectively, of Paleocene-Eocene platform carbonates evolving upward to hemipelagic marls and then to siliciclastic deposits. Vertical facies evolution of the carbonate platform indicates that an initial inner- to mid-ramp setting underwent a relative deepening and then was followed by multiple emersion episodes intercalated by proximal marine deposition (i.e., innermost to inner ramp environments). This latter was followed by a return to open marine facies which then persisted until the final drowning of the Adriatic platform that in our study area occurred in the late early Eocene.

Our results show in both sections a negative excursion in the carbon-isotope record that, associated with biostratigraphic data, can be correlated with the PETM N-CIE and is comparable to other coeval $d^{13}C$ records, both in shape and amplitude. These negative shifts are associated with anomalies in Hg concentration, strengthening the hypothesis that magmatism effectively occurred during this time interval, and its effects are also recorded in shallow-water deposits. These findings corroborate the hypothesis that vulcanism (the NAIP?) might have played a key role in climate change at the PETM.

E-mail: mfranceschi@units.it

Keywords: Hg enrichment, volcanism, pXRF, climate change,SPBE

In the Early Jurassic, there is a globally recognized perturbation of the carbon cycle occurred at the Sinemurian-Pliensbachian transition, named“Sinemurian-Pliensbachian Boundary Event” (SPBE, ~ 192.5 Ma). The SPBE is associated with environmental and climate perturbations such as increased runoff, changes in marine shallow water carbonate production, enhanced preservation of organic matter and dysoxic conditions in the oceans. Evidence mainly comes from the marine realm, while other sedimentary settings around the world has been less investigated. Recent works have highlighted the presence of a prominent negative perturbation of the $\delta^{13}C_{org}$ in Lower Jurassic lacustrine succession of the Sichuan Basin, which has been correlated to the SPBE (Franceschi et al., 2022). The causes of the SPBE are still unclear, but a potential link to late phases of volcanism of the Central Atlantic Magmatic Province has been hypothesized based on mercury (Hg) enrichments observed in Sinemurian – Pliensbachian marine successions of the Western Tethys (Shöllhorn et al., 2020). Studies have put forward the hypothesis of a warming trend in the lower Pliensbachian that may have culminated in short-lived hyperthermals (e.g. Silva et al., 2015). In this contribution, we present Hg and TOC content data from the Lower Jurassic lacustrine succession of the Sichuan Basin (Eastern Tethys) in the Dacao section where a high resolution $\delta^{13}C_{org}$ record is already available (Franceschi et al., 2022). Results highlight Hg enrichments coincident with the negative $\delta^{13}C_{org}$ shift that is interpreted as the SPBE. The relative low correlation with TOC data, suggests that Hg could be volcanogenic. This, together with the fact that the Hg enrichment at the Sinemurian-Pliensbachian transition is documented in the continental realm, strengthen the hypothesis of a global-scale link between the SPBE and volcanic activity. Preliminary results of elemental analysis carried out with pXRF further reveals enrichment trends in elements such those of the group of clay minerals that may be compatible with variations in runoff intensity caused by climate change to more humid conditions at the SPBE. Our results provide clues as to how climate changes associated with the SPBE may have been linked to volcanic activity and have had global extent.

Keywords: CPE, Late Triassic, biostratigraphy, chemostratigraphy, Ma'antang Formation

The Carnian Pluvial Episode (CPE; early Late Triassic) was a global perturbation of the C-cycle associated with a marked enhancement of the hydrological cycle, and consequent increase terrigenous sediment and freshwater input to the shallow marine sedimentary environments. Within the CPE interval, negative shifts in the $\delta^{13}C$ of marine and terrestrial organic matter and marine carbonates testify to multiple injection of large amounts of CO_2 into the atmosphere – ocean system, likely linked to the emplacement of the Wrangellia Large Igneous Province. The CPE coincided with a crisis of shallow water carbonate production and with a major biological turnover both in the marine and terrestrial realms. The environmental effects of the CPE have been widely documented in the western Tethys, but much less data are available from other areas. In the last decade, the western Sichuan Basin (China) became a reference locality for the study of the effects of the CPE in the eastern Tethys. However, research has also given rise to debate on the bio-, magneto- and chemostratigraphy of the Carnian successions. To resolve the existing controversies on this key CPE study area, we review the current knowledge on biostratigraphy, petrology and geochemistry of the successions in the Sichuan Basin, and provides an updated bio- and chrono-stratigraphic framework. Furthermore, we highlight the open questions and outline future research directions about the CPE in the area.

Coeval changes of carbonate platform environment and carbon isotope at Permian-Triassic boundaries in South China and Lhasa block

Jiawei He[1], Xiumian Hu[2*], Zhong Han[1]

1. Institute of Sedimentary Geology, Chengdu University of Technology, Chengdu, Sichuan, CHINA

E-mail: huxm@nju.edu.cn

Keywords: Permian-Triassic boundary,Carbonate platform,Carbon isotope,Carbonate microfacies

The Permian-Triassic boundary (PTB) has experienced the largest biological extinction in the geological history, and there has been a significant global carbon isotope excursion, accompanied by the development of unconformity, anachronistic facies and Occurrence of hyperthermal event. However, there are absence of detailed studies in carbonate platform environment in response to the carbon isotopic excursion around the PTB. This study measured three carbonate platform sections throughout the PTB located on the South China (Liangfengya section near Chongqing, Taiping section in Guangxi) and Lhasa block (Wenbudangsang section near Gaize). High-precision carbonate microfacies and carbon apposition stratigraphic analysis were carried out, and 14 types of carbonate microfacies were recognized. Carbonate microfacies show that during the latest Permian, the Liangfengya section and the Taiping section are in the inner ramp environment as a whole, and the Wenbudangsang section is in the outer ramp environment. The carbonate carbon isotopes during PTB can be divided into four stages: NC1 (before carbon isotope excursion event), NC2 (carbon isotope excursion event initiation stage), NC3 (carbon isotope excursion event continuous stage) and NC4 (after carbon isotope excursion event). Comprehensive studies on sedimentary microfacies, carbon isotope changes and fossil records show that there is an evolutionary sequence of NC2 with unconformity development and anachronistic facies development followed by the NC3 stage. Taking the duration of NC2 stage in the Meishan section as the standard (~58 kyr), the occurrence time of sedimentary events in different sedimentary sections is restored by stratigraphic thickness interpolation. The hard ground structure first appeared in the Liangfengya section at ~ 9kyr later the start of NC2 stage, and the last appeared in the Wenbudansang section at ~ 46kyr later the start of NC2 stage. Stratigraphic loss occurs at ~ 6kyr later the start of NC2 stage in areas where microbialites are not developed, and at ~ 37kyr later the start of carbon isotope negative bias in areas where microbialites are developed. At the same time, the emergence of hard ground structure or stratum loss is often accompanied by the development of anachronistic facies, in which the main development of microbialites and oolitic limestone is concentrated in NC2 stage, and the main development of dolomite is in NC3 stage. Compared with the PTB , with the intensification of the earth's temperature increase, the carbonate platform in the shallow sea environment will take the lead in the sudden change of the marine environment, spread to the deep-water environment ~ 37kyr later, and accompanied by the emergence of microbialites and oolitic limestone.

Ocean deoxygenation across the end-Triassic mass extinction

Tianchen He[1*]
1. School of Earth and Environment, University of Leeds, Leeds, West Yorkshire, UNITED KINGDOM
E-mail: t.he@leeds.ac.uk

Keywords: ocean oxygen scarcity, redox proxies, western Tethys, eastern Panthalassa, end-Triassic extinction

The role of ocean deoxygenation as a cause of the end–Triassic marine mass extinction is widely debated. Here we present multi-redox proxy data (carbonate-associated sulfate $\delta^{34}S$, I/(Ca+Mg), Fe speciation and trace metals) at sections across the shallow to deep-water marine realms of the western Tethys and eastern Panthalassa. Results show local dissolved oxygen decline in the near-surface ocean of low-latitude Tethys across the extinction, synchronous with the global-scale spread of deeper anoxic waters on continental shelves and slopes. Further, persistent euxinic conditions prevailed across the Triassic–Jurassic boundary in many semi-enclosed basins of the NW European epicontinental sea, coinciding precisely with the major phase of benthic faunal loss at the regional scale. Hence, the coincidence of extreme redox shifts with the extinction losses on a global scale implicates oxygen scarcity as an important factor in the crisis.

E-mail: micha.ruhl@tcd.ie

Keywords: Plate motion, Toarcian, Karoo-Ferrar, Large Igneous Provicne volcanism, LIP

Large igneous province (LIP) emplacement is commonly associated with mantle plume upwelling, leading to surficial magmatism, proposed to have driven past global change events by volcanic carbon emission. One of Earth's largest past environmental perturbations, the Early Jurassic Toarcian oceanic anoxic event (T-OAE; ~183 Ma), has been linked to emplacement of the Karoo-Ferrar LIP. However, the role of mantle plumes in controlling the onset and timing of LIP magmatism is poorly understood.

Here, utilizing global plate reconstruction models, and Lower Toarcian sedimentary mercury (Hg) concentrations from the Mochras borehole (Wales, UK), we demonstrate (1) that the Early Toarcian OAE occurred coevally with Karoo-Ferrar LIP emplacement, and (2) suggest that the timing and duration of LIP-emplacement was governed by a reduction in local Pangean plate motion associated with a reversal in plate movement direction.

With this, we present a new model that mechanistically links Earth's interior and surficial processes, and we show that this mechanism is consistent with the timing of several of the largest LIP volcanic events throughout Earth history and thus, by inference, the timing of many of Earth's past global climate change and mass extinction events.

E-mail: guillaume.suan@univ-lyon1.fr

Keywords: Paleocene-Eocene, extraterrestrial helium isotopes, cyclostratigraphy, hyperthermal event

The Paleocene-Eocene Thermal Maximum (PETM) was one of the most severe episodes of rapid greenhouse warming of the geological past. Identifying the key drivers of the carbon cycle across the PETM requires an accurate, highly resolved chronology of the event and its characteristic phases. The duration of these various phases estimated by cyclostratigraphic and extraterrestrial ^{3}He ($^{3}He_{ET}$) methods, however, vary greatly, hindering a detailed understanding of the impact of rapid warming on Earth System dynamics. To reconstruct sedimentation rates across the PETM, we present new high-resolution $^{3}He_{ET}$ contents measured at CRPG and Caltech of nannofossil ooze spanning the Paleocene-Eocene boundary at ODP Site 1209 (North Pacific). The measured $^{3}He/^{4}He$ ratios approach those measured in modern interplanetary dust particles and show that >99.9% of sedimentary ^{3}He is of extraterrestrial source. Cycle-based age models imply $^{3}He_{ET}$ fluxes of 0.31 ± 0.02 pcc/cm^{2}/ka before and after the PETM, supporting the hypothesis of a constant flux across the event. Assuming this flux remained constant through the PETM, our $^{3}He_{ET}$ -based sedimentation rates reveal an episode of extreme condensation across the PETM onset and indicate that the interval of anomalously ^{13}C-depleted values (body/core) lasted ~185 ka. The termination of the PETM core coincided with a surprisingly fast (<30ka) increase of carbonate fluxes, which remained elevated for ~80 ka, in line with other oceanic records. Based on these results and a comprehensive reassessment of previous $^{3}He_{ET}$ and cyclostratigraphic records, we construct an integrated and globally consistent age model for the PETM in continental, shallow marine, and deep-sea settings. The implications of the new chronology for the causes and consequences of the PETM will be discussed.

Stepwise increasing paleotemperatures in the Late Jurassic-Early Cretaceous epeiric basin of the Eastern Russian Platform

Konstantin Nikashin[1], Svetlana Zorina[1*]
1. Institute of Geology and Petroleum Technologies, Kazan Federal University, Kazan, Tatarstan Republic, RUSSIA
E-mail: svzorina@yandex.ru

Keywords: Paleotemperature, Late Jurassic, Early Cretaceous, epeiric basin, Eastern Russian Platform

Aside from the long-term periods of warm climate, several hyperthermal events are identified in the Jurassic and Cretaceous (Foster et al., 2018), most of which are associated with oceanic anoxic events (OAEs) and black shale accumulation. In the Eastern Russian Platform (North-Eastern Peri-Tethys), several Mesozoic black shale formations are widely occurred, among those the Middle Volgian (Upper Jurassic) Promzino formation and the OAE 1a-related Lower Aptian (Lower Cretaceous) Ulyanovsk formation are known. To reconstruct paleotemperatures and the depositional environments, the stable oxygen and carbon isotopes of biogenic carbonates (more than 200 ammonite, bivalve, and benthic foraminifer shells and belemnite rostra) from the Upper Jurassic-Lower Cretaceous succession were analyzed. The lack of significant diagenetic alterations of carbonates as well as their mineralogy were preliminarily established using element geochemistry, Raman spectrometry, and electron microscopy data.

Based on the first results of the $\delta^{18}O$ analysis, a paleotemperature curve was constructed using equations from (Grossman, Ku, 1986; Anderson, Arthur, 1983). This curve shows quite a warm climate in the Late Jurassic in study region, with water column temperatures ranging in 17–25 °C. Noteworthy, temperatures calculated for benthic foraminifer shells are generally similar to those for ammonites suggesting a low temperature gradient in water column and hence a weak water stratification. Slight positive temperature excursion during the deposition of the Promzino black shales does not match the hyperthermal event (18–23 °C) which is confirmed by temperatures curve constructed for the temperate belt of the Northern hemisphere (Veizer, Prokoph, 2015). Rather abrupt warming of almost 4 °C is reported for the Russian Platform in the Later Jurassic (Price, Rogov, 2009), but the maximum temperature obtained (20 °C) is much lower than that typical for hyperthermal event. Interestingly, our results show an unexpected cold snap (10 °C) in the uppermost Promzino formation which could be probably caused by the strong phase of volcanic activity (Rentgarten, Kuznetsova, 1967). Nevertheless, warm climate reconstructed could maintain high productivity in the highly restricted basin in the Middle Volgian (Zorina et al., 2020) which is among major factors contributing to the enhanced preservation of the organic matter in the Eastern Russian Platform.

Trend of temperature evolution during the Early Cretaceous is partly similar to the global one, but temperatures reconstructed for the study basin in the Later Hauterivian and Barremian generally exceed the global values by more than 5 °C with occasional drop to 8 °C detected in the Later Hauterivian. This discrepancy could be explained by the specificity of basin circulation and strong phases of volcanic activity (Zorina et al., 2020). Rapid rise in temperature to 30–35 °C in the Late Barremian–Early Aptian (combination of our data with those from Zakharov et al., 2013) reflects hyperthermal event OAE 1a. Most probably, the extremely hot climate induced intensification of desalination of surface water and development of thermohaline stratification in the water column, which in turn caused anoxia and the organic matter accumulation (Erbacher et al., 2001).

Keywords: Permo-Triassic, eastern Australia, biotic crisis, coastal plain

This talk summarises results from a multi-disciplinary project that aimed to elucidate responses of lowland terrestrial settings in high paleolatitudes to end-Permian environmental stresses. The study focused on an extensive, north-south-elongate basin system in eastern Australia that preserves a stratigraphically complete succession of late Permian to Middle Triassic age. A suite of high-precision, CA-IDTIMS U-Pb ages from zircons in tuffs provides tight constraints on the timing of events. The succession accumulated on a broad, coastal alluvial plain in a retroarc foreland basin. The Permian succession preserves abundant coal. Abrupt extirpation of the Glossopteris flora is recorded at the top of the uppermost coal seam in the succession, but this event took place some 200-600 kyr before the marine extinction event as determined at the Meishan Permo-Triassic boundary GSSP. Above the uppermost coal is a distinctive dark grey shale ("Marker Mudstone" in the Bowen Basin of Queensland, Frazer Beach Member in the Sydney Basin of New South Wales) that preserves mainly algae, fungi, amorphous organic matter and charcoal fragments. Elements of a new macro- and microflora then become apparent gradually through the overlying strata. These strata are initially drab grey like the underlying Permian succession, but progressively change to stronger hues upward. Chemical Index of Alteration data indicate a major increase through the Permian-Triassic transition, δ13Corg values describe a negative excursion, and there are transient spikes in nickel concentrations in mudrocks across the boundary. Climate models suggest a shift towards warmer and more seasonal climates across the boundary, and this is supported by sedimentological data that indicate fluvial sediment dispersal under increasingly flashy discharge regimes. Deep tetrapod burrows were found subtending from the base of a sharp-bounded sandstone bed at one locality.

No significant, long-term change in overall depositional environment, average grain-size, or sediment dispersal direction is recorded across the boundary, with mobile fluvial systems active both before and after the floral extirpation. However, the Marker Mudstone/Frazer Beach Member record widespread ponding of surface water caused by an excess of water availability following demise of the Glossopteris flora. Presence of charcoal indicates abundant wildfires, and the proliferation of algae and fungi indicates that lakes became eutrophic and were inhospitable to aerobic life. Above this, stratal color changes and together with the deep tetrapod burrows, suggest that the Early Triassic climate entailed periods of drought and/or seasonal drying of the landscape. Geochemical and modelling data indicate a change to a warmer, seasonal, and more humid climate. Floral extirpation was likely caused by climate and fire regimes passing a tipping point, possibly in conjunction with poisoning by airborne volcanigenic heavy metal toxins. The palaeoenvironmental changes across the Permo-Triassic boundary in eastern Australia are comparable to, but slightly less extreme than, those documented from lower palaeolatitudes, suggesting flattening of latitudinal temperature gradients at this time.

Disruption of terrestrial plant ecosystem in Miocene (sub) tropics: a palynological perspective from Fotan Formation, Southeast China

Yi Yang[1], Wei-Ming Wang[2*]

1. Exploration and Development Research Institute, Changqing Oilfield Company, PetroChina, Xi'an, Shaanxi, CHINA
2. State Key Laboratory of Palaeobiology and Stratigraphy, Nanjing Institute of Geology and Palaeontology, and Center for Excellence in Life and Paleoenvironment, Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences, Nanjing, Jiangsu, CHINA

E-mail: wmwang@nigpas.ac.cn

Keywords: palynology, fern spike, ecosystem disturbance, Miocene, Southeast China

The palynological records on "fern spike", i.e., forest was transiently replaced by fern-dominant vegetation and then rapidly recovered, were documented in the geological past around the world, especially following the massive extinction (e.g. Triassic/Jurassic and Cretaceous/Tertiary boundaries). Fern spikes represent the initial colonization by pioneer species following massive destruction of vegetation.

Here, two fern spikes were recognized in the palynological sequences of MP-1 section (late Early–early Middle Miocene) and HK section (late Middle–Late Miocene) from the Fotan Formation in Zhangpu County, Fujian Province, Southeast China, which is the first report about fern spike events in this area.

Based on the appearances of fern spikes and the law of vegetation succession, we found that at least two catastrophic events occurred in our study area during the Miocene, which are considered to be caused mainly by the contemporaneous flood basalt volcanism. Along with the fern spikes we observed the increased runoff and the bloom of *Concentricystes* (algae) as a result of enhanced nutrient inputs after the ecosystem disturbances. Besides, in comparison with MP-1 section, the fern spike in HK section is characterized by 1) the higher abundance and diversity in terms of the composition of fern spores, 2) the appearance of fungal spike, 3) the longer time of duration, and 4) the much higher degree of prosperity of *Concentricystes*, suggesting that the severity of the catastrophic event occurred during the deposition of HK section is greater than that of MP-1 section.

Rapid climatic and environmental change were major contributors to the End-Permian Extinction (EPE). Although well-constrained for the marine realm, relatively few records document the pace, nature, and magnitude of climatic and environmental change across the EPE in terrestrial environments. The Bowen and Sydney basins in eastern Australia were major depocenters within a narrow, north-south-elongate basin system that stretched along the southeastern margin of Gondwana. These basins preserve a stratigraphically complete, upper Permian to Middle Triassic succession, which accumulated on a broad, coastal alluvial plain in a retroarc foreland basin setting. A continental volcanic arc produced numerous zircon-bearing tuff beds, which has facilitated the development of a high-resolution chronostratigraphic framework. We generated geochemical proxy records for pCO2, chemical weathering, and land surface temperature (LST). Regional climate simulations provide additional context. Through the latter half of the Changhsingian, Chemical Index of Alteration (CIA) profiles show increases from long-term averages of c. 70 in the Bowen Basin and c. 75 in the Sydney Basin to 80–85 regionally, suggesting an increase in LSTs from 12–14 °C and 14–16 °C, respectively, to 20–21°C along the entire continental margin. Consistently humid, temperate, broad-leafed Glossopteris forest-mire ecosystems thrived through this interval, despite gradual warming and increasingly seasonal climate. The EPE horizon, evident as the abrupt disappearance of coal-forming forest communities and elevated levels of charcoal in sediments, is marked by a peak in CIA and LST values of 85–90 and 22–23°C, respectively, indicating that the extinction coincided with an episode of intense chemical weathering and peak warmth. These results suggest that a tipping point was reached, which crossed a tolerance threshold for the forest-mire ecosystems that had long dominated the landscape. CIA profiles indicate that erosion following the collapse of vegetation was relatively short-lived in what was a low-gradient landscape. Although the post-EPE climate was 10–14°C warmer and landscapes were no longer persistently wet, results point to overall higher but more seasonal precipitation consistent with an intensification of a monsoonal climate regime in southeastern Gondwana. Aridification, often linked to the EPE, developed gradually in this region, perhaps facilitating the persistence of refugia for moisture-loving terrestrial flora. In the immediate aftermath of the extinction, the region was dominated by flora indicative of more open vegetation with adaptations to periodic water stress. Consistently humid conditions supporting coal-forming vegetation only re-established in the region some 5–10 million years later, during the Middle Triassic.

A biotic crisis driven by an abrupt shift to well oxygenated oligotrophic conditions and a collapse of primary productivity in the epicontinental sea ecosystems during the CTBE

Keywords: CTBE, OAE-2, epicontinental sea, Foraminifera, Dinoflagellata, δ15Norg

The Cenomanian-Turonian Boundary Event (CTBE), also referred to as the Oceanic Anoxic Event 2 (OAE-2), was investigated in a section representing the shallow epicontinental sea of the Central European Basin in Poland. This event was one of the strongest biotic crises of the Mesozoic, which impoverished marine biota, benthic foraminifera in particular. The crisis is expressed in the section examined by significant changes in foraminiferal and organic dinoflagellate assemblages, which indicate a switch to highly oligotrophic conditions associated with a collapse of primary production concomitant with the onset of the OAE-2. This switch correlated with a significant shift in N isotope signature in bulk organic matter, which we analyzed in detail. Yet, despite these biotic and isotopic changes, lithology and depositional conditions remained unchanged throughout the event, which suggests an environmental control on these variations.

Expansion of anoxic conditions in the basinal settings is accompanied by a sudden decrease of δ15Norg values (< −2‰) and high organic primary productivity during the OAE-2. These depleted δ15Norg values are thought to be chiefly driven by the assimilation of recycled ammonium, not nitrate, by primary producers, which was delivered to the photic zone from anoxic bottom waters. High production rate of this 15N-depleted biomass boosted by denitrification and anammox in such “ammonium ocean” caused the residual 15N enrichment in the remaining fixed N pool in the surface layer. Unlike the basinal settings, we observe a drastic increase of δ15Norg values to > +5‰ in the epicontinental setting examined during the OAE-2, which indicates that productivity was dominated by nitrate (and nitrite) and that the ammonium from the ocean did not reach the epicontinental setting. Instead, we propose that the shallow oceanic waters, with strongly 15N-enriched nitrate spread laterally onto epicontinental settings. Yet, our micropaleontological data show that fully oxic and low-productivity conditions occurred at that time in the area, so at such low level of bioavailable N, the additional delivery of strongly 15N-enriched nitrate was able to increase the overall δ15N of organic matter deposited in the epicontinental basin. Our integrated foraminiferal and dinoflagellate cyst study, supplied with N isotopic data, indicate that the biota were impacted by an abrupt shift to well oxygenated oligotrophic conditions and a collapse of primary productivity in the epicontinental Central European Basin. Because the event was concurrent with the development of extensive and extreme oceanic bottom water anoxia that reached the photic zone in oceanic settings, we infer that the biotic crisis in the shelf seas during the OAE-2, and possibly during other OAEs, was triggered by this anomalous nutrient cycling in Earth's oceans.

Paleozoic ironstone suggests redox stratification played a role in Ordovician and Silurian biotic crises

Keywords: extinction, ironstone, ocean oxygenation, ocean anoxic events, Paleozoic, redox stratification

Variable oceanic redox and expanding shelfal anoxia have been increasingly invoked as the causal mechanism in several biotic crises (extinctions) and contemporaneous isotopic excursions that occurred during the early and middle Paleozoic. However, the exact drivers of these anoxic events remain poorly constrained. In this study, sedimentologic, stratigraphic, and geochemical analyses of five Ordovician and Silurian ironstone-bearing successions are used to provide insights into the oceanic redox structure during the early Paleozoic. Eu anomaly and $^{87}Sr/^{86}Sr$ data indicate that ironstone formed from marine fluids with a component of mid-ocean ridge hydrothermal waters that remained largely unmixed during transport over thousands of kilometers to continental margins and epeiric seas. These results suggest that areas of the deep oceans must have been oxygen deficient, thereby supporting the buildup of hydrothermal fluids. Thus, ironstone provides novel evidence that redox stratification, with oxygenated surface oceans above anoxic deep waters, must have at least transiently existed through the Ordovician and Silurian. Furthermore, these data suggest that ironstone is a previously unrecognized proxy of Paleozoic oceanic oxygenation, one that supports the hypothesis that Paleozoic oceans did not become as well ventilated as modern oceans until at least the Devonian. The interpretation of protracted deep-ocean oxygenation and open-ocean redox stratification has important implications for the co-evolution of the biosphere. We propose that widespread transport of deep anoxic water, and with it both toxic and bioessential trace elements, onto oxygenated continental shelves represents a previously unrecognized driver of, or contributor to, numerous Ordovician-Silurian biotic crises and anoxic events. If sub-redoxcline, anoxic, trace-element-rich waters spread from deep oceans onto outer continental shelves, the expected effects would have included elevated primary productivity, expanded neritic oxygen minimum zones, benthic oxygen deficiency, enhanced organic matter burial, modified regional biologic pumps, abrupt facies changes, locally ferruginous or euxinic bottom water leading to sedimentary metal enrichment (e.g., ironstone or elevated pyrite burial), and resultant $\delta^{13}C$ and $\delta^{34}S$ excursions. Each of the aforementioned effects is widely documented for many of the Late Ordovician (i.e., Hirnantian) and Silurian biotic crises (e.g., the Ireviken, Lau, Klonk). Furthermore, the oceanographic and climatic shifts (i.e., glacioeustasy, intensified upwelling, changes in circulation patterns, etc.) interpreted as coincident with these early Paleozoic extinction events are all means by which sub-redoxcline waters could have readily spread into shallower environments. This spread would have occurred either directly through upwelling or indirectly through shoaling of the redoxcline such that it impinged above the shelf-slope break. Thus, the redox stratification model provides novel insights into the underlying oceanographic redox state during the early Paleozoic, which when combined with previously interpreted climatic and oceanographic triggers for early Paleozoic anoxic events, readily explains their widely documented sedimentary and geochemical records.

SEDIMENTARY RESPONSE TO ABRUPT CLIMATE CHANGE ACROSS THE HYPERTHERMAL PERMIAN-TRIASSIC BOUNDARY ON LAND, NORTH CHINA

Keywords: sedimentary response, Permian–Triassic boundary, hyperthermal, paleoenvironment, warming, North China

The Permian-Triassic boundary (PTB, ~252 Ma) witnessed the largest hyperthermal event ever, with the most drastic environmental changes and the most severe biotic extinction worldwide, both on land and in the oceans. The climate heated rapidly in low-latitude areas, caused by a huge and sharp input of greenhouse gases related to large igneous province volcanism (Siberia LIPs) and synchronous massive volcanism worldwide. This study investigates the sedimentary response to environmental changes across the terrestrial PTB in the eastern Ordos Basin, North China. The PTB is indicated by the die-off of tetrapods and plants, decreased bioturbation levels in the uppermost Sunjiagou Formation, and the bloom of microbially-induced sedimentary structures (MISS) in the Liujiagou Formation, supported by the sharp negative shift of carbon isotope and synchronous geochemical proxies. The abrupt sedimentary transition from Lopingian meandering rivers to Induan braided river-aeolian facies to Olenekian shallow lacustrine setting documents palaeoenvironmental changes from semi-arid to arid and then to semi-humid conditions, which is synchronous with the collapse and delayed recovery in palaeoecosystems and is likely to be one of the direct causes. Similar sedimentary responses to extreme climate crises on land have been reported elsewhere worldwide at the PTB (e.g. South Africa, Russia, NE Spain) and across other similar deep-time hyperthermal events (e.g. Paleocene–Eocene Thermal Maximum). Exploring their common features could test the idea that there is a ‘hyperthermal blueprint’ or common pattern to such events through geological time, but at different magnitudes that could inform our understanding of the current, Anthropocene climate crisis. Such a sedimentary response under a regime of warming, aridity and intermittent heavy precipitation on land may not only accumulate or amplify the signals of abnormalities and consequences in shallow marine settings but also connect the land and ocean.

Keywords: Kellwaser event, black shales, axonia, Late Devonian

Anoxic conditions in epicontinental watermasses have been implicated as one of the key drivers for deposition of black shales in the geologic record. However, there are several mechanisms that can trigger anoxia, and distinguishing among them is a significant challenge for the reconstruction of depositional conditions in ancient mud-dominated systems. In this study, we reconstructed the general evolution of watermass conditions through deposition of the organic-rich Late Devonian New Albany Shale (NAS) in the Illinois Basin, USA. Through a detailed sedimentological and geochemical characterization of three cores, we establish a general sequence evolution of the NAS that we extrapolate to 50 wells across the basin using gamma ray logs. The three studied cores have been divided into three stages based on detrital proxies (Zr, Al), carbonate proxies (Ca), and redox-sensitive proxies (Mo, U). Moreover, each stage is characterized by a distinctive facies association arrangement. Our results suggest that deposition of the NAS occurred in three stages (two prograding, and one retrograding), characterized by the occurrence of four variably-related anoxic pulses. The first anoxic pulse was triggered by initial flooding of the basin at the base of a depositional sequence. The second anoxic pulse occurs in the middle of this prograding sequence and is likely related to the Lower Kellwasser Event based on scarce available biostratigraphy. The third anoxic pulse is related to basin flooding at the base of a second prograding sequence and can be confidently assigned to the Upper Kellwasser Event based on biostratigraphy and the presence of a positive carbon isotope excursion in organic matter. The fourth anoxic pulse occurs in a general retrogradational context when black shale deposition reached its maximum areal extent in the basin. This signal matches the expression of the global Hangenberg Event in the Williston Basin (North Dakota, USA), but further bio- and chemostratigraphic constraints are needed to confirm the placement of this event in the Illinois Basin. Overall, we find that anoxia in the epicontinental Illinois Basin was triggered by a variety of different mechanisms through deposition of the NAS. In some cases, anoxia is a local response to changes in relative sea level and, in other cases, basin anoxia is related to global anoxic events with no change in relative sea level. In some instances, however, these two mechanisms are related likely because anoxia in multiple epicontinental seas worldwide is triggered by the same eustatic forcings. We suggest that a similar approach may be useful in reconstructing the conditions that led to black shale deposition in other epicontinental seas of the geologic past.

The disturbance of terrestrial ecosystems during the Permian-Triassic transition in South and North China

Daoliang Chu[1*]
1. School of Earth Science, China University of Geosciences (Wuhan), Wuhan, Hubei, CHINA
E-mail: daoliang_chu@163.com

Keywords: Terrestrial, Permian-Triassic mass extinction, South China, North China

The Permian-Triassic mass extinction (PTME) had a catastrophic impact on both marine and terrestrial ecosystems and was the most severe crisis of the Phanerozoic. It is widely attributed to the global environmental changes caused by the contemporaneous volcanism. The timing and nature of the terrestrial crisis is unclear. The terrestrial sediments in South China record increased abundance of fossil charcoal coincident with the onset of a negative carbon isotope excursion (CIE) and the loss of tropical rainforest vegetation, both of which occurred immediately before the peak of Hg concentrations. We find a significant peak of spore tetrads of lycopsid plants coeval with increases in metal concentrations above the main terrestrial extinction interval in South China, which suggests that survivor lycophyte plants were under huge stress after the loss of the Permian forests. However, the crisis of conifer and the dramatic decrease of total organic carbon content in North China occurred before the negative CIE and significantly preceded the increase of Hg content. These evidences probably suggest that the crisis of different terrestrial ecosystems is asynchronous. To obtain a more complete understanding of the specific processes and driving mechanisms of terrestrial PTME, high-resolution and in-depth studies are urgently needed to reveal the biological and environmental evolution in the terrestrial record.

Keywords: Cretaceous-Paleogene, Impact, Forest fire

Impact of the Chicxulub bolide that brought the Mesozoic to a close is widely recorded by a layer of highly distinctive deposits, including the products of catastrophic sedimentation around the Gulf of Mexico and the North Atlantic, as well as globally-distributed bolide- and target-sourced ejecta from the impact site itself. These deposits also include soot, the origin of which has ascribed either to combustion of inorganic material at the target site, or to wild fires occurring at or close to the time of impact, or subsequently due to ignition of forest killed by the immediate after-effects of the impact (Morgan et al., 2022, and references therein). We describe a section from a mid-slope succession on the Pacific margin of Mexico, about 2500 km from the impact site, which on the basis of faunal and floral changes, radiometric dating, and an iridium anomaly, clearly represents a Cretaceous-Palaeogene (K-Pg) boundary section. The deposit consists largely of debrites that contain not only re-sedimented shallow marine faunas but also large sections of silicified tree trunks with charred bark and cambium but pristine xylem, and no evidence of decay or bio-erosion (Cevallos-Ferriz et al., 2021). Raman spectroscopy of the charcoal indicates temperatures up to more than 1000 C. The presence of fossil wood within deepwater deposits implies its incorporation into a debris flow whose matrix yield strength exceeded the buoyancy of the wood.

The adjacent slope and coastal succession shows widespread and large-scale sliding at the K-Pg boundary. We interpret the presence of shallow marine and terrestrial material within debrite of the K-Pg boundary section to indicate resedimentation by the back-wash of a slide-generated tsunami. Adopting upper crustal P wave velocities of 6 to 8 km s^{-1} (e.g. Rosalia et al., 2019) depending on the ray path, arrival times of the first seismic shocks from the impact would have been no more than 5 to 7 seconds post-impact. Based on historic seismogenic mass failures (e.g. Løvholt et al., 2019), sliding would have occurred almost immediately, and the associated tsunami would have arrived within minutes to tens of minutes. Since the trees incorporated into the debris flow by the tsunami were already charred, the high-temperature event responsible must already have occurred by this time, i.e. within minutes to tens of minutes of the impact. This rules out secondary burning of dead trees in the days to months following impact. Numerical modelling of the impact plume or 'fireball' (Svetsov and Shuvalov, 2018), and re-entry of ejecta into the atmosphere (Morgan et al., 2013) indicate substantial heat flux within seconds to minutes of impact. Experimental evidence (Belcher et al., 2015) appeared to indicate

that sustained heat flux would be required to ignite live wood, and that the required conditions would only be achieved relatively close to the impact site (in contrast to the estimates of Svetsov and Shuvalov, 2018). However, our evidence shows that heating sufficient to very rapidly ignite live trees occurred almost immediately after impact at distances of at least 2500 km from the impact site.

A New Liberation Lagerstätte from Southwest China during Carnian Pluvial Episode

Zhiheng Ma[1], Tingshan Zhang[1*], Jingwen Chen[2], Jianli Zeng[1], Xi Zhang[1], Shixin Li[1], Hongjiao Li[1]
1. School of Geoscience and Technology, Southwest Petroleum University, Chengdu, Sichaun, CHINA
2. Fuzhou University, Fujian Key Laboratory of Mineral Resources, Fuzhou, Fujian, CHINA
E-mail: zhangtingshan@swpu.edu.cn

Keywords: Liberation Lagerstätte, Carnian Pluvial Episode, Xiaowa formation, South China

We report the Luxi biota, a new Liberation Lagerstätte from the Triassic Carnian Xiaowa Formations in Yunnan, South China, with close faunal links to the biota of Cassian Formation in Italy. The biota described from the marls of the Julian 2 siltstone were deposited during a major, Tethyan-wide climate crisis - the so-called Carnian Pluvial Episode(CPE) - characterized by an amount of terrigenous clastics input the marine and a demise of carbonate platforms. The biodiversity of the Luxi biota includes Cephalopoda (Ammonitida, Phragmoteuthida, Orthocerida, Nautilida and Belemnitida), Gastropoda, Bivalvia, Brachiopoda, Crinoidea and plant fossils. The fossil community from three different lithological parts of the Xiaowa Formation exhibits different preservation forms and combinations in each part. In the lower part, abundant compressed Trachyceras multituberculatum and Halobia yunnanensis were found in black mud-limestone; The middle part is dominated by the lime-siltstone. At the base of the middle part contains three-dimensional preserved Sinobelemnitidae and Michelinoceras with a few pyritized ammonoids(Austrotrachyceras, Sirenites). However, Sinobelemnitidae rapidly disappeared and replaced by some gastropods such as Anulifera, Zygopleura, Neritaria etc.. Based on electronic microscope scanning, some gastropods preserve the protoconch and all protoconches indicate these gastropods were a nonplanktotrophic lifestyle during the larval stage. Besides the gastropods, a few phragmoteuthids(Phragmoteuthis), bivalves(Halobia, Monotis) and brachiopods(Norella, Neoretzia) with low fossilized are also found in this part; The upper part is black shell. It contains a large amount of three-dimensional preserved ammonoids (Austrotrachyceras, Neoprotrachyceras, Sirenites, Yakutosirenites, Anasirenites), brachiopods and crinoid stems. This important discovery indicate (1) bio-community change accompany by the environmental fluctuation during CPE. To be more specific, the three parts of Luxi biota represent a planktotrophic biotic combination transferred to a benthic biotic combination during terrigenous clastics inputting. The benthic biotic combination returned to planktotrophic biotic combination after terrigenous clastics inputting. (2)Due to fossilization has been affected by the carbonate production crisis and an amount of terrigenous clastics inputting, some vulnerable and delicate parts of fossils can be preserved. It provides favorable conditions for the formation of Liberation Lagerstätte.

Keywords: basaltic landscape, erosion, weathering, early Late Permian, hydroclimate change

Chemical weathering and physical erosion are major factors affecting landscape evolution and shaping Earth`s surface. Modern observations and measurements along with modelling suggest significant effects of hydroclimate on catchment erosion and weathering. But to reveal the hydroclimate influences on catchment-averaged erosion and weathering from geological records is challenging. Here we present proxy data on the provenance, source weathering and paleowater salinity from the early Late Permian sedimentary successions in western South China. The analyzed successions are dominated by basaltic mudrocks and sandstones derived from the Emeishan large igneous province. A negative organic carbon isotope excursion (CIE) was observed from all the studied three successions. Based on this CIE, these studied estuary-deltaic successions can be correlated with deep-water and shallow marine successions in South China and with terrestrial successions in eastern Australia where the last Permian glacial-deglacial cycle was recorded. Reported high-precision tuffaceous zircon U-Pb ages support these stratigraphic correlations and constrain this early Late Permian CIE at around 258-257 Ma, corresponding to the middle Wuchiapingian deglaciation. Through this strata interval with CIE, mudrock chemical and mineral compositions consistently demonstrate a decrease in source chemical weathering intensity and detrital zircon data suggest a prominent unroofing of the Emeishan volcanic provenance. Using proposed relationships of chemical weathering rate with land surface temperature and with denudation (total erosion) rate for present-day basaltic landscapes, the denudation rates of the Emeishan basaltic landscape were calculated based on the published seawater temperatures from South China and show high values (~300 t/km^2/yr) in the interval with CIE than in the underlying and overlying intervals (both are ~200 t/km^2/yr). During the acceleration interval, denudation rate is negatively correlated (r^2 = 0.56) with mudrock B/Ga ratio which shows a distinct decrease from >6 to < 3. This decrease in mudrock B/Ga ratio reflected a marine to freshwater facies change and suggest an enlargement in freshwater influx for these middle Wuchiapingian estuary-deltaic environments in South China. Such water salinity changes along with the co-increased sandstone proportion in studied successions and occurrences of terrigenous clastic depositions in deep-water and shallow marine successions support an enhancement in fluvial sediment and freshwater supply, which were possibly related to strengthened rainfalls. It follows that the erosion acceleration of basaltic landscapes was likely associated with hydroclimate change in South China during the middle Wuchiapingian warming. Landscape evolution modelling supports this hypothesized causal linkage and further indicates an increase of precipitation by ~2-3 times for the observed acceleration in landscape erosion.

The Late Miocene Carbon Isotope Shift driven by synergetic terrestrial processes: A box-model study

Jinlong Du[1*], Jun Tian[1], Wentao Ma[2,3]

1. State key laborotary of Marine Geology, Tongji University, Shanghai, CHINA
2. State Key Laboratory of Satellite Ocean Environment Dynamics, Second Institute of Oceanography, Hangzhou, Zhejiang, CHINA
3. Southern Marine Science and Engineering Guangdong Laboratory, --, Zhuhai, Guangdong, CHINA

E-mail: dujinlong@tongji.edu.cn

Keywords: carbon cycle, box-model, late Miocene, carbon isotope, atmospheric CO2

As the most significant carbon isotope excursion in the past 10 Ma, the Late Miocene Carbon Isotope Shift (LMCIS, 7.65 to 6.5 Ma) offers a great opportunity to investigate the carbon-climate dynamics in a warmer-than-today world. However, the driving mechanisms of the LMCIS remain controversial. In this study, we used a 7-box biogeochemical model to simulate the long-term seawater $\delta^{13}C$ and atmospheric CO_2 changes during the late Miocene. Based on the quantitative parameterization of two terrestrial processes (C_4-grasses expansion and enhanced weathering input) during the late Miocene, our results show that the synergy between the two terrestrial processes may ultimately result in the LMCIS via the perturbation of the land-sea carbon fluxes. Moreover, our results reveal that the re-partitioning of alkalinity and nutrients between the land and the ocean may have influenced the long-term atmospheric CO^2 change during the late Miocene.

Rapid climatic fluctuation during the Guadalupian-Lopingian transition: recorded by weathering index of geochemical acid-insoluble residua of carbonate rock, South China

Shi Sun[1], Anqing Chen[1*]
1. State Key Laboratory of Oil and Gas Reservoir Geology and Exploitation, Chengdu University of Technology, Chengdu, Sichuan, CHINA
E-mail: aqinth@163.com

Keywords: Acid-insoluble residua, Continental weathering, Climatic fluctuations, The GLB transition, South China

The Guadalupian-Lopingian boundary (GLB) transition was regarded as a gradual warming period with the termination of the Late Paleozoic Ice Age (LPIA). However, the glacial-nonglacial cycles from Eastern Australia imply that the period was also influenced by climatic fluctuations. We here report on a GLB section of the South China Block confined by the conodont biostratigraphy to constrain weathering intensity and the associated climatic fluctuation during this critical interval. The chemical weathering indices were estimated by analyses of acid-insolubles residua extracted from carbonate rocks. Two weak weathering unitsUnit 1 and 3, Early Capitanian and Early Wuchiapingianand two strong weathering unitsUnit 2 and 4, Late Capitanian and Middle Wuchiapingianare identified. δ 13 C carb generally follow well the variation tracks of weathering indices. Two weak weathering units (Unit 1 and 3) correspond to the P3 glacial and the P4 glacial in high-latitude region of Australia. The strong weathering unit (Unit 2) is closely related to the eruption of the Emeishan Large Igneous Province (ELIP). These climatic fluctuations of the GLB transition also influenced the biodiversity. The CIA-converted land surface temperature and reported seawater temperature reflect the synchronous response of continental climate and marine conditions. The high temperature associated with the peak of the ELIP may be responsible for the GLB extinction.

Tectonic quiescence triggered the early Paleoproterozoic glacial climate and the onset of the Great Oxidation Event

Xingyu Ma[1,2], Genming Luo[1,2*]

1. State Key Laboratory of Biogeology and Environmental Geology, China University of Geosciences, Wuhan, 430074, Hubei, CHINA

Keywords: Paleoproterozoic, Chemical weathering, Snowball Earth, Great Oxidation Event

The Great Oxidation Event (GOE), a milestone event in the evolutionary history of habitable Earth, generally coincided with the Paleoproterozoic glacial climate. However, the causal-effect relationships between these two events remain controversial. Here, we investigate the continental chemical weathering, which is the critical link between these two events, by compiling a global data set of the chemical index of alteration (CIA) in this interval from 2600 to 2000 Ma. Our results demonstrate that the time period from ~2430 to 2340 Ma is generally characterized by limited continental chemical weathering, coinciding with the glacial climate and tectonic quiescence revealed by the compiled data of U-Th-Pb ages of zircons and volume of the large igneous province (LIP). The limited continental chemical weathering suggests that the nutrients fluxed into the ocean would be very low, which would restrict O_2 production. Therefore, we proposed that both the glacial climate and onset of the GOE were attributed to tectonic quiescence, which decreases the CO_2 and reducing gases released into the atmosphere. The resurgence of the tectonic activity ~ 2340 Ma could trigger the termination of glacial climate, result in a significant increase in the continental chemical weathering, and, consequently, promote the large increase in pO_2 indicated by the high $\delta^{13}C$ values in the interval from ~2250 to 2060 Ma.

Isotopic and elemental characteristics of the Ediacaran Doushantuo Formation, South China: New insights for great oxygenation events

Yifan Li[1*], Tan Zhang[1], Tailiang Fan[1]
1. School of Energy and Resources, China University of Geosciences (Beijing), Beijing, CHINA
E-mail: liyifan@cugb.edu.cn

Keywords: continental weathering, Neoproterozoic oceanic oxygenation, Yangtze Platform, isotope

The Ediacaran Period (635-542 Ma), a critical period throughout Earth history, witnessed major marine carbon cycle perturbations, great oxygenation events, biological systems innovations, and regional Ediacaran glaciation events. However, the origin of these negative carbon isotope anomalies and great oxygenation events remain highly debated. Here, we present high-resolution carbon and strontium isotope, and elemental records of drill core samples from the Ediacaran Doushantuo Formation, Yichang City, Hubei Province, South China. The δ13C profiles display five negative carbon isotope excursions (EN1, EN1-1, EN1-2, EN2 and EN3), which consist of three major negative excursions (EN1, EN2 and EN3) and two minor, local negative excursions (EN1-1 and EN1-2). Both EN2 and EN3 excursions display highly basin-scale spatial heterogeneity along the shelf-to-basin transect across the Yangtze Platform. Overall, Doushantuo Formation δ13Ccarb values in deeper intrashelf basin sections are ca. 3-5‰ lower than those in the shallower intrashelf basin, shelf margin and upper slope sections, and are ca. 5-10‰ lower than those in the inner shelf sections, respectively. High spatial heterogeneity in the magnitude and timing of EN2 and EN3 excursion across the proximal to distal transect reflects dynamic oxidation in the surface ocean between elevated oxidant availability with limited spatiotemporal distribution and reduced carbon from the subsurface dissolved organic carbon (DOC) pool. Elevated oxidant availability during the EN2 and EN3 is primarily associated with the long-term late Neoproterozoic oxidation event combined with enhanced continental weathering. Doushantuo Formation 87Sr/86Sr records exhibit two significantly positive 87Sr/86Sr excursions (P1 and P2), roughly coinciding with the EN2 and EN3 excursions. Elevated 87Sr/86Sr ratios during the P1 and P2 events are likely linked to the overall rise in continental weathering rates during the assembly of Gondwana at ca. 0.6-0.5 Ga. Additionally, redox-sensitive trace elements (Mo, U and V) also display significantly enrichments within EN2 and EN3 excursions, which indicates oceanic oxygenation events. A compilation of δ13C, 87Sr/86Sr, and redox-sensitive trace elements record during the Ediacaran suggests that increasing continental weathering provokes oceanic oxygenation that leading to negative carbon isotope anomalies.

Coupled conodont δ18OPO4 and 87Sr/86Sr records indicate hydroclimate changes in North China at the Permo-Carboniferous transition

Yuan Wang[1], Jianghai Yang[1*]
1. School of Earth Sciences, China University of GeosciencesWuhan, Wuhan, Hubei Province, CHINA
E-mail: yangjh@cug.edu.cn

Keywords: Permo-Carboniferous transition, oxygen isotope, strontium isotopes, conodont, paleoclimate

The significance of chemical proxies from semi-restricted marine depositions are debated. Recent studies have shown decoupling of epicontinental isotopic records from open-marine ones and suggested superposition of regional hydro-climate factors, such as freshening, coastal upwelling, temperature, and salinity. We analyzed oxygen and strontium isotopes of conodont apatite (genera Streptognathodus) from Permo-Carboniferous epicontinental successions in southern North China and tested how the connection of epicontinental isotope variability in the sea to large-scale ocean-atmosphere processes. Average δ18O values are around 16.7 ‰ and decrease from 18.0 ‰ to 16.2 ‰ from the early Gzhelian to Asselian. These δ18OPO4 values are consistently lower than that of contemporary open-marine successions. The strontium isotope ratios are between 0.70825 and 0.70948, with an average value of ~0.70858. The 87Sr/86Sr values are consistently higher than the corresponding open-marine records. Optical observations and trace element characters suggest no significant diagenetic influences on the analyzed conodont domains. It is therefore that the obtained δ18O and 87Sr/86Sr values could reflect the oxygen and strontium isotopic features of the seawaters from which these conodont apatites were precipitated. We hypothesized an extensive effects on the epicontinental sea waters from fluvial discharges which supply freshwaters with low δ18O and high 87Sr/86Sr due to the drainages in Proterozoic basements of North China. This study emphasized the linkage of hydroclimate conditions to the biogeochemical evolutions in epicontinental seas and highlighted the cautions to interpret chemical proxies from shallow marine records.

A three-billion-year history of continental weathering

Gaojun Li[1*], Ruiyu Yang[1], Jens Hartmann[2], Jun Chen[1]

1. Department of Earth and Planetary Sciences, Nanjing University, Nanjing, Jiangsu, CHINA
2. Institute for Geology, Center for Earth System Research and Sustainability (CEN), Universität Hamburg, Hamburg, GERMANY

E-mail: ligaojun@nju.edu.cn

Keywords: weathering, continental crust, geological carbon cycle, zircon, oxygen isotopes

Chemical weathering has profound influence on the Earth's habitability because it releases vital nutrients to sustain the biosphere and regulates climate through interaction with carbon cycle. However, reconstructions of continental weathering through the Earth's history are scarce. Based on a novel big-data algorithm applied to the O-U-Pb-Hf isotopic compositions of over 5,000 grains of globally distributed detrital zircons, this work deconvolves a three-billion-year history of continental weathering rate from the time-integrated weathering-alteration of crustal $\delta^{18}O$ registered by detrital zircons with varying temporal and spatial coverage.

Zircon can record the oxygen isotopic composition ($\delta^{18}O$) of its parent crust at the time of crystallization, the value of which principally reflects the time-integrated effect of crustal alteration. The Hf isotopes and U-Pb isotopes of zircon constrain the alteration history between crust generation and zircon crystallization. A new algorithm is introduced to reconstruct the average $\delta^{18}O$ alteration rate of continental crust ($R_{\delta 18O\text{-}CC}$) through time by solving a set of linear equations based on a large population of detrital zircons with varying temporal coverage across the history of crustal alteration. The reconstructed $R_{\delta 18O\text{-}CC}$ shows an overall bell-shape long-term evolution centered at 2 Ga superposed with variations that are coupled with supercontinental assembly cycles. The long-term evolution of the reconstructed $R_{\delta 18O\text{-}CC}$ seems to be correlated with solid-earth CO_2 degassing expected from the age distribution of deleted mantle and the supercontinental cycles. Thus, the $R_{\delta 18O\text{-}CC}$ is interpreted to reflect weathering considering the control of solid-earth CO_2 degassing on the total weathering flux of continental crust. This work demonstrates the great potential that weathering history may have in reconstructing the operation of the Earth system across deep-time.

Environmental co-evolution in South China during the Cryogenic interglacial: Evidence from trace element geochemistry

Yang Chuang[1], Runsheng Yin[1*]
1. State Key Laboratory of Ore Deposit Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences, Guiyang, Guizhou, CHINA
E-mail: yinrunsheng@mail.gyig.ac.cn

Keywords: Cryogenic interglaciation, element geochemistry, volcanism, chemical weathering,material cycling

Earth witnessed two global glaciation events (named Sturtian and Marinoan) during the Neoproterozoic Cryogenian. The Cryogenian interglaciation, occurring between these two glacial events, was a key period for the formation of manganese resources and polymetallic black shales in the world. However, the formation mechanism and environmental changes of this interglacial period remain poorly understood. This study investigates the elemental geochemistry of the Cryogenic glacial-interglacial sequence (Tieshiao and Datangpo Formations) in the Wuhe Section, Guizhou, SW China, and demonstrates that: (1) the Cryogenic interglaciation was driven by large volcanism, which not only directly released large amounts of volcanic components (e.g., Hg, V andTl) into the ocean, but also triggered global warming, leading to enhanced continental chemical weathering and the input of terrigenous substances (e.g., Y, Nb, Ta, Zr and Hf) into the ocean. Volcanism and terrigenous weathering introduced abundant nutrients into the ocean, enhancing marine productivity and the oxygenation of surface seawater, leading to precipitation of Mn from seawater to cause large-scale manganese ore formation in this period; (2) Elements (e.g., In, Sn, Ag, Cu, Zn, Pb and Bi) enriched in submarine hydrothermal fluids show low anomalies during the Cryogenic interglaciation, suggesting that the Cryogenic interglaciation was not driven by submarine volcanism, but more likely by large-scale terrestrial volcanism. Results of this study reveal a close coupling of the evolution of the "ocean-atmosphere-land" system during the Cryogenic interglaciation.

Clay minerals as weathering and paleoclimatic proxies across the Carnian Pluvial Episode (Late Triassic): a composite section from the Dolomites (Italy)

Matteo Pecorari[1*], Piero Gianolla[1], Giuseppe Cruciani[1], Fabio Tateo[2], Marcello Caggiati[1]
1. Physics and Earth Sciences, University of Ferrara, Ferrara, ITALY
2. Institute of Geosciences and Earth Resources, National Research Council of Italy, Padua, ITALY
E-mail: matteo.pecorari@unife.it

Keywords: Clays, Paleoclimate, Triassic, Carnian, CPE, Dolomites

Clay minerals are weathering products par excellence and their formation can be linked to the climate; thus they could be helpful in paleoclimatic reconstructions. The Carnian Pluvial Episode (CPE) is a multi-pulses climatic perturbation associated with almost four negative Carbon isotopic shifts (Dal Corso et al., 2020). The CPE triggered many important consequences on the sedimentary, environment and global ecosystem evolution of the Late Triassic. Several sedimentological, geochemical and paleontological features have been studied to detect changes related to the climatic episode, and the Dolomites have been representing a helpful source of data on this topic (Dal Corso et al., 2018). Nevertheless, through more than 20 years of studies in the Dolomites, clay minerals were not considered yet.

Here we provide the first paleoclimatic study of clay sediments based on mineralogical data (bulk and clay fraction) and geochemical analysis for Dolomites successions, which encompass not only the syn-CPE succession, but also the pre- and post- event stratigraphic intervals. We sampled clayey beds and interbeds from the San Cassiano Fm., Heiligkreuz Fm. and Travenanzes Fm., obtaining a composite section which covers the earliest (Julian) to late (Tuvalian) Carnian time span. Collected samples were XRD-analysed both as “bulk” powders and oriented mounts. Diffraction patterns of the “bulks” were Rietveld-fitted to achieve phase quantitative analyses while oriented mounts allowed complete identification of clay minerals. ICP-OES analyses were conducted for major, minor and trace elements. This approach combines complementary data from mineralogy and geochemistry, allowing to provide a complete picture on the weathering processes and rate occurred across the CPE. Obtained analysed have been integrated to sedimentological and palynological data to improve the paleoclimatic reconstruction.

Interestingly, the samples from the uppermost San Cassiano Fm. and the first two members of the Heiligkreuz Fm. (Alpe di Specie and Borca mbs.) displayed the same clay assemblage, dominated by Illite-Smectite mixed-layer (I/S), followed by Illite, Kaolinite and also Chlorite in several samples. Within this interval, we observed a maximum in the ratio of clay minerals vs. carbonates located few meters above the first Negative Carbon Isotope Excursion (NCIE) detected by Dal Corso et al. (2018), suggesting that clays might record the environmental change connected to the first pulse of the CPE later than other proxies (e.g., palynomorphs).

Samples from the overlying Dibona Mb. (above the second NCIE) show a higher dominance of siliciclastics/carbonates ratio (confirmed also by geochemistry) and contain two different species of mixed-layer phase: the disordered I/S and the regular mixed-layer (Rectorite). In suborder, we found Illite and Kaolinite while Chlorite is absent. The mineralogy of the clay fraction leads to consider this association as representing a humid paleoclimate, if provenance changes are excluded.

The climatic configuration was reversed within the Travenazes Fm., whose samples are dominated by Illite and I/S (prevailing Illite), followed by Chlorite. Kaolinite is absent. These features allowed us to interpret the sharp change in clay mineralogy as a further witness of the return to arid condition in the late Tuvalian, after the CPE.

Keywords: higher plant-derived biomarkers, palynological records, palaeovegetation, palaeoclimate, East Asian monsoon

The sedimentary rocks of the Yinggehai-Qiongdongnan Basin in the northern South China Sea preserve important records of the complicated interactions between terrigenous sediments and the East Asian monsoon climate. It remains obscure how higher plant-derived biomarkers and the inferred floral changes respond to the East Asian monsoon climate in the South China Sea. The late Oligocene-early Pliocene palaeovegetation and palaeoclimate in the Ying-Qiong Basin, South China Sea were comprehensively reconstructed using higher plant-derived biomarkers, palynological records, kerogen maceral compositions, and trace elements of shales. During the period from about 24.9−18.3 Ma, there are trends of higher relative abundances of plant-derived biomarkers including oleanane, des-A-oleanane, rearranged oleananes, taraxastane, bicadinanes, high molecular weight n-alkanes (Cn ≥ 27), C19 tricyclic terpane, and C29 ααα 20R sterane in the younger sediments. Similarly, over this period, there are records of increasing amounts of tropical/subtropical angiosperms and pteridophytes in the younger sediments, and lesser amounts of temperate Pinus and Alnus species. The bloom of the dominant tropical-subtropical higher plants and the large influx of terrigenous organic matter during this period were likely associated with extra precipitation under a warming climate. This warming and more humid climate is related to the establishment of the East Asian monsoon in the South China Sea at about 24.9 Ma in the late Oligocene, which was likely caused by uplift of the northern Himalaya-Tibetan Plateau.

During the period from about 8.2−2.7 Ma (corresponding to the deposition of the upper Huangliu Formation to the lower Yinggehai Formation), there was a remarkable decline of inferred higher plant inputs and vitrinite proportion in the kerogen. The temperate species Pinus and Alnus became more dominant, and ferns became less abundant in the lower Yinggehai Formation compared to the underlying late Miocene sediments. Various higher plant-derived aromatic hydrocarbons including cadalene, retene, 1,2,7-trimethylnaphthalene, 1-methylphenanthrene (1-MP), 1,7-dimethylphenanthrene (1,7-DMP), 6-isopropyl-1-isohexyl-2-methylnaphthalene (ip-iHMN) and other polycyclic aromatic hydrocarbons (PAHs) were identified. Higher plant parameters suggest that the relative abundance of total terrigenous organic matter in the early Pliocene was lower than in the angiosperm-dominated organic matter in the late Miocene Huangliu Formation. Various gymnosperm/angiosperm indices including retene/(retene + cadalene), 1-MP/9-MP, and 1,7-DMP /(1,3- + 3,9- + 2,10 + 3,10-DMP), and the higher plant index, indicate that gymnosperms made a larger contribution to the organic matter when the lower Yinggehai Formation was deposited during the early Pliocene. Combustion-derived PAHs including fluoranthene, benzo[a]anthracene, benzofluoranthenes, and coronene predominate over petrogenic PAHs, indicating that there were more wildfires during deposition of the lower Yinggehai Formation and the upper Meishan Formation. In contrast, there is a mixed input of combustion-derived and petrogenic PAHs in the Huangliu Formation. As also supported by increasing abundances of Pinus and Alnus in palynological records, the combustion-derived PAHs, the gymnosperm/angiosperm parameters, and the trace element proxies provide unequivocal evidence for a weakened East Asian summer monsoon during a cooling climate from the late Miocene to the early Pliocene in the South China Sea.

Provenance and depositional environment in Shuicheng area, western Guizhou Province, China—Evidence from paleontology and geochemistry

Yulin Shen[1*], Zhiying Dang[1]
1. School of Resources and Geosciences, China University of Mining and Technology, Xuzhou , xuzhou city, jiangsu province, CHINA
E-mail: yulinsh@163.com

Keywords: Changhsingian, Calcareous algae, Foraminifera, Palaeoclimate, paleoceanography, Provenance background

Well-developed marine carbonate of the the Late Permian Changhsingian in the Shuicheng area of western Guizhou, with abundant biological fossils such as calcareous algae, foraminifera, brachiopods, gastropods, bivalves, cephalopods, crinoids, echinoids, sponges and ostracods. Based on the systematic paleontological and geochemical analysis, we studied the water medium conditions, palaeoclimate, paleoceanography and provenance background of the late sedimentary period of Changxing Formation in the area. The results show that six fossil assemblages can be delineated from the bottom to top in the Changhsingian vertical sedimentary sedimentary sequence: the Foraminifera-Calcareous algae-Brachiopoda assemblage, the Foraminifera-Brachiopoda-Bivalve assemblage, the Bivalve-Gastropoda-Crinoida assemblage, the Foraminifera-Calcareous algae-Bivalve assemblage, and the Foraminifera-Bivalve-Brachiopoda and Foraminifera-Calcareous algae-Ostracoda assemblages. Among them, calcareous algae and planktonic foraminifera are the most abundant and diverse. The trace elements of Rb, Cs, Ba and Tl are relatively depleted, while the Trace elements of Nb are relatively enriched. The trace elements abundance of Li, Be, Sc, V, Cr, Co, Ni, Cu, Zn, Ga, Sr, Zr, Sn, Hf, Ta, Pb, Th and U are closer the average of the upper crust. Chondrite—normalized REE patterns show that the rocks are enriched in LREE and relatively depleted in HREE, with Eu weak negative anomaly and Ce no anomaly. Study area Changxing Formation main sedimentary period was mainly in warm humid climateparalic sedimentary environment and anoxic environmentthus in favor of abundant calcareous algae and foraminifera growing. A sudden dry and hot climate in the late period, with a sudden rise in the water column, an increase in salinity and temperature, and the emergence of clusters of relatively heat-tolerant ostracods, while other organisms declined sharply or even disappeared. ∑REE-La/Yb discrimination diagram indicate that the Provenance is mainly influended by volcanism during the Emeishan stage, diagenetic parent material is basalt. According to discrimination diagrams of La-Th-Sc, Th-Sc-Zr/10 and Th-Co-Zr/10source materials of the Changxing Formation was mainly deposited in a continental island arc setting and clastic materials from an oceanic island arc were partly added during the late depositional period

The Plio-Pleistocene stratigraphic record of shallow-marine environments from the Western Foreland Basin (WFB), Taiwan, is an excellent climate archive because of its high temporal completeness promoted through high rates of accommodation creation and sedimentation. To date, only a limited interval of early Pleistocene shallow-marine strata (~220 kyrs) has been astrochronologically tuned, revealing traceable climate oscillations.

Here, we astrochronologically tuned the Chinshui Shale and the lower part of the Cholan Formation of the WFB, extending the record of climate oscillations from 3.7 to 1.9 Ma. These strata are tuned to a tropical deep-sea stable oxygen isotope ($\delta^{18}O$) record with an established time scale. The Chinshui Shale is mudstone-dominated and was deposited mostly in offshore settings. The Cholan Formation comprises mainly heterolithic strata deposited in shallower marine settings (i.e., offshore transition and nearshore environment). In this study, we use two borehole gamma-ray profiles from the Chinshui Shale and the Cholan Formation. High gamma-ray values reflect clay-rich mudstone intervals and correlate to lower values of $\delta^{18}O$ in the reference record. Low gamma-ray values point to sandstone-dominated packages and correlate with higher values of $\delta^{18}O$.

Our results show that alternating mudstone-dominated to sandstone-dominated successions during the late Pliocene to early Pleistocene are orbitally paced, and the stratigraphic record of WFB is effectively “complete” for the studied time frame between 3.7 to 1.9 Ma. The results also allow us to i) tune the upper Pliocene–lower Pleistocene Chinshui Shale and lower part of the Cholan Formation, ii) refine the magneto-biostratigraphic framework established for this time interval in the WFB of Taiwan, and iii) lay the groundwork for connecting climatic changes in Taiwan during this time to global climate change impacts.

Geochemical characteristics of Early Cambrian elements and their Paleoenvironmental Significance in the western margin of the upper Yangtze River

Weizhen Chen[1], Jingchun Tian[1*]
1. State Key Laboratory of Oil and Gas Reservoir Geology and Exploitation, Chengdu University of Technology, chengdu, sichuan, CHINA
E-mail: tjc@cdu.edu.cn

Keywords: sedimentary environment,δCe negative anomaly,Redox index,Early Cambrian,Upper Yangtze Region

The petrology and element geochemistry of well js1 in the Early Cambrian Maidiping-Qiongzhusi Formation in the western margin of the upper Yangtze are studied, and the characteristics of elemental geochemistry and sedimentary environment of Maidiping-Qiongzhusi Formation were discussed, so as to provide a theoretical basis for determining the paleoenvironmental evolution of Maidiping-Qiongzhusi Formation and shale gas exploration evaluation.The comprehensive analysis of geochemical characteristic parameters such as organic carbon, whole rock host, trace and rare earth elements shows that the characteristic parameters such as $Al_2O_3/(Al_2O_3+ Fe_2O_3)$, MnO/TiO_2, Zn-Ni-Co, U-Th and Y/Ho of Maidiping-Qiongzhusi Formation in JS1 well area indicate that it belongs to the continental margin sedimentary environment affected by terrigenous debris, and the parent source mainly comes from the mixing of sedimentary rocks and granite. The ree results show that light rare earth elements (LREE) is enriched relative to heavy rare earth elements (HREE) in Maidiping Formation $(La:Yb)_N$=6.05, slightly to the right, and the average δEu is slightly less than 1, indicating normal seawater deposition, shallow water, and not significantly affected by hydrothermal action. The Qiongzhusi Formation has obvious light rare earth elements differentiation $(La:Yb)_N$=7.69), LREE enrichment, HREE depletion, and obvious right dip, with weak negative δCe and δEu anomalies, and transient or intermittent hydrothermal activity disturbance. The comparison of δCe anomaly characteristics (δCe=0.36) and regional geochemical parameters shows that the water body of Maidiping Formation is dominated by oxidation conditions, and the sedimentary evolution process is tidal flat facies and shelf facies regionally, while the sedimentary environment of Qiongzhusi Formation is shallow water and deep water shelf facies of reduction-weak oxidation-weak reduction environment.

Keywords: Riqingwei Basin, Laiyang Group, Sedimentary Environment

The Early Cretaceous marine sedimentary strata in the coastal area of eastern Shandong Province are scattered among rift continental basins. The study shows that a large-scale NE-trending rift basin, named the Riqingwei Basin, was during the Late Mesozoic. However, the sedimentary environment of the basin is still controversial. In this study, 14 siliceous sandstone samples from the Early Cretaceous Laiyang Group in the Taolin section of the Riqingwei Basin were taken as the research objects, and the evolution of sedimentary paleoenvironment was studied by petrology and elemental geochemistry. The geochemical indicators of the samples constrain the paleoenvironmental characteristics. 1) The CIA value of 70 % of the samplesCIA =50-60, reflecting the weak chemical weathering conditions and stable tectonic background in the source area. The PIA value of the samplePIA=36-74, which was lower than that of PAAS, indicating that the weathering degree of the source area was low. The SiO_2 / Al_2O_3 ratio in the study sample fluctuated between 2.84 and 4.11, indicating that the source composition was immature. 2) According to (Fe + Mn) / Ti and MnO / TiO_2 values, The Laiyang period in the study area was formed in the marginal sea environment and some strata were affected by hot water. 3) The Sr / Cu values of the studied samples were greater than 5 and the C values of 70 % the samples were 0.3~0.6; at the same time, the ancient water temperature calculation shows that the max sedimentary temperature of Laiyang period is 28.4 ℃, which generally reflects the climatic conditions of hot and drought. 4) The V / (V + Ni) values of the studied samples were greater than 0.46, and the Ceanom values (Ceanom=-0.032~-0.056), indicating that the sedimentary environment was in anoxic condition. 5) The 100MgO / Al_2O_3 values of the studied samples are greater than 10, CaO / (Fe + CaO) values are 0.10 ~ 0.54, Sr / Ba values are 0.14 ~ 0.67, indicating that the sedimentary environment is a marine environment with low to medium salinity. 6) The MnO / Fe value of the samples in the study area are 0.005 ~ 0.015, indicating the acidic or weak acidic sedimentary water conditions. The ∑REE of the samples is high, the REE distribution curve is gentle weak right-leaning type, the difference of light and heavy rare earth elements is not obvious, and there are Eu positive anomalies and Ce weak positive anomalies. The value of LREE / HREE (10.2-11.97), and the La / Ce ratio of some samples is less than 1. It shows that the Laiyang Group belongs to seawater deposition and is affected by hot water. In summary, the siliceous sandstone of Laiyang Group in Taolin area is mainly formed in the marine sedimentary environment of hot and drought, weak acidity, hypoxia and affected by hot water.

Bio-geochemical and depositional framework of siliciclastic sediments from an oxygenated Neoproterozoic epeiric shelf under warm and humid climate in the backdrop of Neoproterozoic Oxygenation Event (NOE)

ARUNAVA SEN[1*], SOUMIK MUKHOPADHYAY[1], PRADIP SAMANTA[2], SUVRAJIT GHOSH[1], SOUMYADEEP BOSE[1]

2. GEOLOGY, UNIVERSITY OF NORTH BENGAL, SILIGURI, WEST BENGAL, INDIA
E-mail: sagarsen.rock@gmail.com

Keywords: Warm and humid climate, Neoproterozoic Oxygenation Event, Shallow epeiric platform or seaway.

Major, trace and stable isotopic investigations have been carried out on siliciclastic fine-grained sediments of Cave-temple Arenite Member of Neoproterozoic Badami Group of Karnataka, southern India. U-Th-Pb isotopic constraints of overlying limestone units of Konkankoppa Member provided an apparent age of this Basin as 960 Ma (Joy et al., 2019). Age of mafic intrusive from underlying Mesoproterozoic sequence (Pillai et al., 2018) and recent works on tectono-sedimentological and paleogeographic models (Samanta et al., 2021) also suggest an age of 900-800 Ma for initial Badami sediments and correlate it to break-up of Rodinia Supercontinent. The whole succession of the studied Member is composed of three sedimentary cycles, where the middle cycle is a fluvio-marine one. State-of-the-art facies study and sequence stratigraphic analyses have been used to reconstruct the palaeogeographies of the studied marine succession. The sequence model reveals a marine siliciclastic deposition related to a shallow epeiric platform or seaway, where the marine inundation took place from the western margin of the Basin. Depositional environment varies from sand-dominated, shallow waters of upper-shore regimes to comparatively deeper waters of outer shelf, where sediments are muddy and rich in authigenic clays, like ferric-illite and glauconites. Major oxide composition of shales, siltstones and clay rich sandstones have been utilized to infer Chemical Index of Alteration (CIA) and probable climatic condition during marine transgression and regression. Where, the underlying fluvio-alluvial cycle was deposited in a semi-arid to semi-humid condition (Samanta et al., 2021), the studied marine sediments were deposited in a warm and humid climate that preferred pronounce chemical weathering. Biogenically induced trace metals and stable carbon isotopic values have been used to infer the palaeo-productivity of the marine water column. Bi-metal ratios and REE pattern reveal a redox stratification within the water column. Where, shallow marine sediments of inner shelf deposited in an oxic water column, deeper muddy sediments from offshore-transition and outer shelf deposited within suboxic to anoxic-euxinic waters. Shallow marine sandstones bear ample evidences of microbial proliferation, as MRS (Microbially Related Structures), within photic zone. $\delta^{13}C_{org}$ (VPDB) values also infer that shallow water was dominated with photo-autotrophs ($\delta^{13}C_{org}$ values between –22‰ to –25‰), where deeper water might have been a niche for anaerobic and sulphur reducing chemoautotrophs ($\delta^{13}C_{org}$ values <–25‰) (Kodina et al., 1996; Hayes et al., 1999). Presence of clustered framboidal pyrites within deeper most black shales from the outer shelf also supports this contention. This present climatic interpretation, redox stratification of ocean water with an oxic shallow marine milieu and a variation in biotic community with water depth, altogether point towards a warm and humid climate with significant oxygen distribution within the atmosphere and the shallow marine water column, in equilibrium with the atmosphere. Also, the entire sedimentological and bio-geochemical framework reveal that the sedimentation took place during the warmer periods after Super-continental break up and was under an oxygenated environment, in the backdrop of Neoproterozoic Oxygenation Event (NOE).

Sedimentology and sequence stratigraphy of the Aalenian from Southern Germany

Thomas Mann[1*], André Bornemann[1], Jochen Erbacher[1,2]

1. Stratigraphy and Collections, Federal Institute for Geosciences and Natural Resources (BGR), Hannover, Niedersachsen, GERMANY
2. Stratigraphy and Collections, State Office for Mining, Energy and Geology, Hannover, Niedersachsen, GERMANY

E-mail: thomas.mann@bgr.de

Keywords: Middle Jurassic, sea-level change, sedimentation rate, depositional environment

Middle Jurassic sedimentary deposits in southern Germany have accumulated in a shallow-marine shelf environment and are typically dominated by thick clayey lithologies with increasing occurrences of sandstones in the upper parts. The sedimentary evolution and paleoclimatic significance of these often poorly exposed deposits remain largely unexplored. Here we present a suite of high-resolution x-ray fluorescence (XRF) core scanning data from southern Germany covering the entire Aalenian stage. The overall objective of this study is to identify Transgressive-Regressive cycles based on the analysis of three cores obtained during scientific drilling campaigns in 2019-2021. Cores have been analyzed with an Avaatech XRF Core Scanner at a 10 mm sampling interval, an energy of 10 keV and a current of 500 µA to measure element intensities ranging from aluminium through iron. Resulting trends in elemental ratios indicative for subtle grain-size variations such as Si/Al are used to reconstruct shoreline trajectories and establish a sequence stratigraphic framework. Particularly the thick and largely homogenous Opalinuston Formation appears suitable in that respect, likely resulting from extraordinarily high sedimentation rates during the lower Aalenian in southern Germany, thus providing a complete but unexplored archive of paleoclimatic signals. For the upper Aalenian, a fennoscandian sandstone provenance resulting from uplift of the North Sea dome has been suggested. Such an exotic source area has important implications regarding transport processes and, consequently, the underground architecture of upper Aalenian sandstones. Accordingly, this project will also investigate sediment provenance in order to provide a holistic view of the sedimentary evolution of the South German Basin during the Aalenian.

Great Blue Hole (Lighthouse Reef, Belize, Central America): a late Holocene high-resolution storm and climate archive

Dominik Schmitt[1*], Eberhard Gischler[1], Jörn Peckmann[2], Daniel Birgel[2], Flavio Anselmetti[3], Hendrik Vogel[3]
1. Johann Wolfgang Goethe Universität , Institut für Geowissenschaften, Frankfurt am Main, Hessen, GERMANY
2. Universität Hamburg, Institut für Geologie, Zentrum für Erdsystemforschung und Nachhaltigkeit, Hamburg, GERMANY
3. Universität Bern, Institut für Geologie & Oeschger Centre for Climate Change Research, Bern, SWITZERLAND
E-mail: d.schmitt@em.uni-frankfurt.de

Keywords: Holocene, climate dynamics, cyclone frequency, SST

Marine sinkholes, such as the 320 m wide and 125 m deep Great Blue Hole (Lighthouse Reef Atoll, Belize, Central America) are very special geomorphological features of modern reef systems. The former Pleistocene karst cavity was inundated 7.8 kyrs BP by the Caribbean Sea, in the course of the Holocene sea-level rise. Because of anoxic bottom-water conditions and, hence, undisturbed annually-layered sediments, this Belizean sinkhole is a unique sedimentary archive for the understanding of Holocene climate variability and accountable meteorological and oceanographic phenomena. As the Great Blue Hole is located within the Atlantic hurricane belt, the cavern acts as a giant sediment trap for both fair-weather and storm sedimentation. By analysing the 8.55 m long sediment core BH6, frequency variations of tropical cyclones were reconstructed with annual resolution 1885 years through the Common Era, a time window, which is key for studying climatic variations and their effects on human society. As an innovation step, a multi-proxy approach based on textural, compositional and geochemical data was applied, in order to ensure a more reliable differentiation between fair-weather sediments and tempestites. The gained data indicate a likely connection between long-term storm activity patterns and the responses of important climate phenomena to the Common Era climate variability. During five investigated climate intervals, the modes of the El-Niño-Southern-Oscillation (ENSO), the North Atlantic Oscillation (NAO) and the Atlantic Multidecadal Oscillation (AMO) exercised a major control on cyclone activity by internally modulating the thermodynamic environment (sea-surface temperature and vertical wind shear stress dynamics) for enhanced/suppressed storm formation, both on millennial and multi-decadal scales. The beginning of the Medieval Warm Period (1400-900 CE) was an exceptional time period of the Common Era record. At that time, a southward migration of the Intertropical Convergence Zone (ITCU) caused, in combination with hydro-climate changes, a shift in the tropical Atlantic cyclone regime. The storm activity in the south-western Caribbean changed in general from a stable and less active stage (900-100 CE) to a more active and variable state (modern-1100 CE). Additional geochemical analyses of the sediment layers were carried out, in order to more accurately estimate the role of sea surface temperatures (SST) within this positive feedback mechanisms of climate variability, atmospheric and oceanographic boundary conditions and cyclone frequency patterns. Stable isotope measurements (δ18O) of the varved sediments allowed to provide a continuous and 1885 years long SST curve with annual resolution. The relative SST curve was supplemented with absolute SSTs, using a molecular proxy application (TEX86). Over the investigated time series, oxygen isotopes (δ18O) and TEX86 data imply a general SST rise of 0.5°C to 1.3°C, within the south-western Caribbean. Our δ18O data further indicate an obvious variability on multi-decadal time scales. The δ18O variations occur with 32-64 years periodicities. This signal is clearly an evidence of a SST modulation, controlled by AMO variability and phase changes (50-70 years). This in turn confirms the observed relationship between storm frequency and the reactions of the above-mentioned climate phenomena to the Common Era climate variability.

Simulation of Diagenesis Events Based on Digital Rock Techniques

Yuqi Wu[1*], Keyu Liu[1], Chengyan Lin[1], Chunmei Dong[1]
1. School of Geosciences, China University of Petroleum (East China), Qingdao, Shandong, CHINA
E-mail: wuyuqi@upc.edu.cn

Keywords: Digital rock technique, Diagenesis, Discrete element method, Cementation, Dissolution, Pore system

Sedimentary rocks form after the sediments experience a series of diagenesis events, such as deposition, cementation, and dissolution. It is of great difficulty to quantitively simulate the diagenesis events using computationally numerical techniques since these events involve chemical and physical reactions between the fluids and minerals. In this paper, some novel methods based on digital rock techniques are presented to address the issues. The discrete element method is used to simulate the packing of mineral particles, and the dilation operation and quartet structure generate set algorithms are utilized to simulate the cementation and dissolution. The new digital rocks are generated after the original rock undergoes a diagenesis event. Besides, the effects of diagenesis events and diagenesis pathways on rock properties are comprehensively analyzed. The results show that cementation can decrease the porosity, fractal dimension, pore/throat radius, coordination number, correlation of pore space, permeability, and velocity values of the rocks and increase the tortuosity and formation factor of pore space. Comparing the cementation, the dissolution makes a reverse effect on rock properties. The diagenesis pathway also has an impact on the physical properties of digital rocks. In a word, the study will present a comprehensive simulation workflow about deposition and diagenesis and help us to better understand the variations of the flow and mechanical properties of rocks without conducting extensive experiments if rocks experience different diagenesis processes along different pathways.

Sedimentological response of late Triassic Carnian Pluvial Episode (CPE) in lacustrine basin: A case study from Yanchang Formation of Ordos Basin

Xiangbo Li[1*]
1. Northwest (NWGI), Research Institute of Petroleum Exploration & Developement, Lanzhou, Gansu, CHINA
E-mail: lixiangbo911@sina.com

Keywords: Carnian Pluvial Episode,Climate Change,lacustrine response,late triassic,Ordos Basin

The Carnian Pluvial Episode (CPE event) is one of the most significant climate abrupt events on Earth in the Triassic, and the abrupt climate environment has an important control effect on the sediment characteristics of inland lake basins.In this paper, the most important petroliferous basin on land in my country: the Triassic Yanchang Formation in the Ordos Basin is taken as an example. Based on the latest research progress on global paleoclimate, event sedimentation, source rock development mechanism and heterogeneous integration surface in terrestrial basins, based on full reference at home and abroad, and through rethinking and researching some sedimentation and accumulation problems of the Yanchang Formation, the following three points of understanding have been obtained: The Carnian period of the Middle-Upper Triassic Yanchang Formation in the basin has been redefined, and the sedimentary response to the CPE event of the Yanchang Formation has been clarified. The top boundary is equivalent to the stratigraphic boundary between the Chang 4+5 member and the Chang 3 member, and the CPE event roughly corresponds to the deposition of the "Chang 7 member black shale event"; During the Carnian and CPE events, the Yanchang Formation sedimentary lake basin showed the characteristics of "rapid lacustrine transgression and oscillating slow retreat", which is very conducive to the development of high-quality source rocks; Affected by the paleo-climate and CPE events in the Carnian period, the Yanchang Formation developed two upper and lower xenoconformity formed due to abrupt climate and environment, and they both had a significant control effect on the distribution of oil and gas. This research is of positive significance for in-depth discussion of the formation and evolution mechanism of Yanchang Formation lake basin, sedimentary sequence filling and evolution characteristics, and guiding the practice of oil and gas exploration.

Main controlling factors to organic matter enrichment in the shales of Permian Lucaogou Formation, Jimsar Sag

Zehan Zhang[1], Kelai Xi[1*], Miruo Lin[1], Ke Li[1]
1. School of Geosciences, China University of PetroleumEast China, Qingdao, Shandong, CHINA
E-mail: xikelai@upc.edu.cn

Keywords: organic matter enrichment, shale, laminae combinations, Lucaogou Formation, Jimsar Sag

The organic matters distribution characteristics and the enrichment controlling factors in the shales of Permian Lucaogou Formation were studied by integration using cores observation, thin sections identification, x-ray diffraction, rock pyrolysis analysis and element geochemistry analysis. The results showed that the rock types mainly consist of silty dolomite, micrite dolomite, tuffaceous dolomite, dolomitic siltstone, silty tuff and tuffaceous siltstone. There are three major laminae types in the research area, the tuff laminae, terrestrial debris laminae and carbonated texture laminae. The main types of laminae combinations are the “tuff texture + carbonate” binary laminae combination, “tuff texture + terrestrial debris” binary laminae combination, and “carbonated texture + terrestrial debris” binary laminae combination. In general, the rocks mixed with pyroclastic and chemical sediments are the most conducive to organic matter enrichment, and the higher the content of pyroclastic components, the more organic matter accumulation. Microscopically, organic matter is mainly concentrated in the tuff laminae. The content in the carbonate laminae is low, and almost no organic matter is visible in terrestrial detrital laminae. The organic-rich lithofacies are mainly laminar tuffaceous siltstone and tuffaceous dolomite, the organic matter distribution continuously in strip-shapes. The laminated dolomitic siltstone and silty dolomite mainly contain the scattered organic matter, and they show relatively low organic matter content. The massive micrite dolomite and siltstone are characterized by organic-poor features. The main controlling factors to organic matter enrichment in different lithofacies are significantly different. Productivity is the main controlling factor to organic enrichment of silty dolomite and micrite dolomite, while the organic matter in silty and tuffaceous dolomite is mainly controlled by redox environment. The higher specific surface area of clay minerals can easily absorb organic matter to form stable organoclay complex, which allows the organic matter to be effectively preserved in dolomitic siltstone and tuffaceous siltstone.

Characteristics and controlling factors of glutenite reservoir rock quality of retrogradational fan delta: A case study of the Upper Wuerhe Formation of the Mahu Sag, the Junggar Basin

Yongping Ma[1*], Guodong Wang[1], Shuxin Pan[1], Yongqiang QU[1], Juanjuan Guo[1], Linjun Huang[1]
1. Research Institute of Petroleum Exploration and Development Northwest Branch, CNPC, Lanzhou, Gansu, CHINA
E-mail: ma_yp@petrochina.com.cn

Keywords: retrogradational fan delta, glutenite, reservoir rock quality, controlling factor, Junggar Basin

The glutenite reservoir rock of the fan delta facies is associated with a complex sedimentary environment and high heterogeneity, and by far the characteristics and controlling factors of the reservoir rock quality have not been well understood. By comprehensively investigating the lithofacies, petrology, physical properties and diagenesis of the Upper Wuerhe Formation of the Mahu Sag, the Junggar Basin, it is concluded that the Upper Wuerhe Formation develops three major groups of lithofacies, totally consisting of 11 sub-types, and reservoir rock properties of different lithofacies are greatly varied. This research shows that the lithofacies attributed to the tractive current and density current have well-sorted rock particles, low mud content, well-developed secondary dissolved pores, and thus high overall reservoir rock quality. On the contrary, the lithofacies based on debris flow and sheet flow, are observed with high mud content, suppressed development of intergranular and dissolved pores, and thus poor reservoir rock quality. The system tract controls the macro variation of the reservoir rock quality. The best quality is found in the highstand system tract, followed by those of the lake transgression and at last lowstand system tracts. The micro variation of the reservoir rock quality is determined by the mud content, rock particle size and dissolution. The muddy matrix mainly damages the pore connectivity, and presents the strongest correlation with permeability. The reservoir rock with concentrated particle sizes and well-sorted particles has quality better than those of reservoir rocks composed of excessively large or small particles. Dissolution effectively improves the storage capability of the reservoir rock, resulting in an average porosity increment by 4.2%.

A novel approach for studying Source-to-Sink system using stratigraphic forward modelling

Jianlei Gao[1,2], Keyu Liu[1,2,3*], Jianliang Liu[1,2]
1. School of Geosciences, China University of Petroleum, Qingdao, Shandong, CHINA

3. Laboratory for Marine Mineral Resources, Qingdao National Laboratory for Marine Science and Technology, Qingdao, Shandong, CHINA
E-mail: liukeyu@upc.edu.cn

Keywords: Source-to-Sink system, stratigraphic forward modelling, basin analysis, provenance tracing, sediment routing system, depositional processes

The study of source-to-sink (S2S) system has become an integral part of depositional system and basin analysis. Conventionally S2S analysis mostly invokes comparing heavy mineral assemblages, elemental compositions and geochronology of certain minerals (e.g., zircon) from sources and sinks. This approach, however, depends heavily on the availability of outcrop, core or cutting samples from both the provenance (source) and basin (sink) areas, and is not always applicable. This is especially true, when analyzing ancient S2S or in exploration frontier basins, where the provenance may have already been eroded away or buried, or few samples are available from limited subsurface drillings. The other challenging issue with the conventional approach is that the interpretation of the mineralogical, geochemical and geochronological data from individual provenances may not be unique or the data do not have the spatial-temporal resolution to differentiate sediment provenances.

Here, we propose an alternative approach for S2S analysis using stratigraphic forward modeling (SFM), which allows us to study the sediment transport process of the S2S system quantitatively and reproduce the dynamic evolution of the sediment routing system. The procedure involves the reconstruction of a 3D stratigraphic model for the basin (sink) to be investigated using a hydrodynamics-based sedimentary modelling program that mimics the depositional processes during the basin-fill process. Once the model is calibrated and validated with available seismic, well log or core data, it can then be used to generate lithological, sedimentary facies and chronological information at each grid cell. Such information can be extracted to quantitatively determine the contribution from individual sediment provenances, achieving a quantitative analysis of the S2S system. The animated SFM also allows the visualization of the S2S depositional process in 3D. The construction of a SFM requires four major input parameters including (1) initial topography, (2) tectonic movement, (3) base-level change and (4) sediment supply. These input data can be derived from our existing understanding of regional geology (e.g., conceptual model, published literatures), available seismic, well log and core data, and modern analogues. For S2S analysis, it is crucial to preset the sediment supply parameter comprising source locations, sediment compositions, discharge rates, etc. A novel method is designed to preset sediment supply from multiple sources in which the sediment at each source is being released alternatingly to chronologically differentiate the relative contributions from different sources at any given grid cells in the basin at a given time step (duration). A conceptual sedimentary basin model of 80x98 km in dimension with three sediment provenances was used to demonstrate the effectiveness of this novel approach for S2S analysis. SFM also allows us to better analyze and understand the coupling relationship between the dynamic evolution of the S2S system and the internal and external dynamic geological processes such as tectonic subsidence, base level change and paleoclimate.

Sedimentary evolution of the southwestern Tarim Basin during the Cretaceous in response to basin-range coupling: New insights from basin and landscape dynamics modelling

Jia Chang[1], Keyu Liu[1*], Jianliang Liu[1]
1. School of Geosciences, China University of Petroleum (East China), Qingdao, Shandong, CHINA
E-mail: liukeyu@upc.edu.cn

Keywords: sedimentary evolution, basin-range coupling, Badlands, Tarim Basin

Sedimentary basin evolution can be reconstructed through modelling the landscape dynamics processes in response to basin-range coupling. In tectonically active regions, it is difficult to effectively restore the paleogeography and paleogeomorphology using conventional methods due to strong tectonic deformation after the initial sedimentary deposition. Several conceptual models have been proposed regarding the sedimentary evolution during the Cretaceous in the southwestern Tarim Basin, China. However, none of them can adequately account for all the research results of the stratigraphic architecture, paleogeography and sedimentary facies in a quantitative way. This study presents the first attempt to simulate the stratigraphic and sedimentary evolution of the southwestern Tarim Basin during the Cretaceous in three dimensions using a basin and landscape evolution modelling approach. The *Badlands* software was used to simulate the landscape evolution and sedimentation in response to basin-range coupling. The program is able to generate a more refined landscape model by simulating the tectonic process, climatic changes, base level oscillation and sediment flux. A 3D stratigraphic model of the Early Cretaceous is built by using seismic profiles, structurally balanced cross-sections, well and outcrop data. Relevant parameters such as base-level change, tectonic movement, rainfall, sediment and erosion were assigned to the numerical model to simulate the coupling effect of the orogenic belt denudation and basin sedimentary fill. The simulation results show that: (1) the presence of paleo-uplift within the basin can better match the present-day observed sediment thickness and distribution. (2) sedimentary provenance was sourced primarily from the West Kunlun orogenic belt with the Makit Slope to the north and the paleo-uplift within the basin only providing limited amount of sediment volumetrically. (3) there were no lakes in the basin during the Early Cretaceous, and a major river system developed in the basin along the trend of the orogenic belt east-westward. The 3D stratigraphic model has offered some new insights on the spatial distribution of the Cretaceous reservoir beds in the southwest Tarim Basin for further petroleum exploration.

Jurassic basin types and paleogeographic pattern in southwest Depression of Tarim Basin

Junjian Li[1], Liqiang Zhang[1*], Zuotao Wang[2], Yiming Yan[1], Chunyan Sun[2]
1. school of geosciences, China University of Petroleum(East China), QingDao, ShanDong, CHINA
2. Research Institute of Exploration and Development, Tarim Oilfield Company,, Tarim Oilfield Company,PetroChina, Korla, Xinjiang, CHINA
E-mail: zhanglq@upc.edu.cn

Keywords: 3D digital outcrop,structural differences,prototype basin,paleogeographic

The Tarim Basin belongs to the rejuvenated foreland basin, which is characterized by multi-stage superimposition. The southwest depression is affected by the Pamir salient and the tectonic compression deformation is intense. Therefore, it is of great significance to accurately recover the prototype basin of southwest depression for exploration. In this paper, the UAV is used for the first time to build a macroscopic 3-D geological model in the region.,and the distribution and filling characteristics of the southwest depression basin are studied on the basis of 1-D drilling, 2-D outcrop and 3-D seismic data. It is pointed out that there is no “Jurassic pan-lake basin” in the Jurassic which connects the vast area in front of West Kunlun mountain, and based on this, the differential distribution model of Jurassic basin in Southwest Depression is established. Research suggests that large scale intracontinental orogeny developed in southwest Depression of Triassic, and large scale thrust fold belt developed along piedmont under compression environment. The thermochronology data show that the tectonic activity in the west was earlier than that in the east, and the different tectonic activity caused the folding belt to disappear gradually in an arc eastward. During the Jurassic sedimentary period, the southwest depression was dominated by extensional environment, and the orogenic belt root collapsed, resulting in the development of faulted basins between fold belt and orogenic belt. The fold belt became a high palaeogeomorphic position, which separated Jurassic deposits and provided sediments for foreland depressions. The paleogeographic pattern of "fault lake basin in the west and depression in the east" was formed by the fold belt as the boundary. The lake basin types mainly include fault lake basin, small intermountain lake basin within the fold belt and discontinuous depression lake basin.

Paleoclimate evolution recorded by the Paleocene-Eocene salt-lake sediments in Eastern China and its driving mechanism

Jian Wang[1*]
1. School of Geosciences, China University of Petroleum (East China), Qingdao, Shandong, CHINA
E-mail: wangjian8601@upc.edu.cn

Keywords: Paleocene-Eocene, paleoclimate evolution, East Asian monsoon, driving mechanism, Dongying Depression

The Paleocene-Eocene with complex paleoclimate changes is a key period for understanding the evolution of the Paleogene paleoclimate in East Asia. Previous studies focused on this period were mainly based on sedimentological data from Central and Western Asia, the sediments of the Dongying Depression in Eastern China provide a stratigraphic sequence of red-bed clastic rocks, gypsum-salt rocks and shallow-semi-deep lacustrine mudstones with abundant sporopollen fossils and stratigraphic data during the Paleocene-Eocene, which was a period highly sensitive to paleoclimate changes. Selecting the Kongdian Formation (Ek)-the third member of the Shahejie Formation (Es3) of the Dongying Depression as the study object, the evolutional characteristics and the Driving Mechanism of the Paleocene-Eocene climate are investigated by a comprehensive analysis of sedimentological data, geochemical indicators, paleontological data and Milankovitch cycle analysis.

The results indicate that the paleoclimate evolution during the period of the Ek-Es3 member in the Dongying Depression can be divided into eight stages, in which the trends of paleoclimate change in stages 1–4 were similar to those in Central and Western China. The paleoclimate reached the hottest period in the Cenozoic after warming and drying during the first stage, and then showed a long-term drying and cooling trend with the Middle Eocene Climate Optimum (MECO) in the fourth stage. Affected by the uplift of the Tibetean Plateau and the regression of the Tarim Sea, the trends in stages 5-8 are clearly distinct from those in Central and Western China. In the fifth stage, although the paleoclimate in the study area was dry during stage 5, the paleoclimate in eastern East Asia began to evolve towards humid condition. In the sixth stage, the paleoclimate in the study area became oscillatory humid, and the latitudinal zonal paleoclimate pattern started to fall apart. The paleoclimate pattern changed from latitudinal zonation to east/humid and west/arid during stages 7-8, suggesting that the East Asian summer monsoon became prevalent and dominated the climate in eastern China from that time.

Based on the investigation of Paleocene-Eocene global atmospheric evolution and tectonic activities, and the analysis of sedimentary cycles at different scales, it is found that the driving mechanism for the paleoclimate evolution in the study area can be divided into two categories. The dominant mode of eccentricity under the background of planetary wind system during the 1-6 stages and the short eccentricity and precession control mode under the background of East Asian monsoon during the 7-8 stages. The paleoclimate is relatively dry and mainly controlled by the planetary wind system during stages 1-6, and the climatic characteristics reflected by meter scale sedimentary cycle is mainly driven by the eccentricity cycle. In addition, precession and obliquity cycle also have an important driving effect on the development of sedimentary cycle under the modulation of eccentricity. In stages 7-8, the East Asian monsoon became prevalent and dominated the climate in East Asia, while the paleoclimate reflected by the meter scale sedimentary cycle was mainly controlled by the short eccentricity and precession period.

Controlling factors on formation of different quality lacustrine organic-rich shales and forming regularity of shale oil

Jinjun Xu[1*], Fuqi Cheng[1], Shunan Peng[1], Xiangang Cheng[1], Juncai Jiang[1]
1. School of Geoscience, China university of petroleum (East China), Qingdao, Shandong, CHINA
E-mail: xujj2015@upc.edu.cn

Keywords: Lacustrine, organic-rich shale, different quality, accumulation mechanism, shale oil, differential evolution

Unconventional energy resources of oil shale and shale oil become the substitutable field for conventional energy resource. Stronger heterogeneity on organic matter abundance, maceral components, and hydrocaron generation existed in lacustrine organi-rich shale (ORS) deposition, which included high-, fair- and low-quality. Based on the comparative analysis of the organic geochemical characteristics of the ORS from the first member of the Qingshankou Formation (Kqn1) in the Songliao Basin, the third member of the Shahejie Formation (Es3) to the third member of the Dongying Formation (Ed3) in the Bohaiwan Bay Basin, the paleoclimate Es3 to Ed3 in the Bohai Bay basin trended from warm-humid, semi-arid, arid, to warm-humid, along which the bottom water changed from freshwater-brackish, brackish, to fresh-brackish water, and varied from weak reduction–reduction, strong reduction, to reduction-weak reduction. OM of ORS is dominated by aquatic algae with a few exinite, and its productivity varied in different periods. The development of Es3 and Ed3 high-quality ORSs was controlled by productivity-driven, while the ORS of Es1-2 was decided by a combination of preservation conditions dominated and paleoproductivity supplemented. Meanwhile, sag-controlled fault influenced the thick scale of ORS development but not the quality. The sedimentary sand obviously inhibited the development of high-quality ORS. The high-quality ORS of the Kqn1 in the Songliao Basin was controlled by the high paleo-lacustrine productivity under warm and humid conditions and string anoxic reduction conditions with semi-saline water, and dominated by lamalginite and telalginite with supplemented exinite.

Lower mature samples of high-, fair- and low-quality OPSs of the Kqn1 were selected to conduct a thermal simulation experiment to identify the differences in shale oil generation from different quality of ORSs.The results indicate that the high-quality ORS dominated by telalginites or telalginite-lamalginites preferentially starts to generate hydrocarbons and still has high hydrocarbon generation capacity during high thermal stage; fair-quality ORS with low clay mineral content dominated by lamalginites reaches peak hydrocarbon generation and produces movable shale oil earlier, followed by high-quality ORS, low-quality ORS subsequently. High-quality ORS enter the shale oil stage when Ro value above 0.54% (burial depth >1283.3m). Fair- and low-quality ORSs generate shale oil when Ro>0.58% (burial depth >1332.8m). The hydrocarbon production evolution process of ORS could be divided into three stages: early low maturation stage (Ro < 0.58%), major oil production stage (0.58% < Ro < 0.97%), and oil/gas production stage (Ro > 0.97%).

Overall, strong basin-controlled and sag-controlled faults under warm and humid paleoclimate greatly affected the development scale of ORS. The distribution of sedimentary sand had an impact on quality and distribution range of ORS. The key factor was still the paleoproductivity or preservation conditions or both jointly controlling the quality of ORSs. And high-quality ORS containing abundant lamalginite and telalginite will preferentially enter the shale oil stage and arrived at the peak generation of shale oil earlier. Therefore, the sweet spot section of shale oil derived from high-quality will be buried more shallowly. The understanding is favorable to provide favorable theoretical support for the exploration and development of shale oil.

Geochemical characteristics of calcite veins in the ultra-deep Bashijiqike Fm sandstones in the Kuqa Depression, western China: Implications for fluid evolution

Shunyu WANG[1], Jian Wang[1], Keyu Liu[1*], Tao Mo[2], Zhenkun Li[1], Arui Wang[1]

2. Tarim Oilfield Company, PetroChina, Koral, Xinjiang, CHINA
E-mail: liukeyu@upc.edu.cn

Keywords: Calcite veins, Fluid orign, Vein-forming environment, Minor and Rare Earth elements, Carbon and Oxygen isotopes

Subsurface fluid flow and fractures are usually simultaneously induced by tectonic movements. Vein-forming fluids would preferably enter into fractures and develop various veins, especially in ultra-deep tight sandstones. Therefore, geochemical signatures of fracture-filling cements could provide vital record on fluid evolution. The ultra-deep tight sandstones of the Cretaceous Bashijiqike Formation (K1bs) had experienced intensive compression since the Middle-Late Himalayan tectonic movement, producing various veins including quartz bridge, gypsum, calcite, dolomite and ankerite. Calcite veins occur widely. An integrated analysis including optical Cathodoluminescence (CL), Electron Microprobe Analysis (EPMA), LA-ICP-MS and Carbon and Oxygen stable isotopes were employed to determine the elemental compositions and abundances across calcite veins, their formation environments, material sources and precipitation periods. Calcite cements of the wall rocks and veins generally showed bright yellow, orange and dull yellow CL colors. Rare earth elements (REE), Mn and Fe can influence CL intensities and colors. REE and Mn are common CL activators, whereas Fe is a major CL quencher. Due to overlapping of REE and Mn in the CL spectroscopy, higher Mn (>2000 ppm) is stronger CL activator than REE (<200 ppm) in the K1bs Reservoirs. From vein walls to center, Mn and Sr concentrations are quite stable, while the Fe and Mg concentrations increased gradually. This implies that Mg and Fe were incorporated into the calcite lattice at a faster rate, that was also controlled by temperature, crystal growth rate and element concentrations. Post Archean Australian Shale (PAAS) normalized REE+Y patterns of calcite cements show similar characteristics with MREE being slight enriched, while LREE and HREE are slightly depleted. This indicates that pore-dominated and fracture-dominated calcite cements were deposited from marine sediment pore-waters in a weak zone. There was no obvious correlation between δCe and δEu indicated that late diagenesis had little effect on the REE fractionation, thus indicators calculated from PAAS Normalized REE could represent the calcite-forming environment. Some pore cement shows extremely negative δCe and positive δLa, which may be inherited from sea wear. In addition, both δGd and δEu showed slightly positive anomaly. Because Gd is constant from surface to the deep-sea water, a positive δGd is generally caused by the PAAS normalization method. Extreme positive δEu is always associated with hydrothermal fluid injection. Due to the lack of evidence on the hydrothermal mineral combination, Eu2+ from weathering feldspars may be responsible for the slight positive δEu. Using Carbon and Oxygen stable isotope and fluid inclusion homogenization temperatures, the oxygen isotope of the vein-forming fluids or sedimentary fluids can then be calculated by using the oxygen isotope fractionation equation for calcite. Both 13CPDB (-3.36~1.35‰) and 18Ofluid-SMOW (-1.10~2.91‰) indicated that sea water is the major source for the precipitation of the calcite veins.

The Permian source-to-sink evolution and tectonics implications in Northwest Junggar Basin: Evidence from detrital zircon geochronology

Xingyu Chen[1], Zhijie Zhang[2*], Xuanjun Yuan[2], Chuanmin Zhou[2], Yinhe Liu[2], Li Wan[2], Dawei Cheng[2]
1. School of Earth and Space Sciences, Peking University, Beijing, CHINA
2. Research Institute of Petroleum Exploration & Development, PetroChina, Beijing, CHINA
E-mail: zhzhijie@petrochina.com.cn

Keywords: Junggar Basin, Permian, provenance, U–Pb zircon geochronology, source-to-sink system, heavy mineral

The Junggar Basin, located in the NW China, is the main area for oil exploration. However, the study area lacks a complete research consisting of sequence stratigraphy, source area, transport process and deposition. The provenances of the large-scale fans developed in the system remain unclear, which needs further semi-quantitative analysis.

In this study, statistical analysis of heavy mineral assemblage and detailed petrographic investigation of gravel sized clasts, combined with detrital zircon U-Pb geochronology, were conducted from sediments in different periods to understand the sediment provenance and unravel the source-to-sink processes in the studied region. The source-to-sink systems were traced and the evolution was comprehensively analyzed and its significance for tectonic evolution was discussed.

The potential source area mainly exposes the Silurian, Devonian and Carboniferous igneous rocks and sedimentary rocks. Through heavy mineral assemblage and gravel composition analysis, it is clear that the parent rocks of the northwestern margin of Junggar Basin during the Permian are mainly intermediate-basic igneous rocks and intermediate-acid igneous rocks, mainly from the central West Junggar. There are a small amount of mixed remote sources in the northern Mahu Sag and Zhongguai Uplift, which come from the northern and southern parts of West Junggar respectively.

The detrital zircon dating results showed a dominant peak at 310-330 Ma and a secondary peak at 400-440 Ma in the northern Mahu Sag, only one dominant peak at 295-325 Ma in the central Mahu Sag, multiple peaks at 270-350 Ma in the southern Mahu Sag, and multiple peaks at 370-450 Ma in the Zhongguai Uplift. The detrital zircons from core samples reveal marked spatial changes in their age signatures that correlate with the nearby potentially source terranes. The U-Pb detrital zircons data reveal that the Permian to Carboniferous ages as the main contributor, while Silurian to Devonian ages are subsidiary.

The results reveal that the study areas displayed similar zircon U-Pb ages and gravel composition of conglomerate with the discharged basins, which reflects the control of sediment sources in river catchments, and also implies the continuous source supplies and transport pathways for sediments since the early Permian.

Based on a comprehensive analysis, the Northwestern Junggar Basin was divided into four major source-to-sink systems, with central West Junggar as the main provenance and northern and southern West Junggar as the secondary provenance.

The evolution of the source-to-sink systems shows inheritance and evolves from a single provenance into a complex provenance. In the Lower Wuerhe and Upper Wuerhe Formations, the proportion of sediment supply from the southern and northern West Junggar is higher. The variations of U-Pb detrital zircon data are the response of source-to-sink system to the transformation from extension fault to compression depression during the Late Permian. During the late Permian-early Triassic, Junggar Basin may have developed compressional thrust, leading to the uplift of West Junggar. And the tectonic activity in the southern West Junggar is stronger than that in the northern West Junggar.

Sequence stratigraphy, depositional environment and associated lithofacies of lacustrine shale: A case from the Upper Fourth Member of Shahejie Formation, Dongying Depression, Bohai Bay Basin

Guiang Li[1], Chengyan Lin[1,2*], Chunmei Dong[1,2], pengjie Ma[1,2], Xinyu Du[1]
1. School of Geosciences, China University of Petroleum (East China), Qingdao, , CHINA
2. Reservoir Geology Key Laboratory of Shandong Province, China University of Petroleum (East China), Qingdao, , CHINA
E-mail: lincy@upc.edu.cn

Keywords: Lithofacies (assemblages), Shale oil, Sequence stratigraphy, Dongying Depression, Bohai Bay Basin

The lithofacies assemblages in the lacustrine shale of the Shahejie Formation in the Dongying Depression have different compositions due to the complex depositional climate, lake water conditions, and sediment supply. Hence, the lithofacies types and depositional conditions were analyzed based on parasequence division and lithofacies classification. According to gamma ray (GR) integrated prediction error filter analysis (INPEFA), handheld x-ray fluorescence (XRF) measurements, mineral composition, total organic carbon (TOC) content, and sedimentary structures, six parasequences (P1 to P6 from bottom to top) were identified, and seven lithofacies are recognized: (1) organic-poor thin-bedded calcareous mudstone, (2) organic-poor laminated calcareous mudstone, (3) intermediate-organic laminated calcareous mudstone, (4) organic-rich laminated calcareous mudstone, (5) organic-rich calcareous shale, (6) organic-rich laminated carbonate-bearing mudstone, and (7) laminated silty mudstone.

When the climate became warm and wet, the water level of the lake increased with a decrease in salinity, and the corresponding lithofacies assemblages in the P1 to P2 parasequences gradually changed from organic-poor thin-bedded and laminated calcareous mudstone to intermediate-organic and organic-rich calcareous shale. When the climate became humid and warmer, resulting in an increasing water level and terrigenous input, the lithofacies assemblages in the P3 to P4 parasequences changed from organic-rich calcareous shale and laminated carbonate-bearing mudstone to laminated silty mudstone and calcareous mudstone. At the end, the climate became slightly drier and cooler with a decrease in the water level, and the P5 and P6 parasequences were dominated by intermediate-organic and organic-poor laminated calcareous mudstones.

Through elemental analysis and lithofacies observation, we found that the redox conditions of the water may have changed over time. Among the parasequences, the water column of the P2 parasequence was mainly stratified by salinity, that of the P4 parasequence was mainly stratified by temperature, and that of the P3 parasequence was in transition. The synergistic effect of various factors played a key role in the enrichment of organic matter.

This study highlights the depositional processes of the lithofacies assemblages in a lacustrine shale and contributes to the understanding of shale oil accumulation in lacustrine shale.

Occurrence, genesis and significance of analcime in Paleogene lacustrine shale in Cangdong depression, Bohai Bay Basin, China

Junran Wang[1], Chao Liang[1*], Yingchang Cao[1]
1. School of Geosciences, China University of Petroleum (East China), Qingdao, Shandong, CHINA
E-mail: liangchao0318@upc.edu.cn

Keywords: Analcime, Genetic mechanism, Distribution characteristics, Fluids-rock interaction

Natural analcime, an aluminosilicate mineral with multiple genetic mechanisms, widely occurs in fine-grained sedimentary rocks. The assemblage relationship with different authigenic minerals as well as distribution in both plane and vertical can indirect indicate the paleoenvironment, paleostructure and diagenetic fluids evolution. In past 30 years, analcime has been proved to be an important component of high-quality oil and gas reservoirs, which can improve reservoir porosity through a precipitation-dissolution mechanism under the influence of mass organic acids released by source rocks.

The content of analcime ranges from 4.4% to 59%, with an average of 12.9% in the shale of Paleogene Kongdian Formation, Cangdong Depression, Bohai Bay Basin. Based on this, scanning electron microscope, CL microscope, X-ray fluorescence spectrometry, Raman spectroscopy, fluid inclusion microthermometry and laser ablation inductively coupled plasma mass spectrometry were utilized to analyse the occurrence, genesis and distribution of analcime in Ek2 (the most analcime-rich member). The results show that: (1) The occurrence of analcime in shale and interbeded silty bands include dispersed micritic, sparry filling and bedding laminae. (2) The content of analcime has a negative correlation with the clay minerals, symbiosis with hydrothermal minerals include dolomite, pyrite and barite. (3) The distribution of analcime is controlled by both of fault and salinity. (4) The fluid inclusion thermometry results indicate the reservoir was modified by multiple phases of hydrothermal fluids. (5) The REE distribution pattern of analcime is similar to adjacent volcanic rocks, and the differences reflect the influence of diagenetic fluid. Combined with the characteristics of “weak intensity, low amplitude and high frequency” of Cenozoic fissure-erupted magma activity in Cangdong Depression, concluded that analcime was formed in a "closed-semi-closed" lake basin environment under the influence of high-frequency hydrothermal fluids, dominated by hydrothermal and diagenetic fluids driven "water-rock" reactions. The formation mechanism include: non-tuffaceous materials conversion, hydrothermal deposition mineralization, and alkaline lake or pore water precipitation. The last two are closely related to the formation of analcime laminae, which has the greatest contribution to improve shale reservoir porosity and connectivity.

Weak strike slip in Yangjiang-Yitong fault zone and its sedimentary structural response and petroleum geological significance

Dingwei ZHU[1*], Guangrong PENG[1], Jing WU[1], Guofu CAI[1], Zhiwei ZHANG[1], Xiaodong DU[1], Xiaomeng WANG[1]
1. Nanhai East Petroleum Research Institute, Shenzhen Branch, CNOOC China Limited, Shenzhen, Guangdong, CHINA
E-mail: zhudw3@cnooc.com.cn

Keywords: Yangjiang-Yitong fault zone, Yangjiang depression, Fault reservoir control, Extension-strike slip, Magmatism

Previous studies on the Yangjiang-Yitong fault zone mainly focus on the identification marks, development stages and temporal and spatial distribution, and lack of research on the impact of the fault zone on the sedimentary filling and oil and gas geological significance of Cenozoic basins (depressions). The Yangjiang east sag in Pearl River Mouth Basin is located in the north section of Yangjiang-Yitong fault zone. Plenty of oil and gas exploration work has been carried out in recent years, which provides data basis and oil and gas exploration perspective for the study of Yangjiang-Yitong fault zone.

Researchers in this paper recognize that Yangjiang-Yitong fault zone is a large-scale weak strike slip fault zone. The fault zone has an important influence on the source sink system, sedimentary filling and oil and gas accumulation in Yangjiang east sag. To sum up, there are three main points.

First, it promoted the rifting evolution process and the formation of accommodation space of Yangjiang east sag, which was "strongly extensional depression in the early Wenchang period and extensional-strike slip joint depression control in the late Wenchang period".

Second, it formed the sedimentary filling and source rock development mechanism of "multi-stage rifting center superposition, endogenous thick lacustrine sedimentation, magmatic warming promoting hydrocarbon generation and expulsion". Yangjiang-Yitong fault zone limits the scope of rifting, superimposes the rifting centers of different rifting episodes in Yangjiang east sag, promotes the formation of accommodation space and is conducive to the formation of medium and deep lacustrine environment. The basement on the Yangjiang-Yitong fault zone is broken, forming a paleogeographic pattern of alternating depression and uplift. It is dominated by the material source in the basin, and the superposition of multi sequence high-quality source rocks in the under compensation environment. The fault zone was activated twice in Eocene and Miocene, and the magma was abnormally developed. The deep heat flow brought by it greatly reduced the hydrocarbon generation and expulsion threshold and enhanced the oil and gas resource potential of Yangjiang east sag.

Third, it promotes the fault reservoir control mechanism and oil and gas distribution law of "weak strike slip faults control traps, differences control migration, and fault segmentation controls sealing" in Yangjiang east sag. After activation in Miocene, Yangjiang-Yitong fault zone developed a series of NW-NWW trending, tensional and torsional faults, which controlled the development of main traps, vertical transportation and lateral sealing of oil and gas, and then controlled the distribution pattern of oil and gas.

Based on the recognition of the weak strike slip property of Yangjiang-Yitong fault zone and its oil and gas geological significance, it has improved the confidence in the oil and gas exploration of the whole Yangjiang-Yitong fault zone and promoted the exploration process of Yangjiang east sag. At present, many high-quality oil fields have been found in Yangjiang East sag.

Keywords: Dongying Sag, the Upper Es4 Member, carbonate deposits; multiple sources; hydrocarbon accumulation

Lacustrine carbonate-rich fine-grained sediments are widely distributed in the Upper Es4 Member of Dongying Depression. They are rich in organic matter and important target for unconventional oil and gas resources. The geological data and methods including cores, thin sections, X-ray analysis, SEM, EMPA and trace element analysis were integrated to study the source and formation mechanisms of carbonate-rich fine-grained sediments during the warm and humid climate, microorganism bloomed and induced to form the calcite. The strong rifting led to deep hydrothermal upwelling which resulted into thermogenic ankerite. The hydrothermal mineral form into combination of ankerite-gypsum-barite-quartz-pyrite. Ternary diagram of Ni-Co-Zn of the study object also indicated thermogenic source. Glauconite, coccolithophores and trace fossils Paleodictyon are found in carbonate deposits in the study area which indicated transgression. The storage space includes interparticle pores, intraparticle pores, lamina fissures and fractures. Hydrothermal fluids upwelled along the fractures and contribute to the maturation of organic matter thus it is beneficial to the development of high quality source rocks.

E-mail: wanghu19@cug.edu.cn

Keywords: Fractures fill, Fluid inclusions, Bedding fracture opening, Bedding fracture filling

Bedding fracture in shale reservoir is one of the important factors affecting the development of shale oil and gas reservoir. Whether bedding fracture is effective or not directly affects the production of shale oil and gas. Through the field outcrop, core observation and water immersion experiment analysis, it is clear that the bedding fractures of shale reservoir layers exist in the natural state. Imaging logging, wet light identification, microscopic imaging gray analysis and other technologies are used to jointly identify multi-scale bedding fractures on opening. Imaging logging can identify bedding fractures with an opening of more than 5mm, and the density can reach 14 / M; The immersion test method is to identify that the density of bedding seam can reach 1813.5 pieces / m, and the number of bubbles is positively correlated with the number of bedding and natural micro cracks. The density of micro crack seam can be calculated quantitatively by using TOC and silica content. The imaging logging is calibrated by comparing the argillaceous strip, low angle fracture and imaging logging on the core. The bedding fracture with the opening position greater than 5mm has a good response on the imaging logging, and there is no response on the imaging logging for the foliation fracture with the opening position less than 5mm on the core. However, according to this mode, it is inferred that the bedding fracture in the lower part of the underground state is open. Combined with the distribution of calcite veins and the growth mode of calcite veins observed in the core of the study area, four stages of foliation fracture development are proposed. The first stage is the original stage, with sedimentary formation layer; The second stage is the primary stage, and some cracks open along the bedding plane; The third stage is the growth stage. The open cracks continue to grow or merge to form large-scale cracks, or close and disappear; The fourth stage is the old age stage. Some cracks continue to open, and some cracks form calcite filling cracks due to recrystallization. The research results have extensive reference significance for re understanding the size of shale gas reservoir space and exploration and development.

E-mail: liuqh@cug.edu.cn

Keywords: Source-to-sink system, Bedrock type, Catchment area, Sediment discharge, Sandy sediment flux

Sedimentary features of a source-to-sink (S2S) system produce distinct responses to diverse bedrock types (i.e., silicate and carbonate rocks) in the catchment; these majorly influence the sediment flux, volume, and grain size in the sink area. By comparing a modern S2S system of Holocene Erhai Lake Basin (ELB) (in southwestern China) and an ancient S2S of Eocene western Offshore Bohai Bay Basin (OBBB) (in eastern China), we investigated the differences and proportional ranges among sandy sediment flux (Q_f) and sediment discharge (Q_s) from catchment associated with diverse bedrock types in a humid and subtropical lacustrine rift basin by combining with the Google-topographic-map, BQART-model, and seismic-geomorphology analysis. Based on geomorphological and 3D visualization analysis, we identified the differences among multiscale catchment-fluvial segments and their sedimentary responses in S2S systems, and then extracted parameters of catchment-unit area (A), catchment relief (R), and total sediment discharge (Q_s, calculated by BQART model). Furthermore, we analyzed sediment-dispersal patterns and sandy sediment fluxes in the nearshore (Q_f) using regional geologic data, outcrops and the Google Earth database in the Holocene ELB, and using seismic geomorphology in the Eocene western OBBB. Finally, quantitative analysis of the modern and ancient S2S segments was used to investigate the total sandy sediment flux (Q_f), which is supplied by > 60% of the entire sediment discharge (Q_s) for catchments with silicate bedrocks (e.g., metamorphic rock and granite), while the ratio Q_f/Q_s corresponding to carbonate bedrocks is less than 30%. Additionally, the ratio Q_f/Q_s for catchments with mixed silicate carbonate bedrocks ranges between 30% and 60%. These results not only provide a new perspective for investigating sandy sediments in a subtropical lacustrine rift basin, but also yield implications for better understanding of continental S2S system theory for diverse bedrock types.

Genetic mechanism and significance of sparry calcite in lacustrine deep-water fine-grained sedimentary rocks

zhouhai xiong[1*], yingchang cao[1], chao liang[1]
1. School of Geosciences, China University of Petroleum (East China), Qingdao, Shangdong, CHINA
E-mail: xiongzhouhai@126.com

Keywords: Fine-grained sedimentary rocks, shale oil, sparry calcite, diagenesis

Sparry calcite is widely developed in lacustrine deep-water fine-grained sedimentary rocks, which is one of the important reservoirs of shale oil. Taking the fine-grained sedimentary rocks of the upper fourth sub-member and the lower third sub-member of Shahejie Formation(Es_4^s-Es_3^x) in Jiyang depression as an example, by means of thin section observation, inclusion test, field emission scanning electron microscope observation, laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS) analysis, micro-area carbon oxygen isotope analysis, etc., the research shows that the sparry calcite in the Es_4^s-Es_3^x lacustrine deep-water fine-grained sedimentary rocks in Jiyang depression is mainly formed in the middle diagenetic stage. The temperature range is 90 ~ 120 ℃, and the pressure range is 45 ~ 60MPa. According to the aspect ratio of crystal, sparry calcite can be divided into granular, columnar and fibrous. According to the enrichment of albite, quartz and other impurity minerals, granular sparry calcite is further divided into impurity-rich granular sparry calcite and impurity-poor granular sparry calcite. Columnar/fibrous sparry calcite (collectively referred to as “beef” sparry calcite) is also further divided into clay basement and carbonate basement. The development of sparry calcite is the result of the synergistic effect of the thermal evolution of organic matter, the transformation of clay minerals and the dissolution of unstable minerals such as early calcite and feldspar. Impurity-rich granular sparry calcite characterized by poor iron is the main type of sparry calcite in the study area. The material components are mainly derived from the dissolution of early micritic calcite in situ. It is formed by recrystallization driven by organic acid and carbonic acid. The occurrence, structure, mineral composition and element content inherit the characteristics of early calcite to a great extent; The development of beef sparry calcite is controlled by the mechanism of crystallization force and abnormal overpressure. The beef sparry calcite with carbonate basement is poor in iron, and the material components are mainly derived from the dissolution of basement carbonate. The variation range and trend of element content inherit the characteristics of the basement to a certain extent; The beef sparry calcite with clay basement is rich in iron, which is the result of the coupling of clay mineral transformation, calcareous bioclastic dissolution and organic matter thermal evolution. The genetic mechanism of different types of sparry calcite indicates the formation and evolution of shale oil reservoir and the law of generation, migration and accumulation of shale oil.

Dynamic evolution model and exploration significance of sedimentary system of steep slope zone in Paleogene in Panyu 4 sag, Pearl River Mouth Basin

Jinhai He[1*], Guangrong Peng[1], Jing Wu[1], Zhensheng Li[1], Guofu Cai[1], Li Zhang[1], Xiaoyun Peng[1]
1. research institute, Shenzhen Branch of CNOOC Ltd., shenzhen, guangdong, CHINA
E-mail: hejh15@cnooc.com.cn

Keywords: Panyu 4 sag, Sedimentary system, Dynamic evolution model, Paleogene, Steep slope zone

Panyu 4 sag, as a hydrocarbon-rich sag, a series of oil fields in Neogene have been discovered successively. The proved reserves have already exceeded 100 million tons. The drilled wells analysis shows that the development and distribution law of high-quality reservoirs is the key factor restricting the Paleogene exploration in this area. In this paper, by analyzing the formation and evolution process of the paleogeomorphology , and the dynamic mechanism of the development of paleovalley system in the Paleogene steep slope zone of Panyu 4 sag, the sedimentary system of the steep slope belt of Panyu 4 sag was reshaped. Also, the dynamic evolution model of of sedimentary system was established in the Paleogene steep slope belt Panyu 4 sag, which provides reference for the exploration of Paleogene and the study of dynamic sedimentary system in similar areas. The results are as follows: The staged activation of pre-existing faults controls the sedimentary pattern of the steep slope zone. During the sedimentary period of Wenchang Formation, the two groups of pre-existing faults were activated in stages under the influence of the regional stress field [1]. The NE trending pre-existing faults activated and controlled the sag in the early Wenchang Formation, which controlled the sedimentary pattern of the steep slope zone in the early stage of Wenchang Formation in Panyu 4 sag, dominated by the near-source gravity flow deposition. The NW trending pre-existing faults activated and controlled the channel in the middle Wenchang Formation. It controlled the sedimentary pattern of the steep slope zone in the middle and late stages of Wenchang Formation of the Panyu 4 sag, dominated by the traction flow deposition. The transition of the regional stress field triggers the transition of the sedimentary pattern. Affected by the change in subduction angle and direction of the Pacific plate to the Eurasian plate at around 43 Ma(in middle Wenchang period) [2] , a series of NWW trending valley systems developed in the uplift area of the steep slope zone of Panyu 4 sag. While the sections of sag-controlling fault and NE trending pre-existing fault were combined, the gradient of the steep slope zone became gentler. At the same time, influenced by the upward arch of the magma in the center of the sag, relatively shallow sedimentary environment developed in the steep slope zone[3-5]; In the Paleogene steep slope zone of Panyu 4 sag, the nearshore subaqueous fans sedimentary system developed in early Wenchang period, while the northern sub-sag was the dominant development area. The fan delta sedimentary system developed in the middle and late Wenchang period, while the South sub-sag was the main development area. With good reservoir conditions, the fan delta development area in the steep slope zone of upper Wenchang Formation in the south sub-sag is a favorable exploration area.

Recognition and Sedimentary Responses of Milankovitch Cycles in Eocene Shahejie Formation, Dongying Depression, Bohai Bay Basin

Yu Han[1], Yingchang Cao[1], Chao Liang[1*]
1. School of Geosciences, China University of Petroleum (East China), Qingdao, Shandong Province, CHINA
E-mail: liangchao0318@163.com

Keywords: Lacustrine shale, Milankovitch cycles, Sedimentary environment, Laminar combination, Dongying Depression

Several studies have revealed that the Eocene fine-grained sedimentary rocks in Bohai Bay Basin is driven by astronomical forces. However it is still not clarified how orbital cycles specifically control the deposition of fine-grained sedimentary rocks and the coupling relationship of paleoclimate- paleolake- sedimentation. In this study, a combination of core and thin section observation, X-ray diffraction, ICP-MS analysis, total organic carbon (TOC) content analysis and cyclostratigraphy analysis were conducted on the lacustrine shale of the Eocene Shahejie Formation (Es4u to Es3l) in the Dongying Depression of Bohai Bay Basin, in order to recognize the Milankovitch cycles and explore the controlling effect of eccentricity, obliquity and precession on the deposition of the lacustrine shale as well as the paleoclimate evolution. The related achievements are as follows: 1. Through pre-processing, sliding window spectrum analysis and multi-taper method (MTM) of the natural gamma ray data of the well NY1, good orbital signals were recognized. And through correlation coefficient method (COCO), the study interval is divided into two sections according to the change of accumulating rates. Filtered eccentricity, obliquity and precession signal curves were obtained for both sections. 2. For the lower Section, obliquity is the main controlling factor for shale deposition and precession is the secondary controlling factor. When obliquity reaches its maximum, the content of dolomite and clay in Shahejie Formation increases, while the content of calcite decreases and TOC also increases. At this point the laminar combinations are mainly dolomite/calcite lamina and organic-rich clay lamina. When obliquity reaches its minimum, the content of calcite increases, the content of dolomite and clay decreases and TOC decreases. At this point the laminar combinations are mainly calcite lamina and clay silt mixed lamina. 3. For the upper Section, eccentricity is the main controlling factor for shale deposition and precession is the secondary controlling factor. When eccentricity reaches its maximum, the content of clay and quartz in Shahejie Formation increases, while the content of carbonate minerals decreases and TOC also increases. At this point the laminar combinations are mainly calcite lamina and organic-rich clay silt lamina. When eccentricity reaches its minimum, the content of clay and quartz decreases, the content of carbonate minerals increases and TOC decreases. At this point the laminar interface is usually blurry. 4. According to a series of geochemistry data analysis, the chemical weathering index (CIA) for the lower section is relatively low, the Mg/Ca ratio and Ni/Co ratio are relatively high, which indicates that the paleo-environment was arid and reductive. For the upper section, CIA is relatively high and the Mg/Ca ratio and Ni/Co ratio are relatively low, indicating a humid and less reductive paleo-environment. The coupling relationship of paleoclimate-paleolake- sedimentation experienced a transition from the lower section to the upper section of the study interval, which is consistent with the shift from obliquity driven to eccentricity driven. The intensification of East Asia monsoons might be responsible for this transition.

Origin of organic-rich lacustrine shales under constraint of astronomical forcing and volcanism

Miruo Lin[1], Kelai Xi[1*], Yingchang Cao[1]
1. School of Geosciences, China University of Petroleum (East China), Qingdao, Shandong, CHINA
E-mail: xikelai@upc.edu.cn

Keywords: origin of lacustrine shale, astronomical forcing, volcanism, shale oil

As the continuous progress of shale oil exploration and development, lacustrine shales is gradually regarded as a favorable target. Laminated shales with TOC content up to 20% commonly developed in Triassic Chang 73 sub-member in Ordos Basin, which was considered as the key object for shale oil exploration and development. The origin of this laminated shales rich in organic matter has long been of great interest to geologists. In this study, microscopic petrological analysis, in-situ geochemical analysis, spectral and wavelet analysis were used to explore the origin of laminated shales in Chang 73 sub-member. Three types of laminae and two types of laminar combination were generally identified in Chang 73 sub-member. Organic-rich laminae (ORL) and tuff-rich laminae (TRL), with TOC content ranging from 6% to 12%, are mainly composed of clay minerals. They are considered to have high oil generation potential. Silt-grained felsic laminae (SSFL) of low-density turbidity current origin contains large amount of k-feldspar (up to 70% in content) with dissolution pores. These dissolution pores provided good spaces for oil accumulation. Therefore, laminar combination 1, consisting of interbedded ORL and TRL, has superior oil generation conditions but weak oil storage capacity. Laminar combination 2, consisting of interbedded ORL and TRL, has good ability of oil generation and accumulation. Tectonic activity was relatively weak during the sedimentary period of Chang 73 sub-member. Therefore, astronomical forcing and volcanism mainly control paleo-environment evolution and lake-level fluctuation, which further result in laminated shale deposition. In the period of low obliquity, lake-level falling occurs under control by cold and arid paleo-climate. The silt-grained particles carried by low-density turbidity current commonly transported to the center of lake. It induced large-scale deposition of laminar combination 1 during this period. In the period of high obliquity, warm and humid paleo-climate induces lake-level rise. Retrogradation of silt-grained particles carried by low-density turbidity current occurred during this period. SSFL is gradually replaced by TRL. Clay minerals are dominated in the sediments. Therefore, laminar combination 2 generally deposited in the period of high obliquity. In the background of periodic paleo-environmental evolution controlled by astronomical forcing, volcanism will lead to short-term disturbances on paleo-environmental evolution. It will further impact lake-level fluctuation and shale deposition. In the period of intense volcanic activity, massive CO2 release will trigger the greenhouse effect. Heavy rainfall induces lake-level rise even in the period of low obliquity, which result in large-scale deposition of laminar combination 2. Astronomical forcing and volcanism finally induce the alternate deposition of laminar combination 1 and 2, promoting shale oil generation and accumulation.

Discussion on mixing of fine-grained sediments in lacustrine deep water, Dongying Sag , Bohai Bay Basin

Shun Zhang[1], Huimin Liu[1*]
1. Exploration and Development Research Institute, Shengli OilfieldSinopec, Dongying, Shan Dong, CHINA
E-mail: hmliu@vip.163.com

Keywords: fine-grained hybrid sedimentary,sedimentary environment,lithofacies,sedimentary fabric,Dongying sag,sedimentation

Take the example of fine-grained sedimentary rocks in the Lower Member 3 and Upper Member 4 of Shahejie Formation in Dongying Sag.Through core observation in cm-scale,detailed description of small-sized sedimentary structures,thin section identification,analysis of whole rock X-ray diffraction and trace elements test,fine-grained sediments occurrence and their mixed mode were studied,and the effect of basin fluid,climate and water properties on transfer,mixing and sedimentation of fine-grained rocks was analyzed.The mixing sedimentary mechanism of fine-grained rocks was discussed.The results indicate tha the depositional period of shale fine-grained migmatites in Dongying depression is generally characterized by the transformation of climate from semi humid to humid, from bottom to top, it shows the process of increasing injection amount of clastic material source,increasing water depth, decreasing salinity and decreasing reducibility; fine-grained sedimentary rocks in lacustrine deepwater are mixed in both components and structures under macroscopic and microscopic scales.The mixing sedimentation can be classified into homogeneous,lamina-overlapped and heterogeneous mixings with lamina-overlapped mixing the major type of fine-grained rocks.Based on the lamina contact relations,proportion and mineral occurence,the lamina mixing sedimentation is divided into:Lamina-overlapped mixing of sandmud and limestone,lamina-overlapped mixing of mud and limestone,laminate mixing of mud-sand sequence and limestone,lamina-overlapped mixing of limestone,mud and dolostone.The types of mixing sedimentation of fine-gained sediments are often influenced by multiple factors at the same time,and the climate and the hydrodynamic conditions are the main factors.The mixing sedimentation of fine-grained sediments varied in different fluids (turbidity current and bottom current).The climate causes changes of physical and chemical properties of water as well as layering of water body,which controls different types of flocculating settling and chemical deposition of fine-grained sediments.The mixing sedimentation types vary in different structural positions and water depths,and are even different vertically in the same structural position.

Paleoenvironmental study of Lucaogou Formation in Jimsar Sag, Junggar Basin

Jianxiong Dai[1], Yanqing Shi[1], Hancheng Ji[1*]
1. College of Geosciences, China university of Petroleum, Beijing, CHINA
E-mail: jhch@cup.edu.cn

Keywords: Jimusar Sag, Junggar Basin, trace element , paleoenvironmental, paleosalinity, paleoclimate

The Jimusar Sag in the Junggar Basin is a well-studied site in northwestern Xinjiang, China, and its study can provide rich information for the paleoenvironmental and paleogeographic evolution of the Northeast Pangea. In this study, core, thin section and XRF data were used to classify the lithology of Lucaogou Formation samples, and the concentrations of major and trace elements were analyzed using linear and multivariate statistical data of whole-rock elemental data. The results show that the lithology can be divided into two large cycles, the upper cycle is dominated by mudstone, and the lower cycle is dominated by sandstone. There are mixed layers of lime mudstone, lime mudstone, sandy dolomite and sandy limestone in the upper cycle, and dolomite sandstone, lime sandstone, dolomitic sandstone, lime sandstone, sandy dolomite, sandy Mixed layers of limestone. The main and trace element concentrations are mainly enriched in O, Na, Mg, Al, Si, K, Ca, Fe and other elements.

Further, we measure its paleoenvironmental characteristics based on various commonly used indices and elements, such as paleosalinity, paleoclimate, paleowater- depth, etc. Investigating previous literature found that in recent years, there is a lack of research on paleoenvironmental research using major trace elements on paleosalinity, a lack of combined research on weathering in paleoclimate, and a lack of data from paleotemperature and paleohumidity. For the study of paleosalinity, this paper adopts Sr/Ba, and considers the effect of inorganic carbon (replaced by CaO) on Sr and productivity on Ba. After removing the carbonate samples, as well as data with Sr values >1000 ppm and CaO >20 wt%, the correlation between CaO and Sr was significantly reduced. After that, we further judged the salinity of the Lucaogou Formation in the Jimusar Sag by combining carbon and oxygen isotopes. In the study of paleoclimate, this paper not only used the trace element index ratio to judge, but also combined with the transfer function of the main element and the carbon-oxygen isotope, used the CIA-K index to consider the effect of weathering, and then comprehensively analyzed the paleoclimate from the aspects of paleohydrology and paleoprecipitation. Finally, this paper analyzes the water depth through Fe/Mn, Mn/Ti and other indicators.

The study shows that the Lucaogou Formation in Jimsar Sag is dominated by saltwater-brackish water environment with a very small amount of freshwater environment. The climate is generally relatively hot and dry, with intermittent warm and humid climates. The water depth is always in a semideep-deep water environment. By comparing the curve changes and lithology changes of various paleosalinity and paleoclimate metrics, we find that sedimentary rock lithology is closely related to paleo-salinity. Carbonate rocks usually indicate a high salinity environment, and clastic rocks usually indicate a low salinity environment. The sharp fluctuations of the paleosalinity index curve are similar to the characteristics of lithological mixed sedimentation.However, most of the carbonate rocks in the Lucaogou Formation were deposited in situ, and the clastic materials in the clastic rocks may have been brought in with terrigenous freshwater that reduced the salinity of the lake.

Main controls and geological sweet spot types in Paleogene shale oil rich areas of the Jiyang Depression, Bohai Bay basin, China

Shun Zhang[1*]
1. Exploration and Development Research Institute, Shengli OilfieldSinopec, Dongying, Shan Dong, CHINA
E-mail: satisfactoryshun@163.com

Keywords: Paleogene ,Shale oil ,Shale reservoir, Sweet spot

The shale oil wells drilled in the early stage of the Jiyang Depression have achieved industrial-scale flflow, but the oil production in special exploration wells has been less than ideal. The area of continental shale oil and gas
accumulations has not been properly controlled, and geological sweet sections and sweet areas need to be systematically studied. In this study, shale reservoir characteristics are analyzed in detail based on thin sections,fifield emission scanning electron microscopy (FE-SEM) observations and mercury injection experiments of well core samples combined with X-ray diffffraction (XRD) and geochemical indicators. Key factors related to a high yield of shale oil are determined in addition to the shale oil production capacity, and the types of shale oil sweet spots are classifified, while the sweet spot distribution pattern is determined. The results show that the Paleogene shale in the Jiyang Depression is rich in carbonate minerals (mainly calcite and ferrocalcite, followed by dolomite and ferrodolomite) and has a low clastic content, high organic carbon content (2.0–7.0 wt%), and medium maturity (Ro = 0.51%–1.1%). An effffective reservoir space assemblage usually has a three-tier inter communication form within the porosity-fracture network. Laminar lithofacies that are rich in carbonates are the most favorable for containing continental shale oil reservoirs. Shale oil geological sweet spots can be roughly
divided into matrix shale oil, fracture shale oil, interlayer shale oil, and compound shale oil types. The key focus in locating shale oil wells is to fifind geological sweet spots that have an appropriate organic matter (OM) content,
interlayer development, light oil, and high pressure. This study demonstrates that favorable sweet spots are found to have the following conditions: a shale formation pressure coeffiffifficient of > 1.2, shale total organic carbon content of > 2%, organic-rich laminar lithofacies (including interlayer and single-interlayer thicknesses of > 2 cm), burial depth of > 3200 m, middle diagenetic stage B (Ro > 0.7%), and crude oil density of <0.89 g/cm3.

Lacustrine dolostone in the Songliao Basin: A novel mineralogical evidence for seawater intrusion

Yuke Liu[1], Huajian Wang[1*]
1. Key Laboratory of Petroleum Geochemistry, Research Institute of Petroleum Exploration and Development, China National Petroleum Corporation, Beijing, CHINA
E-mail: wanghuajian@petrochina.com.cn

Keywords: lacustrine, dolostone, Songliao Basin, seawater intrusion

Lacustrine dolostones are widely distributed in the black shale deposit in Qingshankou Member 1 in the Songliao Basin, northeast China, whereas little emphasis has been put on their petrogenesis and implications on paleo-lake water as well as continental weathering conditions. Here we reported the in-situ multielement imaging via Micro X-ray fluorescence and high spatial-resolution geochemical results of a dolostone nodule from the Qingshankou Member 1, of which the sedimentary and elemental signatures confirmed its protogenetic origin and effectiveness in recording the geochemical characteristics of paleo-lake during its formation.

According to in-situ multielement imaging results, the well-preserved laminated structures inside the nodule and the features with a magnesium-rich core wrapped with an iron-concentric outer layer and a manganese-concentric shell together indicate its primary form as dolomite and a gradual transformation into ankerite as well as manganese-ankerite. The elemental variation implies a varied bottom water redox condition, which involved from sulfidic to ferruginous and manganous zones. The extremely positive $\delta^{13}C$ values (up to +9.5 ‰) of the dolostone indicate the presence of microbial methanogenesis. And the supremely high $\delta^{26}Mg$ results (up to -0.85‰) demonstrate intensivecontinental weathering. Relatively low Y/Ho ratios, middle rare earth elements enrichment features and inconspicuous europium positive anomalies of this nodule point to a lake-water dominated source. However, the Sr isotope values in the core of the nodule (0.7076~0.7080) are close to the contemporaneous seawater (0.7074), whereas different from the modern river (0.7120) and the host black shale (0.7100). On the premise of excluding the influence of hydrothermal fluids, the significantly low Sr isotope values of the lacustrine dolomite might be caused by seawater interference during its dolomitization. Our findings demonstrated that the lacustrine dolomite within black shales is not only a faithful tracer of diagenetic water environment and continental weathering process, but also a novel fingerprint mineralogical evidence for episodic seawater intrusions in the Songliao Basin during late Cretaceous period, which supplemented other paleontological and geochemical records.

Sedimentary environment and characteristics of Dalazi formation in the eastern depression of Yanji Basin

Wu Xie[1], Zhiyuan Xue[1*]
1. , , , , CHINA
E-mail: 1598529174@qq.comm

Keywords: Yanji Basin, Dalazi formation, sedimentary characteristics, fan delta facies

The development period of the lower Cretaceous Dalazi formation in Yanji basin is the heyday of the development of Yanji Basin. A set of source rock is developed in the Dalazi formation in the east of the basin. This group is not only the main reservoir, but also an important exploration target. In order to better analyze the sedimentary law of Yanji Basin and predict the favorable facies belt, the sedimentary environment and sedimentary characteristics of Dalazi formation in the eastern sag are studied in detail by analyzing a large number of logging data, seismic data and observed core photos. The Dalazi formation as a whole is a set of sand mud interactive sedimentation of transgressive system, and the lake water depth is large. The histogram of mudstone color index shows that the mudstone color in this period is mostly dark. It is a reduction environment and the environment is relatively stable. Dark mudstone with large thickness and good oil generation conditions is deposited in some well areas. According to the analysis of composition maturity and heavy minerals, the sedimentary characteristics of this formation are multi provenance and near provenance, and the provenance direction mainly comes from the East. According to the sandstone triangle analysis, the lithology of reservoir sandstone is mainly lithic arkose, a few are arkose, and the sedimentary formation is fine clastic oil-bearing sedimentary formation. The sedimentary facies model of this period is: shore shallow lake facies—semi deep lake facies—fan delta facies. Based on the analysis of the sedimentary environment and characteristics of Dalazi Formation in the Eastern sag, as well as the oil and gas shows in YC2 well , it shows that there is a good oil and gas migration and accumulation system in this area, which is favorable for oil and gas accumulation and has a certain exploration prospect.

Study on High-resolution Sequence Stratigraphic Structure Model of Dalazi Formation in Yanji Basin

Zhiyuan Xue[1], Wu Xie[1*]
1. , , , , CHINA
E-mail: 1515553199@qq.com

Keywords: Yanji Basin , Dalazi Formation , Maximum Entropy Spectrum , Astronomical Cycle , High-resolution Stratigraphic Framework

In the Dalazi Formation of Yanji Basin, fan delta facies and lacustrine facies are mainly developed, and alluvial fan facies are locally developed, of which the second member of Dalazi Formation is the key oil-bearing layer for exploration and development. In the process of stratigraphic correlation and division, it is found that the sandstone layer of the Dalazi Formation has a certain sedimentary thickness, and the sandstone has a certain continuity. The sand-mud interbeds frequently appear in this interval, and the stratification marks of the conventional logging curves are not obvious. In order to improve the accuracy of small layer division and correlation, based on high resolution sequence stratigraphy theory and astronomical cycle theory, the maximum entropy spectrum analysis, spectrum analysis and wavelet time-frequency analysis technology are used to process and analyze the natural gamma curve(GR) data. Sequence boundary is identified by combining the logging lithology information. According to the prediction error curve in the maximum entropy spectrum analysis, it is identified that the second member of the Dalazi Formation contains a long-term base level uplifting semi-cycle and a long-term base level subsiding semi-cycle. On this basis, the middle-term base level cycle and short-term base level cycle are identified by combining the spectrum analysis technology and wavelet time-frequency technology. Finally, the second member of Dalazi Formation in Yanji Basin is divided into 1 long-term base level cycle, 6 middle-term base level cycles and 16 short-term base level cycles, and the sequence stratigraphic division scheme is proposed. Based on this, the high-resolution stratigraphic framework is established, which provides accurate geological basis for the subsequent comprehensive reservoir evaluation and sand body prediction.

Sedimentary evolution research of Tongfosi-Dalazi Formation, Eastern Depression of Yanji Basin

[1], dong Wang[1*]
1. , , , , CHINA
E-mail: wangdong_lnpu@126.com

Keywords: sedimentary evolution,cycle,maximum entropy spectrum,lake level,fan delta

Yanji Basin is a Mesozoic rift basin in eastern Jilin Province. The existing exploration data show that Tongfosi-Dallazi Formation is the most favorable area for oil and gas reservoir in Yanji Basin. The structural characteristics of the basin are complex, and large and small faults are developed. The sample analysis results show that the physical properties of sandstone reservoirs are generally deviated, which belongs to the type of medium porosity and low permeability reservoirs. The source rocks in the eastern depression are relatively developed, and the sandstone thickness is large, which has certain resource development potential. And in the eastern depression Yan12well in1280m still see oil and gas shows, porosity of12-13 %, permeability of$4 \times 10^{-3}\mu m^2$, indicating that there is a relatively good reservoir physical properties distribution area, but the specific distribution is not clear.

On the basis of basic geological research such as regional tectonic background and regional stratigraphic characteristics, the sedimentary evolution process of Tongfosi-Dallazi Formation in the eastern depression of Yanji Basin is described in detail in this paper : 1.Tongfosi-Dallazi Formation in Yanji Basin is divided into a third-order cycle and six fourth-order cycles by using sequence stratigraphy analysis ; 2.The maximum entropy spectrum analysis method is used to obtain the change rule of the lake level in the eastern depression of Yanji Basin : The basin mainly experienced a complete process of water inflow and water recession in the Tongfosi-Dalazi sedimentary period, in which the Tongfosi Formation and the first member of the Dalazi Formation are water inflow, the second member of the Dalazi Formation is the highest water level period, and the third member of the Dalazi Formation begins to reduce water level. 3.Sedimentary characteristics and sedimentary facies were studied. Fan delta facies and lacustrine facies were mainly developed in Tongfosi Formation and Dalazi Formation, in which fan delta facies identified fan delta plain and fan delta front subfacies. The lake facies can identify shallow lake, semi-deep lake-deep lake subfacies. The fan delta sedimentary system developed in the Tongfosi and Dalazi Formation, but the Dalazi Formation fan delta facies is the most developed, and the source supply is sufficient. The lacustrine sedimentary system is mainly developed in the Tongfosi Formation, and the Dalazi Formation is only developed in some areas of the basin.

Identification and quantitative characterization of silty laminae and beds in lacustrine organic-rich shales

Jianyu Liu[1*], Guodong Wang[1], Yiren Fan[2]
1. Western Exploration Department, Petrochina Research Institute of Petroleum Exploration and Development-Northwest, Lanzhou, Gansu, CHINA
2. School of Geosciences, China University of Petroleum, Qingdao, Shandong, CHINA
E-mail: liujianyu0108@163.com

Keywords: Silty laminae and beds, lacustrine shale, organic-rich shale, formation evaluation

Influenced by sedimentary environments such as sediment provenance, paleoclimate, the geochemistry of the water body and paleoproductivity, various laminae and beds are developed in the lacustrine organic-rich shales. Silty laminae and beds developed in the shale formation in the freshwater lake basin are important reservoir spaces and efficient channels for oil and gas migration. In addition, the identification and characterization of silty laminae and beds are critical to the sedimentary environment analysis, formation evaluation and sweet spot optimization. Researchers carried out a lot of studies on the drilled rock samples which contain silty laminae and beds, including core description, mineral composition analysis, scanning electron microscope, particle size, nitrogen adsorption and other experimental methods. Mathematic methods such as unsupervised clustering, fractals and joint characterization are used in the quantitative characterization of silty laminae and beds. However, drilled rock samples are limited and expensive, it is challenging to realize the fine evaluation of heterogeneous organic-rich shale formations.

Chang 7 member organic-rich shale formation in the Ordos basin is studied in this research. We used conventional logging and electric imaging logging to realize the identification and quantitative characterization of silty laminae and beds in lacustrine organic-rich shales. It mainly includes the following three steps:

(1) Lithology identification: the logging response characteristics of pure shale, silty laminae and beds, pyrite enriched layers and tuff layers in the organic-rich shale formation are analyzed. The criterion of lithology identification is established, and it can be clear that the silty laminae and beds with thickness greater than 1cm can be identified by the electric imaging logging.

(2) Identification of silty beds: the essence of silty beds identification based on the electric imaging logging is edge detection. A new method based on image processing and morphology is established, including the comprehensive process of electrical imaging logging, edge detection based on Sobel horizontal operator, and open operation. The silty laminae and beds with thickness greater than 1cm can be identified by this new method.

(3) Quantitative characterization of silty laminae and beds: based on the identification of organic-rich shales and silty beds, the thicknesses of silty beds are counted. It is clear that the distribution of the thickness of silty beds can be characterized by fractals. Therefore, the total thickness calculation model of silty laminae and beds can be established by the comprehensive analysis of electric imaging logging and drilled rock samples.

This research indicates that the silty laminae and beds identified by electrical imaging logging and core observation have a good consistency. This new method can be used in the uncored wells to realize the identification and quantitative characterization of silty laminae and beds. Moreover, the results are critical in the sedimentary environment analysis, formation evaluation and sweet spot optimization.

A comparative study of lake level fluctuation based on sedimentary facies and hydrogen index: a case from the Cenozoic Nima Basin in Tibet

kangzhi tian[1*], Haisheng Yi[1], Guoqing Xia[1]
1. institute of sedimentary geology, Chengdu University of Technology, Chengdu, sichuan, CHINA
E-mail: Tiankangzhiwd@gmail.com

Keywords: Nima Basin, Tibet, Lake level fluctuations,hydrogen index,sedimentary facies

Lake level fluctuations are extremely sensitive to regional and even global climate and environmental changes. Meanwhile, the source rocks are mostly developed and distributed during the lake-flooding period. Identifying the level fluctuations of ancient lakes is beneficial to the prediction and search of source rocks, and promotes the exploration and development of oil and gas resources. Therefore, it is significant to restore the indicators that record the level change of ancient lakes. In modern lakes, lake shorelines and lakeside terraces can directly reflect the fluctuation of lake levels. However, these geomorphological signatures are generally difficult to preserve in ancient lake deposits. Lake level fluctuations derived from traditional sedimentary facies changes are more intuitive, but the resolution is low. As an indicator of the redox environment, the hydrogen index can make up for the shortcomings of the above methods.

The Niubao Formation of Paleogene in the Nima Basin, Tibet, with clear outcrops, rich lithology, and fossils, is suitable for studying lake level fluctuations. Investigated the development horizon of source rocks in this section, this study discussed the relationship between source rocks and lake level and the superiority of hydrogen index in studying paleo-lake level fluctuations.

We discuss lake level and its controlling effect on source rocks by comparing the lake level fluctuation curves based on sedimentary facies and hydrogen index respectively. Through the research of sedimentary petrology, kerogen type, hydrogen index, and organic matter maturity of the samples, it was found that deep lacustrine facies has higher TOC compared to shallow and semi-deep lakes. The increase of lake paleo-depth plays a leading role in the quality of source rocks. However, when the lake level rises to a certain extent, the TOC of source rocks is mainly controlled by paleoproductivity. Compared with the lake level curve based on sedimentary facies, the hydrogen index also identifies lake level changes in similar lithologies. This more detailed method of describing the level fluctuations of ancient lakes is of great significance for guiding oil and gas exploration.

Keywords: Tight oil and gas,Reservoir densification,Hydrocarbon charging,Bohai Bay Basin

The tight sandstone in the Bohai Bay basin is rich in oil and gas resources, mainly distributed in the third member of Shahejie Formation (Es3). The differential tectonic evolution leads to obvious differences in diagenetic evolution history and oil and gas filling history in different regions of the basin. However, there is still a lack of research on the relationship between reservoir densification process and oil and gas filling.

Based on the relationship between reservoir densification and oil and gas filling, tight sandstone oil and gas reservoirs can be divided into three types"Accumulation before tightness" type (type I) “Accumulation synchronization with tightness” type (type II) "Accumulation after tightness" type (type III).

Based on the time coupling relationship between reservoir densification and main hydrocarbon generation and expulsion period, the coupling relationship between diagenesis and accumulation of tight sandstone reservoir in the Es3 Formation is characterized by multi-layer ring distribution centered on Bozhong Depression. The outer ring area includes the north of Jizhong Depression and Changwei Depression. The sub outer ring area mainly includes Liaohe Depression, Linqing Depression and the north of Liaodongwan Depression. The middle ring area mainly includes the south of Jizhong Depression, Jiyang Depression and Huanghua Depression. The inner ring area is mainly Bozhong Depression.

Two periods of oil and gas charging occurred in the Es3 formation, respectively in the middle and late Paleogene and Neogene to Quaternary. From the periphery of the basin to the center, there is an evolution law of “early one-stage hydrocarbon charging” → “two-stage hydrocarbon charging, early mainly” → “two-stage hydrocarbon charging, late mainly” → “late one-stage charging”. The evolution of reservoir porosity in the Es3 Formation presents the characteristics of “compaction and cementation porosity reduction” → “dissolution porosity increase” → “cementation porosity reduction” → “weak dissolution porosity increase”.

The densification time of the reservoir from the outer ring to the center presents the evolution law of "middle Paleogene → middle to late Paleogene → late Paleogene to early Neogene → middle to Late Neogene". For the first stage of oil and gas filling in the middle and late Paleogene, from the outer ring to the middle ring, the coupling type presents the distribution law of " type III → type II or type III → type I or type II". For the second stage of oil and gas filling from Neogene to Quaternary, the whole basin is dominated by type III coupling relationship.

The outer ring and sub outer ring are mainly tight oil and gas reservoirs with type III coupling relationship, which is likely to form relatively dispersed continuous tight oil and gas accumulation; In addition to type III oil and gas reservoirs, tight oil and gas reservoirs with type I and type II coupling relationship are also developed in the middle ring and inner ring, which is likely to form relatively concentrated trap tight oil and gas accumulation, and the exploration is relatively favorable.

Keywords: Ordos Basin and its periphery,Meso-Neo Proterozoic,property of prototype basin,tectonic and depositional evolution

The tectonic and sedimentary evolution of Meso-Neo Proterozoic in Ordos Basin and its periphery is ascertained in order to restore the original tectonic and sedimentary pattern and to explore oil and gas. In this paper, based on geological, seismic and logging data, the tectonic and depositional evolution of Meso-Neo Proterozoic have been studied in Ordos Basin and its periphery. The research shows that the Ordos Basin and its periphery underwent four tectonic and sedimentary evolutionary stages in Changchengian, Jixianian, Qingbaikou and Sinian Period of Meso-Neo Proterozoic. They are rift, passive continental margin, marginal subsidence and marginal depression, respectively.The Changchengian System was mainly composed of a set of terrestrial-littoral facies quartz sandstone, and developed braided river, delta, littoral shallow sea, shallow sea and deep sea sedimentary facies. The Jixianian System was mainly epeiric sea sedimentary facies with shallow water, including sand flat, dolomitic flat, flint dolomitic flat, open platform and shallow sea facies. Within Qingbaikou Period, the sedimentary environment of Ordos Basin and its periphery was retention marine basin and continental slope. There was glacial deposits in the Sinian System developed continental glacier, littoral sediment and shelf sedimentary facies.

Environmental magnetism and cyclostratigraphic analysis of the lacustrine successions of the Lower K1sh formation in the Early Cretaceous Songliao basin, northeastern China

Shujing Zhang[1], Huaichun Wu[1*]
1. School of the Ocean Sciences, China University of Geosciences (Beijing), Beijing, CHINA
E-mail: whcgeo@cugb.edu.cn

Keywords: SK-2 borehole, lacustrine, Early Cretaceous, environmental magnetism, cyclostratigraphy

Continuous cores of the lower Cretaceous in Songliao Basin, northeastern China, have been drilled out by the International Continental Drilling Project of SK-2 borehole, providing unprecedented geological materials for investigations of the early Cretaceous continental paleoenvironment and paleoclimate. In this study, we systematically studied the lacustrine successions of the lower Shahezi Formation (K1sh) in depth 4542-5694 m using the techniques of environmental magnetism, microscopic imaging, geochemical stratigraphy and cyclostratigraphy. Magnetic analysis reveals that there is an inverse correlation between magnetic susceptibility (MS) and lithology, where mudstones hold the largest values, and sandstones hold the smallest. The main magnetism carriers in the lower K1sh are pseudo-single-domain (PSD) and/or multi-domain (MD) ferromagnetic minerals, whilst the mainly dominant minerals of MS are paramagnetic and ferromagnetic minerals. To further explore the genesis of the environmental and climatic variations, MS was utilized as an alternative proxy to proceed with cyclostratigraphic analysis. Sedimentary cycles of 113.04 m, 34.11 m, 13.34 m and 6.00m are significant in power spectrum, which are in ratio highly accordant with long eccentricity (405 kyr), short eccentricity (124 kyr), obliquity (47 kyr), and precession (21 kyr) cycles in Early Cretaceous, proving the considerable impact of astronomical cyclicity on sedimentary rhythmicity. Long eccentricity controlled sedimentary facies, short eccentricity and precession are regarded to have mutually shaped the lake level oscillations. It should be noted that semi-precession periods identified from MS and the U sequence is most likely to directly drive the sand-mudstone alternations with the seasonal discrepancies of summer insolation. Finally, by tuning the inferred long and short eccentricity cycles to 405 kyr and 124 kyr orbital eccentricity theoretical curves, we established floating astronomical time scales (FATS) of 3356.99 kyr and 3248.80 kyr respectively, both of which fall into the range of the published U-Pb ages. Sedimentation rate was estimated ranging from 27.50 cm/kyr to 28.91cm/kyr, confirming the rapid deposition characterized within the fault lacustrine basin. In summary, our study acquired experimentally detailed magnetic characteristics of the early Cretaceous terrestrial sediments, shed new light on the astronomically forced configurations of paleoclimate on these magnetic properties, and provided a preliminary geochronological constraint for further marine-terrestrial comparison towards coeval strata.

Establishment of an age-calibrated astronomical time scale for the Chang 7 Member of the Triassic Yanchang Formation within the Ordos Basin, Central China

Yang Li[1], Renchao Yang[1*]
1. Earth science and Engineering, Shandong University of Science and Technology, Qingdao, Shandong, CHINA
E-mail: yangrc100808@foxmail.com

Keywords: Triassic time scale, Detrital zircons, Tuff zircons, Geochronology, Milankovitch cycles, Indosinian Orogeny

Astrochronology provides a method for developing highly detailed internal time scales for understanding Earth's history and rates of processes. During the Triassic, large continental lakes formed in the Ordos Basin of Central China. The lacustrine facies of the 7th Oil Member (Chang 7 Member) of the Yanchang Formation in the southern Ordos Basin displays cyclic changes in clay content, color and other properties. U–Pb geochronology of zircons from a basal tuff (ca. 239 Ma) and of detrital zircons from two sandstone beds within the reference Well N36 were used to constrain the stratigraphic ages and to identify possible provenance of the siliciclastics. Detailed time-series analysis was performed on the natural gamma (GR) logs and on the elemental concentrations of Fe and of Al. The resulting astronomical time scale for the Chang 7 Member, as constrained by the U-Pb dating, spans the interval from ca. 239 Ma through ca. 229 Ma; therefore, it was deposited during the Ladinian and Carnian (late Middle through earliest Late Triassic). The distribution of detrital zircon dates show that the Chang 7 Member in the southern Ordos Basin has multiple provenance characteristics. The southern Ordos Basin is far from this provenance area, which is reflected in the low sediment accumulation rate (0.5-2 cm/kyr). In contrast to underlying members, the lacustrine sediments of the Chang 7 Member hosts a large number of tuffs and seismites. This change is interpreted as a product of the initiation of collisional tectonics that formed the North Qinling orogenic belt on the southern margin of the Ordos Basin.

Enrichment mechanism of organic matter in saline lacustrine basin

Chenxi Zhu[1*], Fujie Jiang[1]
1. College of Geoscience, China University of Petroleum (Beijing), Beijing, CHINA
E-mail: lx_zcx@163.com

Keywords: paleoenvironment,organic matter enrichment,saline depositional environment, lacustrine basin

The organic matter enrichment is the basis of oil and gas resources evaluation. The lacustrine shale oil and gas resources is rich from Mesozoic and Cenozoic in China. However, due to the small area of the lacustrine basin, the hydrological conditions of the lake is disturbed by the sedimentary environment and affect the balance of evaporation and precipitation resulting from the small area of lacustrine basin (Katz, 1995), which leading to the change of lake water properties and complex organic matter enrichment (Pedersen and Calvert, 1990). The Dongpu Depression is a typical continental faulted lacustrine basin in Bohai Bay Basin in China. During the sedimentary period of the lower sub-member of Es3 (Member 3 of the Shahejie Formation), the deposition environment of saline and fresh-water were developed in the north and south region, respectively. In the past 50 years of exploration and development, 93.7% of oil and 80% of natural gas have been found in salt water sedimentary environment (Zhang et al., 2017).

The shale deposited in the north region develop salt rocks (mean value: 8.24%) and carbonate minerals (mean value: 34.79%) with an average TOC of 1.17%. The shale in the south region develop rare salt rocks with an average TOC of 0.44%. The carbonate minerals are relatively few (with an average of 20.5%). Combined with the data analysis of major and trace elements, it is considered that the climate was arid during the sedimentary period of the lower sub-member of Es3. The salinity of the ancient lake in the northern region is high, and halophilic algae such as dinoflagellate are developed, which increases the paleoproductivity in this period. In the southern region, the salinity of ancient lake is low, green algae are mainly developed, the degree of chemical weathering is medium, and the terrigenous input is high.

According to the further analysis of the organic matter enrichment mechanism of the saline sedimentary environment in the north, it is found that the TOC shows an obvious positive correlation with the paleoproductivity, which increases first and then decreases with the paleosalinity, reaching the maximum when the paleosalinity is 11 ‰. Based on the palynological analysis, it is found that when the salinity of the northern region is 12 ‰ ~ 13 ‰ and the TOC content is as low as 0.2%, the sporopollen development mainly includes Ephedra and Podocarpidites. It may be that the seasonal arid climate leads to the increasing terrigenous input, which is not conducive to the enrichment of organic matter. When the salinity is 10 ‰ ~ 12 ‰, the TOC content exceeds 1.5%, the dinoflagellate and acritarcha algae are developed. In addition, the humid climate and stable ancient lake leads to the anoxic bottom water, which is conducive to the enrichment of organic matter.

Pore evolution characteristics and shale oil enrichment model of sandstone bearing shale series

Xiaoliang Wei[1], Shun Zhang[1*], Huimin Liu[2]

2. Sinopec Shengli Oilfield Company, Sinopec Shengli Oilfield Company, Dongying, Shandong, CHINA
E-mail: satisfactoryshun@163.com

Keywords: sandstone bearing,shale oil,Pore evolution,enrichment model

In recent years, China has found huge shale oil resources in sandstone bearing shale series, which has greatly increased China's shale oil production. This kind of shale oil has attracted the attention of academic and industrial circles. We found shale series with the same characteristics in the north of Dongying Sag, Bohai Bay Basin, and analyzed its mineral composition, reservoir physical properties and oil characteristic. The result shows that this kind of lithofacies is mainly developed in the ancient steep slope area in Dongying sag. Although the sandstone layer is close to the organic-bearing or organic-rich shale, some sandstone layers didn’t storage oil prioritily. This is because the intergranular pore cementation in the diagenetic evolution process is earlier than the generation of oil. The shale series in the deep-water area is more rich in organic matter and clay mineral, the number of micropores and mesopores is greater than that of shallow water shale series. Sandstone provides limited porosity, so although more sandstone is developed in shallow water shale series, deep water shale series has higher porosity. However, sandstone significantly improves the permeability. Due to the development of more macropores, shallow water shale oil has high gas oil ratio and free hydrocarbon content. Therefore, the shale oil in shallow water shale series has higher fluidity than that in deep water shale series. On this basis, the pore evolution model and shale oil enrichment model of sandstone bearing shale in this area are proposed.

Analysis of provenance and tectonic background of Lower Cambrian black shale in Western Hunan and Hubei

1*

1. , , , , CHINA
E-mail: 397466473@qq.com

Keywords: Cambrian,Western Hunan and Hubei,Geochemistry,Black shale,Material source,tectonic setting

Based on the geochemical analysis of the black shale of Niutitang Formation in Gucheng Village (GCC) section and Yanwutan (YWT) section in Western Hunan and Hubei, the provenance and tectonic background of the black shale of Lower Cambrian in Western Hunan and Hubei are discussed. According to the combination ratio characteristics of major, trace and rare earth elements, the provenance background of the two sections is of mixed origin. The tectonic background is dominated by passive continental margin in GCC section and continental island arc in YWT section. There are great differences in sedimentary and mineral characteristics between the two sections. Niutitang Formation in GCC section is stratified. Niu1 member is siliceous shale and argillaceous shale, Niu2 member is micritic limestone, and Niu3 member is limestone and mudstone; The Niutitang Formation of YWT section is not stratified, mainly developing carbonaceous tabular shale, and the lower part is enriched with pyrite, nickel, cobalt, vanadium and other metals and phosphorus nodules. The quartz mineral content in YWT section is much higher than that in GCC section, and pyrite is also more developed than that in GCC section. The main reason for the difference of characteristics is the different tectonic background, followed by the influence of hydrothermal activities and the different depth of water body.

Study on Chang 8 sedimentary system and sand body distribution law in Huanxian-Heqi area

Wu Tianqi

School of Earth Science and Technology, Southwest Petroleum University

Ordos Basin is the most important oil and gas resource exploration and development base in China at present. Recently, a major breakthrough has been made in the exploration of Chang-8 oil reservoir group in Huanxian-Heqi area, and oil-rich sand belt has been found. Although the lithology, sedimentary structure, structure and fossil characteristics of cores in the early stage determined that Chang-8 oil reservoir group has shallow water sedimentary characteristics,However, the unclear understanding of the provenance, sedimentary system types and sand body distribution characteristics of Yanchang 8 reservoir group restricts the further exploration. Based on the analysis of lithology, sedimentary structure, structure and fossil characteristics in Huanxian-Heqi area, this study systematically carried out the work of provenance, sedimentary system, sand body distribution law and so on.

The sedimentary center of Ordos Basin is distributed in NW-SE direction, and Huanxian-Heqi area is located in the southwest of the sedimentary center, which is mainly influenced by the western and southwest provenances from the regional background analysis. During the long sedimentary period, the ancient water depth of the lake basin was high in the central and western parts and low in the eastern part. Compared with the Chang 82period, the Chang 81lake basin has expanded in scope and the water body has gradually deepened. Expansion to the south is obvious.The bottom shape of the lake is higher in the west and southwest, and lower in the middle and east. During the 82period, the delta plain was mainly located in the west and south of Huanxian-Heqi area, with braided channel and flood plain deposits, which were distributed from southwest to northeast. Delta front deposits are located in the northeast direction of the plain, and underwater distributary channels are mainly developed.The water depth extending to Huanxian-Heqi-Wujiao-Baima-Haojiajian area gradually increased, and developed into estuary dam, far sand dam and sheet sand deposit. The water depth of Chang 81period is higher than that of Chang 82, and the delta plain is mainly located in the west of Huanxian-Heqi area. Delta front deposits are located in the central and eastern part of the study area, and underwater distributary channels are mainly developed.The Zhonghuan County-Hedao-Heqi-Wujiao-Haojiajian area is distributed on the outside of the delta front, with deep water body, with far sand bar and sheet sand.

The favorable reservoir sand bodies in Chang 82section are mainly the superimposed sand bodies of underwater distributary channel, mouth bar and far bar in delta front; The water depth of Chang 81section in Huan-Heqi area is longer than that of 82section, and the favorable area moves southward. The reservoir sand bodies are mainly the superimposed sand bodies of underwater distributary channel, estuary bar and far sand bar in delta front.

Study on Reservoir Characteristics in Eastern Sag of Yanji Basin

Dong Wang[1], Jingwei Zhu[1*]
1. , , , , CHINA
E-mail: 13966453934@163.com

Keywords: yanji basin, rock formation function, pore structure, physical characteristics, heterogeneity

Reservoir characteristics are the key factors affecting the distribution and accumulation of oil and gas, which are of great significance to the exploration and development of oil and gas reservoirs. This paper analyzes and evaluates the reservoir characteristics of Tongfosi-Dalazi Formation in eastern Yanji Basin. Through thin-section observation and analysis, the contact relationship, morphological change and content of diagenesis products of rock debris were analyzed for various types of diagenesis in the study area to study the distribution and development of secondary pores; Combined with the existing physical property data, the distribution law and correlation of porosity and permeability in the study area are analyzed to find the layers with better physical property conditions; Based on the characteristics of mercury injection curve, the pore types and structure of different layers are analyzed, and the reservoir performance in the study area is judged by combining with the physical property data; The heterogeneity of the study area is evaluated by using the characterization parameters of permeability heterogeneity, and then the connectivity of sand bodies is studied to reveal the law of oil-water movement.

The results show that the sandstone reservoir rocks in the study area are feldspathic sandstone, lithic feldspathic sandstone and feldspathic lithic sandstone. The main diagenesis types include compaction, cementation and dissolution. The physical property of reservoir is characterized by low porosity and low permeability. The pore type is dominated by secondary pores with strong heterogeneity. This paper makes an objective and general expression of the overall reservoir capacity, and correct reservoir evaluation is of great significance to oil and gas exploration.

Mineralogical and geochemical characterization of calcareous shale in the lacustrine basin: Implications for paleosalinity, paleoclimate, and paleoredox conditions

Danish Khan[1*], Longwei Qiu[1], Chao Liang[1], Yongqiang Yang[1]
1. School of Geosciences, China University of Petroleum East China, Qingdao, Shandong, CHINA
E-mail: danish20124@yahoo.com

Keywords: Shale lithofacies, paleosalinity, paleoclimate, depositional environment, Shahejie Formation, Bohai Bay Basin

Shale is an important self-sourced reservoir rock in many sedimentary basins worldwide. In this research work, a geochemical history of variations of sedimentary environment in the lacustrine basin is analyzed based on extensive shale samples collected from the lower 3rd member (Es_3^L) and upper 4th member (Es_4^U) of the Paleogene Shahejie Formation in the Boxing Sag (Dongying Depression, East Coast of China). The representative shale samples were analyzed for total organic carbon (TOC) contents, mineralogical composition, the concentration of different elements (major, minor, and trace), kerogen types and vitrinite reflectance (R_o), and different sedimentary structures to understand the evolution of the depositional settings and their effect on the distribution of shale lithofacies in this basin. The TOC content in this shale is ranging from 0.08% to 13.6% (average 2.45%). R_o values range from 0.55–1.19% (avg. 0.85%) with type-I to type-II kerogens. The studied shale is composed of calcite (average 37.83%), dolomite (avg. 10.47%), quartz (avg. 23.8%), plagioclase (avg. 3.91%), clay (20.84%), and pyrite (2.85%). Seven lithofacies have been determined including mixed shale, calcareous shale, laminated limestone, argillaceous shale, dolomitic shale, siliceous shale, and siliceous dolomite based on mineral composition, TOC contents, and sedimentary structures. Different geochemical proxies including Sr/Ba, Ca/Ca+Fe, C-values, CIA values, Ti/Al, Al/Al+Fe, Al/Ti, V/V+Ni, Ni/Co, and Fe/Ca+Mg were used to interpret salinity, paleoclimate, detrital influx, provenance, paleoredox and water depth of the depositional environment in the studied shale. The detailed interpretation of the sedimentary environment suggested that during the deposition of Es_3^L shale, the terrigenous influx was high in shallow to a deep open lacustrine system with higher primary biogenic productivity. Semi-humid climatic conditions with higher precipitation rates prevailed during the deposition of this shale. On the other, relatively limited terrigenous input with low bioproductivity prevailed during the deposition of Es_4^U shale in the study area. Semiarid to humid climatic conditions with strong evaporation prevailed during the deposition of this shale. In this research work, a detailed depositional model of the Es_3^L– Es_4^U shale in Boxing Sag is established. The interpretations deduced from the current research work are likely to not only can expand the knowledge of shale lithofacies and genesis of lacustrine fine-grained sedimentary rocks, but can also offer a theoretical foundation for lacustrine shale oil exploration and development.

Characteristics and distribution law of the lithofacies assemblages of fine-grained sedimentary rocks in the Ek2 in the Cangdong sag, Bohai Bay Basin, eastern China

Nuannuan Ji[1], Shiyue Chen[1*]
1. School of Geosciences, China University of PetroleumEast China, Qingdao City, Shandong Province, CHINA
E-mail: chenshiyue@vip.sina.com

Keywords: Cangdong sag,Ek2 fine grained sedimentary rocks, Lithofacies;,Lithofacies assemblages, Distribution law

The thick fine-grained sedimentary rocks in the second member of the Kongdian Formation (Ek_2) in the Cangdong sag, Bohai Bay Basin, eastern China, are typical lacustrine source rocks and have recently been regarded as the main target for shale oil exploration. Fine-grained sedimentary rock with strong heterogeneity and poor plane continuity, is the basis for the accumulation of shale oil and gas. Therefore, it is of great significance to strengthen the study of lithology, lithofacies and lithofacies assemblages of fine-grained sedimentary rocks.

Based on the observation and description of cores from Well G108-8, Well GD12, and Well GD14, combined with analysis of thin sections and X-ray diffraction data, lithofacies of the Ek_2 fine-grained sedimentary rocks can be divided into six types, including laminated felsic fine-grained sedimentary facies according to mineral compositions and sedimentary structures, massive felsic fine-grained sedimentary rocks, laminated mixed fine-grained sedimentary rocks, massive mixed fine-grained sedimentary rocks, laminated carbonate fine-grained rocks, and massive carbonate fine-grained sedimentary rocks. Due to the vertical frequent alternation of lithofacies, lithofacies assemblages are proposed to describe the distribution law of the Ek_2 fine-grained sedimentary rocks, which can be named felsic lithofacies assemblages, felsic bedded with carbonate lithofacies assemblages, mixed lithofacies assemblages, carbonate bedded with felsic lithofacies assemblages, and carbonate lithofacies assemblages. The mineral compositions, sedimentary structures, and containing lithofacies types show significant differential among these lithofacies assemblages, which can be consisted with the evolution of sedimentary environment.

The method of combining the acoustic travel time (AC) log and density log is established to identify lithofacies assemblages in the study area, which can be used to study the distribution law. Lithofacies assemblages transformed from mixed to felsic bedded with carbonate in the lower part of the Ek_2^1, while from felsic to carbonate in the upper part of the Ek_2^1. From the margin to center of the lacustrine basin, lithofacies assemblages have two trends during the sedimentary period of Ek_{21}. Lithofacies assemblages present felsic, felsic bedded with carbonate, and mixed from the margin to center with the humid climate and strong detrital input. Furthermore, lithofacies assemblages present mixed, carbonate bedded with felsic, and carbonate from the margin to center with the arid climate and weak detrital input.

Compositional zoning in calcite cements records transgressions: Cretaceous terrestrial sandstones, Kuqa Depression, NW China

Zhenkun Li[1], Jian Wang[1*], Yingchang Cao[1], Tao Mo[2], Wenhui Zhu[2], Shunyu Wang[1]
1. School of Geosciences, China University of Petroleum (East China), Qingdao, Shandong, CHINA
2. Tarim Oilfield Company, PetroChina, Korla, Xinjiang, CHINA
E-mail: wangjian8601@upc.edu.cn

Keywords: Compositional zoning, Calcite cements, Transgressions, Kuqa Depression

Concentric compositional zones of early calcite cements can reflect changes in fluid properties and are further indicative of changes in sedimentary environments. Concentric compositional zoning revealed by cathodoluminescence is common in early non-ferroan calcite cements in Cretaceous sandstones of the Kelasu thrust belt within the Kuqa Depression. Optical microscopy, cathodoluminescence (CL), LA-ICP-MS and stable-isotope analysis were used to investigate the petrographic and chemical characteristics of these calcite cements. In cathodoluminescence, the zoned cements consist of alternating brightly luminescent zones and non-luminescent zones. Concentrations of Fe^{2+} are both low in non-luminescent and brightly luminescent zones (<200ppm). Mn^{2+} Concentrations in brightly luminescent zones (880~3020ppm) are higher than Non-luminescent (<620ppm). Non-luminescent zones show negative δCe, while brightly luminescent zones show positive δCe. These data imply that non-luminescent zones precipitated in oxidizing diagenetic environments, and brightly luminescent zones precipitated in reductive environments. The $\delta^{13}C$ values of non-ferroan calcite cements range between -4.8‰ and 0.8‰ PDB, while the $\delta^{18}O$ values are between -14.9‰ and -6.6‰ PDB, which is interpreted to indicate precipitation from meteoric water. Kuqa Depression experienced multiple transgression-regression of Tethyan seawater from the Early Paleocene to Late Eocene. During transgression, seawater inundated the unconformity and prevented meteoric water from recharging the Cretaceous sandstone aquifer, causing the pore waters to tend to stagnate and become more reductive, and resulting the brightly luminescent zones to precipitate. During regression, oxygen-rich meteoric water from the Southern Tien Shan dissolved the surface-deposited carbonates and continuously recharged the sandstone aquifer along the unconformity, and causing non-luminescent zones to precipitate. Thus, a cycle from brightly luminescent zone to non-luminescent zone records once transgression-regression (The last cycle only includes a brightly luminescent zone). Four zoning cycles can be observed in Cretaceous sandstones of Dabei 12 well, which indicates that transgression may have occurred four times in this area. Three zoning cycles can be observed in Cretaceous sandstones of Bozi 9 well, implying that transgression may have happened three times in this area. Two zoning cycle can be identified in Cretaceous sandstones of Keshen 10 well, so this region may have experienced twice transgression.

Lithofacies and Sequence Studies of Lime-rich Fine-grained Sedimentary Rocks in the lower Es3 and upper Es4 Boxing Sag

sun ya li[1], longwei qiu[1*], yongqiang yang[1]
1. , , , , CHINA
E-mail: qiulwsd@163.com

Keywords: Boxing sag,lime-rich fine-grained sedimentary rocks, lithofacies types,sequence stratigraphic division

It’s the basis of shale oil theory research and exploration and development to accurately divide the sequence and summarize the lithofacies characteristics and evolution law of the high-TOC lime-rich fine-grained sedimentary rocks in Boxing Sag.The study shows that the fine-grained sedimentary rocks in the Boxing subsag have the following characteristics: (1) The fine-grained sedimentary rocks in the study area are characterized by rich gray matter. CO isotopes of different lithofacies microareas show that the δ13C values (-6.257, -0.313) are consistent with the carbonate values of Ordovician system in North China. Therefore, it’s speculated that the gray matter may be mainly derived from the surrounding Ordovician uplift.2On the basis of mineral content, sedimentary structure and TOC content, fine-grained sedimentary rocks are divided into 11 lithofacies: organic-rich massive siliceous clastic type (carbonate type) mixed fine-grained sedimentary rocks, organic-bearing layers argillaceous dolomite, organic-rich lamellar (massive) (layered) carbonate-type mixed fine-grained sedimentary rock, organic-rich lamellar argillaceous limestone, organic-rich lamellar (layered) carbonate mixed fine-grained sedimentary rocks, organic-rich lamellar mudstone facies, and organic-rich layered siltstone facies. (3) Combined with seismic, logging, logging, geochemical parameters and other data, the sequence stratigraphic framework of the lower Es3-upper Es4 in Boxing subsag was established, and it was divided into two three parts. level sequence. Sequence one, the lake transgression domain and the highstand domain developed, which may be due to the erosion of the lowstand domain under the Es3; the highstand domain was divided into late highstand domain and early highstand domain by lithofacies assemblages and logging curves; sequence two,there are complete low-stand domain, lake transgression domain and high-stand domain. Then, the logging curve is processed by cyclolog software, and the lower part of Es3 is further divided into 10 sublayers (C1-C10), and the upper Es4 is divided into 9 sublayers (C1 -C9) (4) Lower Es3: A small amount of organic-rich massive clastic mixed fine-grained sedimentary rocks developed in the late high stand area, and a large amount of organic-rich massive (laminar) carbonate mixed fine-grained sedimentary rocks developed with the decrease of terrigenous input. When the content is higher, organic-rich layered carbonate-type mixed fine-grained sedimentary rocks develop; a large number of organic-rich layered carbonate-type mixed fine-grained sedimentary rocks develop in the early highstand, and a small amount of organic-rich layered carbonate-type mixed fine-grained sedimentary rocks develop when the water is shallow. The TOC content of the lake transgression area can reach up to 13.6%, and a large amount of organic-rich lamellar limestone and a small amount of organic-rich lamellar carbonate migmatite are developed. Upper Es4 member: a large number of interbedded siltstones interbedded with interbedded multi-stage siltstone containing organic intermittent lamellar argillaceous limestone and organic massive carbonate-type mixed fine-grained sedimentary rocks are developed in the high standing domain; The TOC content can reach 8.35%, which is similar to the lower Es3. In the low-stand region, the shallowest water body has strong evaporation, and many organic layered argillaceous dolomite and organic laminar mixed fine-grained sedimentary rocks are developed.

Obliquity-forced aquifer-eustasy during the late-Cretaceous greenhouse world

Zhifeng Zhang[1,2], Yongjian Huang[1,2*], Chengshan Wang[1,2], Mingsong Li[3], Pengcheng Ju[4], Xiang Li[1,2]
1. School of Earth Science and Resources, China University of Geosciences (Beijing), Beijing, CHINA

E-mail: huangyj@cugb.edu.cn

Keywords: Songliao Basin, Astrochronology, Cretaceous, Aquifer-Eustasy

The mechanism of short-term and high-magnitude sea-level oscillation has long been debated between glacio- and aquifer-eustasy (Miller et al., 2005; Haq, 2014), largely due to the sparse robust evidence for the aquifer-eustasy, and the little knowledge about hydrological dynamics behind it. Non-marine/ continental greenhouse archives (e.g. lake level) and their temporal correlation to marine successions (e.g. sea level) could give clue to aquifer-eustasy (Wagreich et al., 2014). The Songliao Basin (SLB), in Northeast China, is one of the largest Mesozoic terrestrial inland basins and has deposited the near whole Cretaceous successions (Wang et al., 2013). The greenhouse Late Santonian-Early Campanian Lower Nenjiang Formation (K_2n^{1+2}), recovered from three boreholes in SLB provides a unique opportunity for validating and decoding the aquifer-eustasy. Initially the cyclostratigraphy of logging gamma ray (GR) and Thorium (Th) series from three boreholes was implemented, which in junction with the radioactive ages renewed the chronology framework of SLB. Using the astronomically tuned GR and Th series, the lake level of SLB, which is recovered from sedimentary noise modeling (Li et al., 2019) and presents the water table of groundwater reservoir, shows a clear out-of-phase relationship with the coeval sea level, validating the aquifer-eustasy hypothesis. The lake level shows prominent ~1.2Myr cycles and a well-coupled relationship with sea level and obliquity modulation, indicating that the orbital obliquity drove the lake level and modulated the water exchange between ocean and continent during the Cretaceous greenhouse period. The strong precipitation indicated by the negative excursion of Ostracods $\delta^{18}O$ (Chamberlain et al., 2013) well correlates to the high lake level, high obliquity, and low sea level, suggesting that during obliquity modulation maxima, more moisture was precipitated into the high-latitude continents, consequently recharging the aquifer and raising the lake level while drawing down the sea level and vice versa. The close correspondence between reported marine incursion layers (Hu et al., 2015) and lowstand of sea level casts a doubt on marine incursion hypothesis in the SLB, more work is needed to reconcile this paradox. Overall, this study gives robust geological evidence for aquifer-eustasy and firstly decodes its role on Cretaceous short-term eustasy.

Genesis and sedimentation of the Middle Proterozoic en echelon rift in the western margin of the North China Plate

Meng Li[1*], Xiangbin Yan[1], Yuanling Guo[1], Wei Zhang[2]
1. Petroleum Exploration and Production Research Institute, SINOPEC, Beijing, CHINA
2. Exploration and Development Research Institute, SINOPEC North China Company, Zhengzhou, Henan Province, CHINA

Keywords: Western margin of the North China Plate, En Echelon rift, Middle Proterozoic, Boundary transform fault, Formation mechanism

The en echelon rift located at the margin of continental plates is rare in the world, and its genetic mechanism has not been widely concerned. In the western margin of the North China Plate, a series of Mesoproterozoic rifts are developed in the Ordos Basin, which are characterized by en echelon distribution in the NE direction. At present, there are still different understandings about the genetic mechanism of this rift zone. This paper reviews the research progress of Columbia supercontinent, studies the characteristics of middle Proterozoic rift in Hangjinqi area, and puts forward a new interpretation scheme. Under the tectonic background of the Columbia supercontinent cracking, the western margin of the North China Plate moved relative to adjacent plate, resulting in the formation of boundary transform faults. Under the action of the translation shear, the localized extensional (T) faults developed in en echelon style, and a series of NW trending rift belts developed continuously. At the strike turning point at the end of the boundary transform fault, the associated T rupture strike shows NNE-NS-NNW deflection from east to west, and finally forms the diverging rift in the Hangjinqi area. The boundary transform fault is related to the spreading of the mid-ocean ridge within the supercontinent and is also subjected to the counterclockwise rotation of the North China plate. In this paper, the tectonic origin of the boundary shift fault is proposed, which explains the formation mechanism of the middle Proterozoic en echelon rift and the northern divergent rift on the western margin of the North China Plate. The Middle Proterozoic Yanlian rift in Ordos basin plays an important role in controlling stratigraphic deposition and hydrocarbon accumulation.

Detrital zircon U-Pb age characteristics of the Cambrian Jianchang Formation in eastern Liaoning, North China Craton and its geological significance

Zijie WU[1*], Longwei Qiu[1], Chonghai Lu[1], Haipegn Wang[1]
1. School of Geosciences, China University of Petroleum East China, Qingdao, Shandong, CHINA
E-mail: midnight29@163.com

Keywords: North China Craton, Detrital zircon, Jianchang Formation, provenance

The Jichang Formation (F.) in eastern Liaoning is mainly distributed in Benxi area and Dalian. The Jichang F. overlies the Kangjia F. or Qiaotou F. of the Late Mesoproterozoic-Early Neoproterozoic, in Benxi, and a layer of sandstone with a thickness of nearly 2m developed at the bottom, which is obviously different from the Dalian area. Scholars have mostly explored the relationship between the NCC and the two supercontinents, Rodinia and Gondwana, by analyzing the detrital zircon ages in the Precambrian strata of the NCC. In order to find more informations, we collected sandstone samples from the sandstone at the bottom of the Jichang F., which had never been studied before, and carried out a zircon LA-ICP-MS U-Pb chronology study. The dating results show that the detrital zircon ages in the sandstone of the Jichang F. have 5 peaks of 2490Ma, 2145Ma, 1824Ma, 1178Ma and 517Ma. It is worth noting that the above-mentioned age peaks greater than 1000Ma have been reported in the Xihe Group strata in the eastern Liaoning (Zhang et al., 2020; Zhao,2020;), indicating that many parts of the Precambrian zircon in the sandstone in the Jichang F. should have inherited the Xihe Group. These zircon ages are interpreted as being partly from the North China Craton itself, and other part comes from cratons such as Laurentia, Siberia, Baltica, Sao Fransico, etc (Zhao et al., 2020; Wang et al., 2021). The age of the youngest zircon is 513.4±12.9Ma, which limits the lower limit of the deposition of the Jianhang F., and its age is determined at Stage 4 of the Cambrian Second Series. At the same time, it also shows that the NCC had the mixing of new biological sources close to the age of stratigraphic deposition in the Cambrian. Some scholars have suggested that there may be at least two periods of magmatic activity at 520 Ma and 430 Ma in the deep part of the NCC, and 520 Ma coincides with the aggregation peak of the Gondwana supercontinent. Therefore, we speculate that the age peak of 517 Ma found in the Jiachang F. indicates a key node in the Early Paleozoic evolution of the NCC, probably related to a global tectonic event controlled by its deep processes.In addition, the age of 700-1000 Ma is not found in the detrital zircon ages of the Jiancahng F., but these ages have been found in the Jinxian Group and Early Cambrian strata in the Dalian area. Therefore, after the deposition of the Xihe Group and before the second Cambrian, the Benxi area began to expose the surface and did not accept deposition, while the Jinxian Group and the Early Cambrian strata were deposited in the Dalian area. Therefore, the magmatism during this period may not have affected the Benxi area, resulting in the sandstone provenance of the Jiachang F. have no such informations.

Effects of Qinghai-Tibet Plateau Uplift on Paleogene-Neogene Sedimentary Evolution in the Southwestern Margin of Qaidam Basin

wang yan qing[1], SONG GUANG YONG[1*]
1. research , PetroChina Hangzhou Research Institute of Geology,Hangzhou,china, hangzhou, zhejiang, CHINA
E-mail: 305098792@QQ.COM

Keywords: sedimentary evolution, Paleogene-Neogene, Qaidam Basin, Qinghai-Tibet Plateau

The stages and spatial differences of the uplift of the Qinghai-Tibet Plateau have important scientific significance for further understanding the uplift mechanism of the Qinghai-Tibet Plateau, discussing the effects of climate and environment, and guiding oil and gas exploration. This paper takes the Qaidam Basin located in the northeastern part of the Qinghai-Tibet Plateau as the research object, and conducts a comprehensive analysis of the distribution, evolution characteristics and differences of sedimentary systems. Combined with the research results on the uplift of the Qinghai-Tibet Plateau in recent years, this paper discusses the control effect of the Qinghai-Tibet Plateau uplift on the Paleogene-Neogene sedimentary differences in the Qaidam Basin. The research results show that five major provenance sedimentary systems developed in the Paleogene in the western Qaidam Basin, i.e., NBZL braided delta, QHQ-YYS fan delta, ALE-TMLK braided delta, QMTA-DCS braided delta and GS braided delta. While four major provenance sedimentary systems developed in the Neogene, i.e., NBZL braided delta, QHQ-YYS fan delta, Aral braided delta, and Gs braided delta. The NBZL braided delta sedimentary system exhibits the evolutionary characteristics of retrogression, the ALE-TMLK fan delta sedimentary system exhibits retrogression to progression, the ALE-TMLK braided delta sedimentary system exhibits regression to strong progression, and the GS braided delta sedimentary system shows the evolution characteristics of regression-progression. The QMTA-DCS braided delta sedimentary system developed in the Paleogene and not developed in the Neogene. It can be seen that due to the influence of the uplift of the Qinghai-Tibet Plateau, the distribution and sedimentary evolution of each provenance system in the western Qaidam Basin showed obvious differences. The uplift of the Qinghai-Tibet Plateau in the Paleogene was relatively small, and the ancient Kunlun Mountains in the southwestern margin of the basin provided provenance, forming the QMTA-DCS large-scale braided delta deposits. The Mantage Mountains blocked the direct flow of the ancient Kunlun Mountains water system into the Qaidam Basin, but went westward along the mountain through the Kunlun Mountain Pass, and merged into the Qaidam Basin along the Alar River and the Timurik River, forming the largest Alar braided delta sedimentary system in the region. In the KB and DCS areas, the petroleum exploration was suggested to focus on the Paleogene braided delta reservoirs and the Neogene shallow lake beach-bar reservoirs. It supports the discovery of the Paleogene braided delta oil reservoirs in the KB area and the Neogene coastal shallow lake beach-bar oil reservoirs in the ZHQ-WN area. In conclusion, the detailed first-hand data in this paper are of great significance for restoring the lithofacies and paleogeography of the Qaidam Basin, understanding the stages and spatial differences of the uplift of the Qinghai-Tibet Plateau, and guiding oil and gas exploration in the Qaidam Basin.

Neoproterozoic geodynamics of South China and implications on the Rodinia configuration: the Kunyang Group revisited

Li Sun[1], Wei Wang[1*]
1. School of Earth Sciences, China University of Geosciences, Wuhan, Hubei, CHINA
E-mail: wwz@cug.edu.cn

Keywords: Sedimentary provenance, Kunyang Group, Detrital zircon geochronology, South China Block, Rodinia

The late Mesoproterozoic to early Neoproterozoic strata in the Yangtze Block hold a key position in deciphering the tectonic evolution of the South China Block and implicate upon the reconstruction of the Rodinia supercontinent. The sedimentological, geochronologic, and geochemical data on the Kunyang Group, southwestern Yangtze Block, were evaluated for a better understanding of the regional geodynamics and refinement in its paleoposition in the Rodinia supercontinent. Our findings constrain the deposition of the Kunyang Group sediments occurring during 1152 Ma and 1000 Ma, under a stable environment with alternating neritic and littoral facies sedimentation. In contrast, deposition of the Meidang Formation, traditionally thought to represent the upper part of the Kunyang Group, continued up to 866 Ma in an active setting at varying basin depths and hydrodynamic conditions. Moderate to high SiO2 contents (57.7-95.4 wt%), highly variable K2O/Na2O ratios (0.01-55.8), and critical trace element abundances (Zr: 57.6-578 ppm, Th: 1.95-28.3 ppm, Sc: 0.75-24.3 ppm), detrital zircon age distribution, sedimentological characteristics, and bimodal magmatism cumulatively underline a transition from continental rift to passive continental margin setting, followed by an active continental margin setting. The onset of oceanic subduction below the SW-NW margin of the Yangtze Block caused a hiatus in sedimentation, marked by an unconformity between the Kunyang Group and Meidang Formation.

Paleocurrent data, zircon U-Pb ages, and Lu-Hf isotopic characteristics indicate that the Kunyang Group received detritus from some interior sources and exotic terranes, such as the Gawler Craton in Australia, the Transantarctic Mountains in East Antarctica, and the Ongole domain in the Eastern Dharwar Craton of India. The Yangtze Block was likely located to the west of Australia and East Antarctica and north of India in the Rodinia supercontinent. Paleocurrent data also confirm an external location for the Yangtze Block in the Rodinia paleogeographic configuration.

Late Neoproterozoic–early Paleozoic basin evolution in the Cathaysia Block, South China: Implications of spatio-temporal provenance changes on the paleogeographic reconstructions in supercontinent cycles

Erkun Xue[1,2*], David Chew[2]
1. State Key Laboratory of Geological Processes and Mineral Resources, School of Earth Sciences, China University of Geosciences (Wuhan), Wuhan, Hubei, CHINA
2. Department of Geology, School of Natural Sciences, Trinity College Dublin, Dublin, County Dublin, IRELAND
E-mail: vcxek163@163.com

Keywords: Cathaysia Block,Detrital zircon ages,Provenance variation,Tectonic evolution,Gondwana

The role of the Cathaysia Block, South China and its linkage with orogenesis in the Rodinia and Gondwana supercontinents remain unresolved because of uncertainties in its position in supercontinent reconstruction(s) (Cawoood et al., 2017). Lithostratigraphic, geochronologic, geochemical (including isotopic) and paleocurrent data from late Neoproterozoic to early Paleozoic sub-basins in the Cathaysia Block reveal spatio-temporal, tectono-sedimentary and provenance diversity that show linkages with previously adjacent terranes and orogens in East Gondwana. The abundance of siliceous and conglomeratic rocks, local unconformities and pinch-out indicate that the basins were source from proximal late Cryogenian terranes, and experienced late Ediacaran transgression and middle Cambrian uplift. Cryogenian to early Ordovician strata all contain a major 1000-900 Ma (late Grenvillian) detrital zircon population, whereas 1300-1050 Ma (early Grenvillian) zircon populations are significant only in pre-late Ediacaran strata (Wang et al., 2018). A 850-700 Ma zircon population is most prominent in middle Cambrian strata, where it is sometimes associated with a 650-500 Ma (Pan-African) zircon peak.

The Grenvillian zircon population implies significant sediment input from eastern Indian (990-950 Ma) and western Australia (1300-1050 Ma) sources, underlining the fact that the Cathaysia Block was located between these two terranes in the northern part of East Gondwana (Yu et al., 2010). The diminishing contribution of early Grenvillian detritus in the late Ediacaran strata can be related to the Pinjarra Orogeny (550-520 Ma), whose uplift blocked the transport of detritus from Australia (Cawood et al., 2007). Middle Cambrian provenance variations with the abundance of 850-700 Ma zircons indicates derivation from the Wuyishan terrane of South China, supported by the associated change in the detritus from felsic and andesitic volcanic rocks to granitic rocks. Given that the Cathaysia Block was a passive continental margin, this provenance change was likely caused by the uplift of the southeastern Cathaysia Block, related to the far-field stress effects of the late phase of the Kuunga Orogeny (530-480 Ma) (Xu et al., 2016). The decrease in the abundance of early Grenvillian and Pan-African zircons implies that they were transported into the basins through independent drainage systems. This is consistent with the local and temporal variations in paleocurrent orientations during the Cambrian, further implying diverse and complex drainage system(s) in the southwestern Cathaysia Block during this period.

E-mail: xuyajun19@163.com

Keywords: detrital zircon U-Pb-Hf isotopes, Hainan Island, Eastern Tethys Ocean, paleogeography

How was the northern margin of East Gondwana configured before and after the opening of Paleo-Tethys Ocean and where was the eastern extension of the branched Ailaoshan Ocean still have been debated. The Cambrian-Ordovician and Carboniferous successions in Hainan Island provide key records of tectonic evolution of the island with its surrounding terranes and their absolute and relative paleopositions to the northern margin of East Gondwana before and after the opening of Paleo-Tethys Ocean and further constrain on the eastern extension of the Ailaoshan Ocean. U-Pb ages and Hf isotopic compositions of detrital zircons from these successions reveal two distinct changes in sedimentary provenance. The first transition of sources, between the middle Cambrian and late Ordovician, reflects a shift from the local Precambrian basement of Hainan Island to a mixed detritus input that mainly supplied by the northern margin of East Gondwana. Integrated with the similarity in provenance of the Ordovician in the Hainan Island and Indochina, this transition implies the juxtaposition of Hainan Island and Indochina along the northern margin of East Gondwana by the late Ordovician. The second transition of sources is characterized by the presence of ca. 370 Ma juvenile arc affinity detritus derived from the subduction of Paleo-Tethys Ocean along the southern margin of the North Qiangtang-Indochina-Hainan continental silver and the disappearance of Gondwana-derived materials in the Lower Carboniferous, along with detritus input of mid-Mesoproterozoic basement in the island, which responded to the separation of the North Qiangtang-Indochina-Hainan continental silver from the northern margin of East Gondwana and the initial subduction of Paleo-Tethys Ocean. The tectonic evolution of Hainan Island and its surrounding terranes during the Paleozoic, integrated with regional tectonic framework, suggest that the Ailaoshan Ocean as a branch of Paleo-Tethys Ocean extended eastward to the north of Hainan Island and separated the North Qiangtang-Indochina-Hainan continental silver from the South China Block.

Neoproterozoic (Tonian and Cryogenian – early Cambrian) sedimentation in NW India: implications on the transition from Rodinia breakup and Gondwana assembly

Jun Zhang[1*], Manoj K. Pandit[2]

1. School of Earth Sciences, China University of Geosciences, Wuhan, Wuhan, Hubei, CHINA
2. Department of Geology, University of Rajasthan, Jaipur, Rajasthan, INDIA

E-mail: im.jun.zhang@foxmail.com

Keywords: Sedimentary provenance, Sindreth and Punagarh basins, Marwar Supergroup, NW India, Rodinia-Gondwana transition

The breakup of Rodinia and the assembly of Gondwana supercontinents during the Neoproterozoic era has been hailed as a major global event of redistribution of continental blocks. Tonian (Punagarh-Sindreth basins) and Cryogenian – early Cambrian (Marwar basin) sedimentary rocks in NW India were investigated to better understand the Neoproterozoic tectonic evolution of this region and Rodinia to Gondwana transition. The collinear (NNE – SSW trending) Punagarh and Sindreth basins received a dominantly felsic detritus with negligible heavy mineral sorting. Mild to weak chemical weathering in their source region for Punagarh and Sindreth sedimentary rocks is reflected in their low CIA (53.1-62.2) and high ICV (0.76-1.04) values. The clastic composition and geochemical characteristics of Punagarh and Sindreth rocks suggest a back-arc basin setting, and volcanic arc and cratonic interior region source for the sedimentary detritus. The Punagarh basin was proximal to the craton while the Sindreth basin was closer to the arc system. In contrast, the Cryogenian – early Cambrian Marwar Supergroup sedimentary rocks comprise mature quartz arenite with high CIA (77.8-94.8) and low ICV (0.18-1.00) values that suggest a strong chemical weathering in the source region, and significant physical sorting during transportation and sedimentation. The dominance of quartz (87-94%), Zr enrichment, and detritus derived from the cratonic basement indicate deposition of Marwar sediments in a tectonically stable basin, temporally coinciding with the Gondwana assembly. Collective inference of provenance and tectonic setting for Punagarh, Sindreth, and Marwar basins underline a transition from an active to a passive continental margin in NW India at ~760 Ma. The inference of a Neoproterozoic active continental margin in NW India is in agreement with the subduction of the peripheral Rodinia supercontinent during its breakup. Further, the passive continental margin sedimentation in the Marwar Basin suggests the presence of an open sea between NW India and western Gondwana during the Gondwana assembly.

Carboniferous sedimentary records and geochemistry evidence related to the subduction initiation of the Paleo-Asian Ocean in eastern part of northern margin of North China Craton

E-mail: geodqx@foxmail.com

Keywords: North China Craton, passive continental margin, subduction initiation, the Paleo-Asian Ocean, Carboniferous

The tectonic setting of northern margin of the North China Craton (NCC) during Carboniferous has sparked fierce debate for a long time. In this study, we present new zircon U-Pb ages of Carboniferous sedimentary records in eastern Jilin Province (NE China) along the northern margin of the NCC. We systematically collected samples of metamorphic rhyolite (FY-1), underlying metamorphic greywacke(CD-1) and gabbro(HT-1) from the Changde metavolcanic rock sequence, and carried out LA-ICP-MS zircon U-Pb dating, zircon Hf isotope and geochemistry analysis for the three samples. (1) Previous research suggested that the age of the Changde metavolcanic rocks belonged to the pre-Devonian. However, the zircon U-Pb dating for Sample FY-1 in this study yields an age of 345.3 ± 2.3 Ma in the Early Carboniferous[1]. The $\varepsilon_{Hf}(t)$ values of Sample FY-1 are 3.46-12.2, and the two-stage model ages (T_{DM2}) are 571-1132 Ma, which indicate that the rock originated from the partial melting of the young lower crust. The Early Carboniferous metamorphic rhyolite shows enrichment of light rare earth elements and large ion lithophile elements, and depletion of heavy rare earth elements and high field strength elements. The geochemical characteristics and the discriminant diagrams of tectonic environment suggest that the metamorphic rhyolite is A-type rhyolite and formed in the post-collision extensional environment. (2) The detrital zircon U-Pb ages of Sample CD-1 contain abundant old ages including Carboniferous to Ordovician ages of 353-462 Ma and Neoproterozoic age of 861 Ma, and a small amount of Mesoproterozoic to Proterozoic ages of 2325-2456 Ma and Neoarchean detrital zircon ages. One of the youngest detrital zircons from Sample CD-1 is 351±7 Ma, further indicating that the metamorphic greywacke was deposited during the Early Carboniferous (ca. 351-345 Ma). The crystallization age curve and summary plot of detrital zircons show that Sample CD-1 was mainly deposited in a passive continental margin. (3) The youngest zircons of Sample HT-1 are concentrated in 245-247 Ma in the Middle Triassic with a few captured zircon ages of Carboniferous, Neoproterozoic and Neoarchean. The discriminant diagrams of tectonic setting show that the gabbro formed in an extensional setting. In addition, the final closure of the Paleo-Asian Ocean occurred during the Permo-Triassic suggested by our previous researches[2-3]. Therefore, it was a passive continental margin of the NCC during the Early Carboniferous[4-5]. In central Jilin Province, we also found that the provenance content of felsic magmatic rocks recorded by detrital heavy minerals in the Carboniferous strata is decreasing, whileas that of basic-intermediate magmatic rocks is increasing. The above results may reflect that the enhanced subduction process of the ancient ocean with the increase components of volcanic island arc in the Late Carboniferous. By collecting the results of previous ages of Carboniferous magmatic zircons, detrital zircons and zircon Hf isotope in the northern margin of the NCC[6-8], we further suggest that the timing of provenance change and tectonic setting change from passive continental margin to active continental margin environment is at ca. 320 Ma.

Paleotethyan evolution of NE Iran

Yang Chu[1*]
1. Lithospheric evolution, Institute of Geology and Geophysics, Chinese Academy of Sciences , Beijing, CHINA
E-mail: chuyang@mail.iggcas.ac.cn

Keywords: Paleotethys, NE Iran, Subduction initiation, initial collision

The timings of the onset of oceanic spreading, subduction and collision are crucial in plate tectonic reconstructions, but not always straightforward to resolve. The evolution of the Paleo-Tethys Ocean dominated the Paleozoic-Early Mesozoic tectonics of West Asia, but the timeline of events is still poorly-constrained. In this study we present detrital zircon ages from NE Iran, in order to determine the timing of tectonic events in the region, and the wider implications for regional tectonics, paleogeography and climate change. Paleozoic clastic rocks record two major age peaks at ~800 Ma and ~600 Ma. The consistency in age patterns shows a dominant provenance from the Neoproterozoic basement of northern Gondwana. We interpret deposition on a long-lasting passive continental margin after the initial spreading of the Paleo-Tethys Ocean. Initial collision between the South Turan (Eurasia) and Central Iran (Gondwana) blocks caused coarse clastic deposition, the protolith of the Mashhad Phyllite, in a peripheral foreland basin on the Paleozoic passive margin. The Mashhad Phyllite yields major zircon age clusters at 450-250 Ma and 1900-1800 Ma, with a clear provenance from the active, Eurasian, margin. The Paleozoic ages reveal a long-lived subduction zone under the South Turan Block began in the latest Ordovician. Analysis of the age spectra allows us to constrain the timing of initial collision as no later than 228 Ma, which is also a constraint on the maximum depositional age of the Mashhad Phyllite. Based on our new results and previous data, we discuss the interaction between the Rheic and Paleo-Tethys oceans, and explain how a new subduction zone may have initiated after continental collision.

The Jan Mayen microcontinent: an understanding of its sediments, and relationship between tectonic evolution as the distal domain of volcanic passive margin, in the North Atlantic

Ye Jiang[1*]

1. Exploration & Development Research Institute, Oversea Technical Support Center, CNOOC International Limited, Beijing, CHINA

E-mail: jiangye@cnooc.com.cn

Keywords: Jan Mayen microcontinent, Volcanic passive margin,Stratigraphic correlation,Tectonic evolution

The Jan Mayen microcontinent (JMMC) is located in the central part of the Norwegian-Greenland Sea of the North Atlantic, conjugate with the Jameson Land basin on the Greenland continent margin and the Vøring basin on the Norwegian shelf margin of the Beltic continent in accordance with similar Paleozoic-Mesozoic stratigraphy. The JMMC extends southwards from the Jan Mayen Fracture zone towards northern Iceland and its architecture shows the characteristic of detachment faults which is similar to the Mesozoic fault system of the Vøring basin. The distribution of SDR, volcanic intrusion and explosion can be interpreted on the seismic data which indicates the JMMC is the distal domain of the Volcanic passive margin in the North Atlantic mostly during the Cenozoic age, also indicts the lithospheric extension and break while the embryonic oceanic crust generating through the detachment movements and mantle upwelling. The stratigraphic correlation, tectonic event records, and the faults architecture help to setup the tectonic evolution model by the analogic basin analysis and is supposed to start from the Paleozoic-Mesozoic orogeny to rifting, and then be influenced by the twice seafloor spreading of the age 55Ma and 25 Ma. The first seafloor spreading of 54Ma age caused the continental crust break-up and formed the volcanic passive margin between the Greenland and Beltic, especially the JMMC's separating from the conjugate Norwegian shelf margin. The second seafloor spreading of 25Ma age caused the oceanic ridge jump due to the Iceland mantle plume drifting off the Greenland and also caused the JMMC's separation from the Greenland continent as an 'abandoned orphan’floating on the oceanic crust.

Sedimentary Responses of Late Triassic Soft Sedimentary Deformation to Paleoearthquake Events in the Southwest of North China Plate

Yu Wei[1*]
1. Institute of Sedimentary Geology, Chengdu University of Technology, Chengdu, Sichuan, CHINA
E-mail: yw3019@foxmail.com

Keywords: Seismic events, Trigger mechanism, Sedimentary sequence, Seismites, Chang-7 Member

The tectonic events caused by paleoearthquakes have a good response in sedimentary filling. Outcrops and cores from the Chang-7 Member of the Late Triassic Yanchang Formation, Ordos Basin in Northern China, yield a wide variety of soft sedimentary deformation structures (SSDSs), many of which are laterally extensive for more than 150 km. They include various types of folds, soft sediment liquefaction deformation (liquefied sandstone dyke, liquefied breccia), gravity-driven deformation (load structures, ball-and-pillow structures), hydraplastic deformation (loop bedding, convolute deformation) and brittle deformation (intrastratal faults and stair-step microfaults, microcracks). In most cases, deformation is represented by hybrid brittle-ductile structures exhibiting lateral variation in deformation style. These occur in delta front to semideep to deep lake sands and mudstones (shales).

From bottom to top, the sedimentary sequence of seismites in the Chang-7 Member is described as follows: underlying aseismic layer, microfissure and seismic breccias, stair-step microfaults, liquefied sandstone dyke, liquefied convolute deformation, seismically breccia and ball-and-pillow structure, liquefied homogeneous layer and overlying aseismic layer. The seismites recognized in outcrops and cores indicate earthquakes with magnitudes between 6 and 8, which are interpreted as a response to splicing collision orogenic events of the South China Block (SCB) and North China Block (NCB) during the Late Triassic period. Systematic study of the spatial and temporal distribution of these seismites improves the understanding of the tectonic context and evolutionary history of sedimentary basements. This study can provide a new perspective on the evolution of tectonic activities in the basin.

Neoproterozoic crustal thickness evolution in northern Tarim and the implications for breakup of Rodinia supercontinent

Yifan Song[1], Zhong Li[1*]
1. State Key Laboratory of Lithospheric Evolution, institute of Geology and Geophysics, Beijing, CHINA
E-mail: lizhong@mail.iggcas.ac.cn

Keywords: crustal thickness evolution, Tarim, Rodinia, supercontinent breakup

Understanding supercontinental cycles can help us better comprehend earth's evolution. The debate over the geodynamic drivers for breakup of supercontinents has focused on the “Bottom up” process related to mantle plumes or “Top down” process related to exterior subdution. We explore the crustal thickness by detrital zircon for Ediacaran sedimentary rocks and magma source based on the Hf - Nd isotope data from northern Tarim.The Hf - Nd isotope values decrease with crustal thickening and switch to increase with extensional thinning environment. The cyclic secular trends in thickness and isotope were attributed to alternating regimes of compression and extension resulting from advancing to retreating, and multistage accretion process is controlled by the outward migration of subduction zone. Crustal thickness recovery based on detrital zircon combined with isotope changes can play an important role in understanding the geodynamic drivers of crustal evolution and supercontinent cycle.

THE CLOSING TIME OF PALEO ASIAN OCEAN: EVIDENCE FROM SEDIMENTOLOGY

Hao Fan Gong[1*], Jun De Zhang[1], Lei Sun[1]
1. Energy Geology Lab, Shenyang Center, China Geological Survey, Shenyang, Liaoning, CHINA
E-mail: gongfanhao@qq.com

Keywords: paleo Asian Ocean, Closing time, flysch, zoophycos ichnofacies,

The Central Asian orogenic belt is one of the largest accretionary orogenic belts in the world, formed in the paleo Asian Ocean subduction, arc and micro continental blocks of collage. The closing time of paleo Asian Ocean is a important scientific issues.

In this study, we discoveried a marine clastic rocks of the flysch formation duiring the end of Late Carboniferous and Early Permian period, in Xiwuqi area. The type of rocks are mainly feldspathic lithic sandstone developed grad bedding and parallel bedding.It is accompanied with the zoophycos ichnofacies.

U-Pb Ages of Sedimentary Rock indicated that the deposition forming time should yanger than 289Ma.The magmatic arc of detrital zircons mainly come from its north late Early Carboniferous and Late Carboniferous, Xilinhaote Xiwuqi area.

Keywords: Beishan orogenic collage, Baishan Formation, Yuanbaoshan area, Central Asian Orogenic Belt, Paleo-Asian Ocean

The Beishan orogenic collage in NW China is located in southernmost part of the Central Asian Orogenic Belt[1]. In the northern Beishan orogenic collage, the Carboniferous Baishan Formation, which consists of andesite, dacite, rhyolite and volcaniclastic rocks, is widely distributed along northern and southern sides of the Hongshishan-Baiheshan-Erlegen Ula SSZ ophiolite melange belt[2-3]. In this study, two zircon U-Pb isotopic ages of 300.0 ± 2.5Ma and 300.3 ± 1.9Ma in the Late Carboniferous were obtained from the andesite and breccia-bearing granite porphyry from the Baishan Formation in the Yuanbaoshan-Heishishan area, Inner Mongolia (NW China). The volcanic rocks are relatively enriched in large-ion lithophile elements (eg. Rb, K, Ba, and U) and light rare earth elements and depleted in high field-strength elements (eg. Nb, P, and Ti). They exhibit geochemical characteristics related with active continental margin volcanic arcs, which indicate that the subduction process of the Paleo-Asian Ocean has continued to the Late Carboniferous during the Late Paleozoic in the northern Beishan orogenic collage. Geochemical study further suggests that the magma source of the andesite in the Carboniferous Baishan Formation is a mantle wedge metasomatized by fluid in the subduction zone, and the breccia-bearing granite porphyry is mainly the product of the continental crust melting. The volcanic rocks from the Baishan Formation changed from neutral and calc-alkalic rock series in the northern part to intermediate-acid or acid and high potassium calc-alkalic rock series in the southern part along the ophiolite melange belt[3]. The distribution thus indicated a southern subducted polarity of the Paleo-Asian ocean plate in the northern Beishan orogenic collage in the Carboniferous based on previous research[4]and this study.

The change of sedimentary environment and provenance and its tectonic significance in the early-middle Jurassic in northeastern Sichuan Basin

Dawei Cheng[1*]
1. PETROCHINA, research institute of petroleum and develioment, petrochina, Beijing, CHINA
E-mail: chengdawei123@petrochina.com.cn

Keywords: heavy mineral composition, zircon U-Pb age, paleocurrent direction, Micang Mountain, Daba Mountain

detailed sedimentary description was conducted for the lower-middle Jurassic formations on Tieshan field profile, near Dazhou northeastern Sichuan Basin. Sedimentary environment, provenance property and their coupling relationship were studied. Sedimentary facies description, paleocurrent direction, heavy mineral composition and detrital zircon U-Pb ages were analyzed in this study. Results show that the Zhenzhuchong member is characterized by sufficient debris sources supply and is dominated by fluvial-delta environment. From the Dongyuemiao to lower Lianggaoshan formation the study area was dominated by lacustrine deposits. The detrital supply began to increase in the lower Lianggaoshan member and significantly increased from the middle Lianggaoshan member accompanied by paleocurrent direction change and lake shrinkage. Comprehensive analysis on provenance indicated that changes in provenances were related to environment changes. Both of them were controlled by orogenesis around the basin. Inferred from the characteristics of zircon age distribution the provenances change at the end of Ziliujing Formation, middle Lianggaoshan member and end of Lianggaoshan Formation is respectively resulted from uplifs of Micang Mountain, Daba Mountain and Qinling Mountain.

Sedimentary record of latest Ordovician to Silurian arc-continent collision processes in the South Qilian belt during the closure of the Proto-Tethyan Ocean

Zhen Yan[1*], Changlei Fu[1], Jonathan Aitchison[2], Renjie Zhou[2]
1. Chinese Academy of Geological Sciences, Institute of Geology, Beijing, CHINA
2. The University of Queensland, School of Earth and Environmental Sciences, Brisbane, Queensland, AUSTRALIA

Keywords: arc-continent collision, foreland basin, proveance, South Qilian belt, Proto-Tethyan Ocean

Arc-continent collisions are important tectonic processes that drive growth of continents and development of orogenic belts and associated sedimentary basins throughout geological time. They continue today along tectonically active plate boundaries such as those in the SW pacific and the Caribbean. The Qilian orogenic belt along the NE margin of the Tibetan Plateau is the northernmost orogen of the Tethyan domain in southern Eurasia, which preserves a record of long-lived subduction-accretion processes associated with the Proto-Tethyan Ocean and an arc-continent collision during early Paleozoic time. Results of our recent geological mapping demonstrate that Early Paleozoic volcano-sedimentary strata in the South Qilian belt are dominated by highly dismembered Cambrian-lower Ordovician intraoceanic subduction-accretion system, regarded as the basement of Middle Ordovician Andean-type intermediate to felsic arc. Their volcano-sedimentary successions are intruded by granitoids of Late Ordovician in age. As the collision between both arcs and Central Qilian block progressed from 450 to 420 Ma in response to closure of the Proto-Tethyan Ocean, a foreland basin system developed nonconformably across them. Sedimentary units in this basin are dominated by deep-marine to fluvial deposits to the upward, with a northward shallowing of the water-depth and a northward radial transport pattern, followed by a southwestward radial transport pattern up-section. Compositions and ages of these sediments within foreland basin demonstrate that the initial deposition was mainly originated from a mixed source of 530-480 Ma oceanic-crust and 490-450 Ma continental arc in the South Qilian belt and 910 Ma rocks of the Central Qilian block, while subsequently shifted to the 480-450 Ma arc-accretionary complex and Andean-type arc. These results indicate that the united Central and South Qilian belts in the NE Tibetan Plateau were uplifted and eroded during the latest Ordovician-Silurian in response to closure of the Paleo-Tethyan Ocean and arc-continent collision.

Neoproterozoic sedimentary records in South China: Implication for the supercontinent reconstruction

Liang Qi[1*]
1. Institute of Sedimentary Geology, Chengdu University of Technology, Chengdu, Sichuan, CHINA
E-mail: liangqi_cdut@163.com

Keywords: South China, Neoproterozoic, Detrital zircon

The South China Block, consisting of the Yangtze and the Cathaysia blocks, is one of the largest Precambrian blocks in eastern Asia. Neoproterozoic paleogeography of the South China is directly linked to the formation of Rodinia, its break-up, and the subsequent amalgamation of Gondwana (Cawood et al., 2018, 2020). In this paper, we compiled ~40000 published Precambrian detrital zircons from ~450 (meta)sedimentary samples in ~140 papers, in order to use the detrital zircon U–Pb age and Hf isotope datasets as an alternative approach to delineate the early history of the South China Block.

The lithotectonic associations of Neoproterozoic and older rocks units can be defined into five domains: Cathaysia, Jiangnan, Hainan, Western Yangtze and Northern Yangtze. Detrital zircon age spectra of the samples from the Hainan Block display age patterns distinct from the samples that accumulated on the other domains, with a major peak at ca. 1430 Ma, reflecting their spatial separation. Detrital zircons from clastic rocks within the Cathaysia, Jiangnan, Western Yangtze and Northern Yangtze all display a pronounced age peak at ca. 800 Ma, which consistent with derivation from local sources within the South China. However, Neoproterozoic sedimentary rocks from the Cathaysia Block and West Yangtze also contain abundant late Mesoproterozoic to early Neoproterozoic (ca.1200-800 Ma) detrital zircons. The timing and character of the ages of zircons, Hf isotope, and MDS plots match the records of North India (Lesser Himalaya, Greater Himalaya) and Indo-Antarctica, indicating that the Cathaysia Block and West Yangtze received detritus from North Gondwana. On the other hand, zircons from the western margin of Cathaysia Block and southeastern margin of the Yangtze Block provide evidence of bidirectional sources, suggesting the closure of paleo-South China Ocean before late-Neoproterozoic.

Overall, the Yangtze Block assembled with the Cathaysia Block along the northern margin of India during early Neoproterozoic, and together they were linked to North India from Tonian. The assembly of Gondwana in the early Paleozoic led to the collision of South China and India with the rest of Australo-Antarctica (Mulder et al., 2019), until opening of the Paleo-Tethys at ~400-385 Ma, after which South China drifted towards the assembling Asian continent (Xu et al., 2017).

Petrology and gecochemistry of the Silurian sicliciclastic rocks: constrain on the provenance and tectonic setting of deposition in SE Yangtze block

Tao Yu[1*]

1. SinoProbe Center, Chinese Academy of Geological Sciences, Beijing, CHINA

E-mail: yutaoyt@cug.edu.cn

Keywords: Yangtze block, Sedimentary basin, Sedimentary facies, Provenance analysis

The Jiangnan Orogen is a suture zone between Yangtze block and Cathaysian fold belt, which is a huge tectonic melange belt in the south China and one of the most important tectonic-magmatic-metallogenic belts in China. Knowledge of the provenance and tectonic setting of the lower paleozoic in NW Zhejiang region closely adjacent to the Jiangnan Orogen eastern section is essential to understanding the mechanism and timing of the amalgamation between the Yangtze and Cathaysia blocks. In this paper sandstone detrital fragments, detrital heavy mineral assemblage, geochemistry of siltstone and sandstone, paleocurrent data are used to constrain the provenance and depositional setting of the Silurian clastic sedimentary rocks from SE Yangtze block.

Silurian deposits in the SE Yangtze block consist of sandstone, siltstone and shale. They were deposited in a shallow environment, showing water-depth deepening northwestward. Petrographic features show that the lithic sandstones and arkose lithic sandstones, which have low compositional maturity and textural maturity. In the sandstone samples, the average content of quartz clasts are 27%, feldspar clasts are 17%, rock debris are 56%, among them, quartz is mainly single crystal quartz, feldspar is mainly plagioclase, and a small amount of potassium feldspar. The composition of rock debris mainly includes rhyolite, slate, and a small amount of andesite, etc. In the discriminant diagram of the tectonic background of the source area of sandstone, the sandstone sample falls into the transitional island arc area, which indicates that the debris comes from the source area of the island arc background. Minor pyroxene, chromite, magnetite and garnet grains occur in the sandstone. Geochemical analysis shows that sandstone and siltstone have a wide variable content of Fe203T+MgO, Cs, V, Ni, and Ti. They also show a distinct negative Nb-Ta trough compared to the average upper continental crust (UCC) and have a light rare earth element (LREE) enrichment pattern with obvious Eu anomalies, similar to subduction-related rocks in an arc setting. Paleocurrent indicators pointto a southeastward origin. These results demonstrate that the Late Ordovician deposition took place in a northwestward-facing active continental margin along the southeast Yangtze block.

E-mail: lixiaobo@jlu.edu.cn

Keywords: basin history, Proterozoic, paleogeography, sandstone

The Neoproterozoic Changlongshan Formation in the Yanshan Rift Trough is a set of terrigenous clastic coastal clastic beach facies under the transgressive cycle. The sandstone in the lower part has high maturity, and the provenance characteristics in different locations of the basin are complex. The Changlongshan Formation from Shangchangmao section in Xingcheng area, Liaoning Province, is located at the southeast edge of Yanshan Rift Trough. Through profile observation, microscopic observation, and heavy mineral analysis, we found that the sedimentary environment and sequence of the Changlongshan Formation in the Xingcheng area is similar to that in the Liujiang area of Qinhuangdao and Huailai of Hebei Province. The overall grain size of strata is from coarse to fine, which is a set of transgressive sequences. Sandstone has high compositional maturity, small weathering coefficient, and developed authigenic pyrite. It should be a shallow sea environment with strong to weak hydrodynamic conditions, gradual deepening of the water body, and redox conditions of reducibility or weak oxidation conditions. The sandstone of Changlongshan Formation might have a simple origin, mainly composed of regenerated sedimentary rocks and basic igneous rocks. The provenance of the basic igneous rocks might be related to a large number of emplaced diabase dikes from late Paleoproterozoic to Mesoproterozoic in the Yanliao area. The transgression history of the Changlongshan Formation is one of the sedimentary responses of the breakup of the supercontinent Rodinia.

Evolution of the 1.60-1.35 Ga Northern Marginal BasinsNorth China Craton

Yan Deng[1,2], Huajian Wang[2*], Xiaomei Wang[2], Shuichang Zhang[2]
1. School of Earth and Space Sciences, Peking University, Beijing, CHINA
2. Petroleum Geology Experimental Center, Research Institute of Petroleum Exploration and Development, Beijing, CHINA
E-mail: wanghuajian@petrochina.com.cn

Keywords: North China Craton, the Yanliao Basin, Mesoproterozoic, Gaoyuzhuang Formation, Xiamaling Formation

The continental rifting processes in the northern margin of the North China Craton (NCC) during 1.7−1.3 Ga was considered related with the breakup of the Columbia supercontinent. Two rift basins, the Yanliao Basin and the Zha'ertai-Bayan Obo-Huade Basin in the northern NCC have similar stratigraphic sequences and ages. The ~1.32 Ga anorogenic magmatism wide-spread in these two basins indicated a final separation of the NCC from the Columbia supercontinent. Based on the precise chronological framework and stratigraphic constraints, we scrutinized the 1.60−1.32 Ga sedimentary successions in the Yanliao Basin, which suggested a relatively stable stage with limited chasmic activities during 1.60−1.40 Ga, and a reactivation stage with continued crustal extension during 1.42−1.32 Ga. Carbonate-dominated rocks and clastic-dominated rocks formed during the above two stages, respectively, should deposit in open system since a ~1.58 Ga large-scale transgression. So, the Yanliao Basin might have a good connectivity with the open ocean during the early Mesoproterozoic era, forming a unified continental margin rift system with the Zha'ertai-Bayan Obo-Huade Basin in the northern NCC, and belong to a huge gulf between NCC and the Columbia supercontinent.

Provenance and tectonic setting of the Lower Silurian clastic rocks in the southeast Upper Yangtze Block, South China: Implications for paleographic evolution of South China and initial formation time of Xuefeng mountain belt

Peng Ren[1,2,3], Chuanlong Mou[2,3*]
1. School of Earth Sciences, China University of Geosciences (Wuhan), Wuhan, Hubei, CHINA
2. Chengdu Center, China Geological Survey, Chengdu, Sichuan, CHINA
3. Graduate School, Chinese Academy of Geological Sciences, Beijing, CHINA

Keywords: Detrital zircon, Sedimentary provenance, Xiaoheba Formation, Xuefeng mountain belt

The Xuefeng mountain belt is located in the western part of the Jiangnan belt and generally considered to have formed in the early Paleozoic, which is significant to understanding the tectonic and paleogeographic evolution of South China. However, the initial formation time and nature of the Xuefeng mountain belt in the early Paleozoic are still controversial. In this work, petrology, whole-rock geochemical data, and detrital zircon U-Pb ages are applied to analyze the sources and tectonic settings of the Lower Silurian Xiaoheba Formation on the west flank of the Xuefeng mountain belt. Samples were collected from three sections dominated by fine-grained sandstones with two pelitic rocks. Major oxides and trace element signatures suggest the Xiaoheba Formation was deposited in a passive margin setting, with the detritus mainly derived from felsic igneous rocks and experienced sedimentary recycling. LA-ICP-MS detrital zircons U-Pb dating from four samples display a prominent age population of 1000–900 Ma and a subordinate population of 900–700 Ma, with minor populations of ca. 2500 Ma, ca. 1700 Ma, 1300–1200 Ma and 650–500 Ma. Combining detrital zircon ages with geochemical and paleocurrent data, we suggest the zircon grains represented by Grenville-aged grains and Pan-African aged grains were largely derived from north India and southeast Antarctica, with limited input from west Australia. Those zircon grains were first deposited in the late Neoproterozoic to early Paleozoic strata of the Cathaysia Block and subsequently transported to the study area due to intraplate orogenesis. The grains with an age of 900-700 Ma within the Xiaoheba Formation were probably inputted from the Neoproterozoic basement of the Jiangnan-Xuefeng Uplift. These results imply that early Silurian sediments deposited in a stable passive margin setting along the southeastern Yangtze block and the Xuefeng mountain belt was a basement uplift rather than a Paleozoic orogenic belt. In addition, we suggest that the Xuefeng mountain belt had formed during the deposition of the Xiaoheba Formation. However, the uplift appears to be discontinuous, rather than a continuous barrier that blocked the detritus derived from southeastward in this period. The two youngest zircon grains yielded a weighted average age of 436±7.4 Ma, indicating the maximum depositional age of the Xiaoheba Formation and further suggesting that the initial uplift time of the Xuefeng mountain belt was roughly in the early Telychian.

Keywords: Tarim Craton, Yili-Central Tianshan Block, Neoproterozoic collision-fragmentation-drift, Debris provenance tracer, Assembly and breakup of the Rodinia supercontinent

Neoproterozoic tectonic setting and evolutionary affinity of the Tarim Craton and the Yili-Central Tianshan Block (YCTB) in the southern Central Asian Orogenic Belt are still controversial, which in turn hinders the understanding and reconstruction of the evolution of the Rodinia supercontinent. The Cryogenian System (Nanhua System) in the northwestern Tarim Craton mainly consists of a set of proximal and fast-filling terrigenous clastic deposits. Based on the systematic study of zircon U-Pb chronology, petrology, geochemistry and Sr-Nd-Pb isotope of these clastic sandstones and igneous gravels, this study proposes that these clasts are mainly derived from early Neoproterozoic (Tonian) igneous rocks and their equivalent debris, and provide key evidence for the tectonic assembly and breakup between the Tarim Craton and the YCTB during the Neoproterozoic.

Six granitoid and one rhyolitic tuff boulders were collected from the conglomerate unit of the Cryogenian strata and gave a range of crystallization age spectrum of ca. 930-850 Ma. These igneous boulders mostly exhibit calc-alkaline to high-K calc-alkaline affinities with high contents of SiO2 (66.7-78.3 wt%), total alkali oxides (Na2O + K2O = 6.0-8.6 wt%), and low contents of P2O5 (≤0.15 wt%) and ASI (0.4-1.1), and show relatively enriched LREE and LILEs with significant negative Eu anomalies (δEu = 0.02-0.8) and Nb-Ta-Ti trough, akin to those typical I-type granites. Nd and Hf isotope of these igneous boulders show slightly negative εNd(t) values from -5.11 to -0.52 and varying εHf(t) values from -17 to 12and yield model ages of 1.5-2.0 Ga and 1.2-2.3 Ga, respectively, distinct from those reworking magmas of ancient Archean- early Paleoproterozoic Tarim Craton basement (3.5-2.5 Ga). Besides, detrital zircon ages and Hf isotope of four sandstondes in this study and compiled data from the sandstones of Cryogenian sequence reveal a hybrid provenance from abundant felsic magmatic rocks with similar age range (960-850 Ma) of aforementioned igneous boulders and anonther Archean- and Paleoproterozoic- craton basement.

Our study shows that such previously existing huge magma belt aross the northern margin of the Tarim Craton continued to provide a large amount of sedimentary debris not only for the Aksu Group, but also for the subsequent Neoproterozoic Cryogenian and Ediacaran basins in the northwestern Tarim. It is worth noting that the existing Precambrian igneous rock chronology and geophysical data observations show that the northern margin of Tarim was a typical passive continental margin in the early Neoproterozoic, and there is no such a magma belt. Further analysis shows that this magmatic belt and the Tonian magmatic belt of the YCTB are not only consistent in age spectrum, but also share very similar petrological, geochemical and isotopic characteristics. Therefore, the results of this work support the Neoproterozoic collision-fragmentation-drift hypothesis for the Tarim Craton and the YCTB, which may represent the final assembly and subsequent complete breakup of the Rodinia supercontinent.

Sedimentary evidence for hitherto unrecognized synsedimentary tectonics affecting the Furongian Chaomidian Formation (Shandong Province, China)

A.J. (Tom) Van Loon[1], Renchao Yang[1*], Aiping Fan[1], Zuozhen Han[1]
1. Shandong Provincial Key Laboratory of Depositional Mineralization & Sedimentary Minerals, Shandong University of Science and Technology, Qingdao, Shandong Province, CHINA
E-mail: yang100808@126.com

Keywords: breccias, Late Cambrian, Shandong, sliding, synsedimentary tectonics

Shandong Province (E China) is commonly considered to have been a tectonically quiet region during the Late Cambrian (Furongian). An epeiric sea extending at the time from China to Korea covered a large part of the North China Plate. During the Furongian, accumulation of sediments kept pace with the subsidence of the basin. The youngest fully Furongian formation in the study area, which is situated near the city of Laiwu, is the Chaomidian Formation, which consists mainly of limestone/shale alternations, limestone/marlstone alternations, thin-bedded lime mudstones, limestone conglomerates and breccias, gravelly grainstones, cross-bedded grainstones and microbialites. Some levels occur that are spectacular mixtures of breccia and conglomerate (the so-called bamboo-leaf breccia), which resulted from the formation of 'fountains' of pore-water/sediment mixtures (due to overpressurization) that escaped under high pressure and broke up overlying limestone layers. This resulted in breccia fragments of about a decimetre in diameter, many of which are oriented vertically.

One of these layers of bamboo-leaf breccia was broken up. The resulting blocks (up to several metres wide and several decimetres high) show characteristics that indicate that the blocks slid down a (probably very gentle) slope. They are now embedded in an oolite layer that started accumulation before the sliding of the blocks took place, and that continued after emplacement of the blocks.

Oolites originate in shallow water, most commonly at depths of not more than ~2 m (max. some 10 m). Since the blocks of bamboo-leaf breccia are embedded in an oolite that started forming before the sliding of the blocks, and continue without interruptions to after this event, all these processes occurred at very shallow depths. Considering the local geology, the blocks must have slid down over distances of some hundreds of meters. Their depositional site was still very shallow, and there are no signs of any special process that may have triggered the sliding. It must therefore be deduced that an inclination of the sedimentary surface must have exited that allowed the sliding. Such a slope was not present before, so that only tilting or a fault-induced slope can be held responsible. In both cases, some tectonic activity must have been involved, although such activity has never been noticed before.

Provenance Analysis of Early Neoproterozoic Metasedimentary Rocks in Western Central Tianshan Block and Paleogeographical Reconstruction

Linxi Wang[1], Hu Huang[1,2*], Mingcai Hou[1,2]

1. Institute of Sedimentary Geology, Chengdu University of Technology, Chengdu, Sichuan, CHINA
2. State Key Laboratory of Oil and Gas Reservoir Geology and Exploitation, Chengdu University of Technology, Chengdu, Sichuan, CHINA

E-mail: 118huanghu@163.com

Keywords: detrital zircon, multidimensional scaling plot, paleogeographical reconstruction, early Neoproterozoic, western Central Tianshan Block

The Central Tianshan Block (CTB) is one of the Precambrian microcontinents in Central Asian Orogenic Belt (CAOB). It can be divided into the western Central Tianshan Block (WCTB) and eastern Central Tianshan Block (ECTB). To investigate their relationship and paleogeographical location, we collected metasedimentary rocks of the Kekesu Group in WCTB. The results of detrital zircon LA–ICP–MS U-Pb dating, combining with previously magmatic ages, suggest that the Kekesu Group was deposited during the earliest Neoproterozoic. Detrital zircon populations of the Kekesu Group were dominated by ca. 2.0–0.9 Ga grains with age peaks at ca. 1480 and 920 Ma. The Archean to the end of Paleoproterozoic zircon grains had variable $\varepsilon_{Hf}(t)$ values from +12.5 to -8.7, and most (88%) of the Mesoproterozoic to early Neoproterozoic zircons had positive $\varepsilon_{Hf}(t)$ values (+13.9 to +0.6). The Kekesu Group has similar zircon age populations and $\varepsilon_{Hf}(t)$ values with the Kawabulake Group in ECTB. Combining with magmatism, we suggest that WCTB and ECTB have similar tectonic affinities and locations during the earliest Neoproterozoic. The zircon age probability density plots and multidimensional scaling (MDS) plot of kernel density estimates suggest that some microcontinents in southwest CAOB, including the Issyk-Kul, Kokchetav, Erementau-Niyaz and Ishkeol'mes terranes, might be located near the northern Laurentia and southeast Siberia in earliest Neoproterozoic. These terranes and Xingxingxia Group in ECTB have similar sources mainly derived from the northern Laurentia. Afterward, the sources have changed. The strata in Central Tianshan Block and Yili Block have similar sources mainly derived from Grenvillian and Sveconorwegian orogens, and these blocks were located between the East Greenland and southwestern North China Craton during Rodinia assembly.

Micro Slope break and its control on sequence, sedimentation and hydrocarbon accumulation of Pinghu Formation in K Area, Xihu Sag

Lei Li[1*]
1. shanghai branch, CNOOC, Shanghai, CHINA
E-mail: lilei3209@126.com

Keywords: Micro Slop break,hydrocarbon accumulation,pre-existing structures

Based on the analysis of the pre-existing structures and palaeogeomorphology, the typical and characteristic micro-slope break zones are identified in the study area, and their genetic type is flexural slope break. The NW-trending pre-existing structure formed during the Indo-Chinese Movement was reactivated during the Pinghu Movement, forming the structure 'down-fault and up-torsion ', which was a flexural slope break during the Pinghu Formation. The controlling effects of micro-slope break zone on sequence development pattern, sedimentary system distribution characteristics and dominant reservoir distribution are established. Based on the hydrocarbon source conditions, reservoir conditions, migration conditions, trap conditions and preservation conditions, the hydrocarbon accumulation model of ' hydrocarbon generation in low slope belt-separation trough controlling migration and accumulation-micro slope break controlling trap and reservoir ' is proposed, which effectivelyrdin guides the evaluation of the K Area. According to the comprehensive analysis of the control of micro-slope break on sequence, deposition and hydrocarbon accumulation of Pinghu Formation in the K area of Xihu Sag, the scale of slope break zone research is extended, and the slope break zone theory is enriched.

The Doushantuo formation, the onset of the Ediacaran rifts in South China

Ke CHEN[1*]
1. Shale gas, Oil&Gas Survey, China Geological Survey, Beijing, CHINA
E-mail: chenke2020@163.com

Keywords: Doushantuo Formation, Ediacaran rift, South China, sequence stratigraphy

The Ediacaran Doushantuo Formation (ca. 635–551 Ma) in South China is one of the most intensively investigated units in the world, as it contains exceptionally well-preserved fossils of multicellular eukaryotes including early animals. The majority of the Doushantuo Formation was deposited on a rimmed carbonate shelf of the Yangtze platform, with a shelf margin shoal that restricted the shelf lagoon from the open ocean. However, the previous studied were mostly based on the outcrops without detailed analysis of the interior of the platform. We analysis the drilled data in the interior of the Yangtze platform, indicating that there existed two rifts, one is the Deyang-Anyue rift in the West and the EXi rift in the East. This study established a stratigraphic framework of the Doushantuo formation by litho-, chemo-, bio-, and sequence stratigraphy. Regional correlation across South China relies on two distinctive marker beds, the cap carbonate at the base and the organic-rich black shale at the top of the Doushantuo Formation. During Ediacaran and Lower Cambrian, the Doushantuo Formation, the Dengying Formation, and the Niutitang Formation represent different stages of the rifts at the Yangtze platform from bottom to up. Firstly, the Doushantuo Formation indicates the beginning of the rifts in South China. Secondly, carbonatite of the Dengying formation was controlled by syn-sedimentary faults, which forming the "graben-horst" structural model, with Deyang-Anyue and EXi rifts. Finally, a set of organic-rich shale filled up the rifts by Niutitang Formation during the Early Cambrian. The rifts provided the geological background of location for the conventional and unconventional nature gas exploration.

A late Paleozoic extension basin constrained by sedimentology and geochronology in central Inner Mongolia, eastern CAOB

Yanyang Wang[1*]

1. Institute for Overseas Exploration and Project Evaluation, Sinopec petroleum exploration and production research institute, Beijing, CHINA

E-mail: wyy.syky@sinopec.com

Keywords: late Paleozoic extension, Paleo-Asian Ocean, basin and uplift

According to sedimentary structure, petrology and sequence analysis from seven sections (S1–S7) across the West Ujimqin basin, the late Carboniferous to Permian sedimentary facies have been recognized and summarized as four sedimentary systems, i.e. the late Carboniferous-early Permian sedimentary system (SA) comprising the alluvial fan–delta–littoral facies, the late Carboniferous sedimentary system (SB) including the littoral facies–delta facies–platform margin facies, the early Permian sedimentary system (SC) characterized by delta front and prodelta facies, and the middle Permian sedimentary system (SD) with alternations of littoral and delta facies. According to the spatial and temporal distribution of the four sedimentary systems, the basin filling process can be divided into three stages. The first stage (324–290 Ma) is dominated by bidirectional terrigenous sediments containing the SA from alluvial fan to delta and littoral facies in the northwestern and the SB from littoral–delta to platform margin facies in the southern, respectively. The second stage (290–270 Ma) is characterized by delta front and prodelta facies of the SC marked by thick-bedded matrix-supported conglomerate, rapid accumulation of terrigenous sediments and volcanic debris, syn-sedimentary deformation and slump. The third stage (270–255 Ma) formed the SD with the alternations of littoral and delta facies, which is represented by complex terrigenous clasts and intra-basin carbonate. These shallow and proximal sedimentary systems from fan delta to littoral facies indicate that there was not oceanic sedimentary system in the eastern CAOB during the late Carboniferous to Permian except for some small red sea basins, which provides convictive evidence that the Paleo-Asian Ocean (PAO) had closed before the late Carboniferous. Detrital zircon dating reveals bidirectional provenances of the West Ujimqin basin, indicating that it was a limited basin between two uplifts, which implies presence of the late Paleozoic “basin and uplift” tectonic framework that developed on the eastern CAOB during the late Paleozoic.

Detrital zircon ages and Hf-isotope characteristics of the Neoproterozoic – Cambrian Marwar Supergroup sediments, NW India: implications on the East Gondwana assembly

Manoj K. Pandit[1], Wei Wang[1*]
1. Department of Geology, University of Rajasthan, Jaipur, Rajasthan, INDIA
E-mail: wwz@cug.edu.cn

Keywords: Detrital zircon, U - Pb geochronology, Precambrian - Cambrian sediments, NW India, East Gondwana

The Precambrian – Lower Paleozoic sedimentary successions in northwest India have been investigated to evaluate the assumption that they record the collision between Western and Eastern Gondwana continental blocks and contain detritus derived from the East African Orogen. The detrital zircon U – Pb age distribution patterns and Hf-isotopic characteristics of Marwar Supergroup (Pc – C transition)sedimentary rocks, together with paleocurrent analysis, suggest a proximal provenance within the Eastern Gondwana. The time equivalent successions from the Qiangtang terrane and the northern margin of Neoproterozoic India display similarity in the provenance record, along with additional input of late Mesoproterozoic and Neoproterozoic detritus from East Antarctic-Eastern India and Western Australia. Detritus from the uplifted East African Orogen are abundant in the north African sedimentary deposits, which constitute part of the Western Gondwana, but are absent in the equivalent successions in the Indian Eastern Gondwana. The consistency in sedimentary provenance of the late Neoproterozoic to early Palaeozoic strata in NW India, combined with the lack of evidence for deformation/metamorphism since at least ca. 760 Ma, argues against collision between eastern and western segments of Gondwana in this northern domain of the supercontinent. These domains remained as passive continental margins, separated by a large-scale embayment of the proto-Tethys ocean, until the late Paleozoic fragmentation of the continental blocks.

Deep structural characteristics and formation and evolution of Dongying Depression

Can Wei[1*], jianping Yang[1]
1. , , , , CHINA
E-mail: 563259619@qq.com

Keywords: Dongying depression,Deep structure,Construction style,Differences,Formation and evolution

The deep structure of Dongying depression has always been the research focus of many scholars. This paper mainly studies the deep structure of the fourth member of Shahejie formation from Kongdian formation to Shahejie Formation in Dongying depression, including the section style and plane style of deep structure. It is found that the structural styles are mostly extensional structural styles and extensional strike slip structural styles, such as "Y" shaped structure, flower like structure, warped fault block, graben Horst structure, salt mud diapir structure and so on. In addition, the distribution of regional tectonic belts and their horizontal and vertical differences in Dongying sag are also a research scope of this paper. Dongying depression is located in Jiyang depression of Bohai Bay basin. It has experienced the influence of multi-stage tectonic movement and plate movement, forming a unique structural pattern and multi-stage faults. With the evolution of the profile, combined with the large tectonic movement at that time, the tectonic evolution history can be reasonably deduced, and the key "red bed" strata in this study have experienced basin rifting expansion stage, regional uplift stage, secondary rifting stage and so on.

Keywords: Paleo-Pacific plate subduction,Chaoshan Depression,fore-arc basins,migrating arc,tectono-sedimentary evolution

The South China Block is characterized by giant and multistage magmatic belt associated with the subduction of the Paleo-Pacific plate in the Mesozoic. In contrast to the extensive research on this magmatic belt, the associated fore-arc basins are still poorly known, in particular the tectono-sedimentary evolution of fore-arc basins in response to the Paleo-Pacific plate subduction. Chaoshan Depression (CSD), one of a Mesozoic basin in northern South China Sea, was a typical fore-arc basin associated with the subduction of the Paleo-Pacific plate from the Jurassic to the Early Cretaceous. Thick Mesozoic sediments with precise stratigraphic age frame that determined by micropaleontology and zircon U-Pb ages of volcanic interlayers have been revealed in CSD and thus provide a great opportunity to investigate the evolution of fore-arc basin in response to complex subduction processes. In this study, we complied a large number of zircon U-Pb ages of the arc-related magmatic rocks to trace the magmatic belt, combined with well and seismic reflection of CSD to explore the sedimentation changes. The exposure of early Jurassic magmatic belt was possibly very limited, which was insufficient to provide great detritus to the CSD and shallow marine environment was inferred for the CSD. From the middle Jurassic, quick subsidence occurred in CSD and followed by rapid increase in the sea water characterized by Radiolarian siliceous rock that continued to the late Jurassic. This scenario was possibly caused by landward migration of the arc resulted from the flat subduction of the Paleo-Pacific plate. Since the Cretaceous, there was a prominently tilted denudation with NW increasing in erosion thickness and followed by a dramatic change of sedimentary environment in the CSD. These changes were consistent with the seawards migration of the magmatic zone in response to the rollback of the subduction slab. The plenty detritus eroded from this magmatic belt facilitated large deltas in the CSD. Our study shows how the migrating arc resulting from the changing pattern of the subduction plate controlled the evolution of fore-arc basin and provide new insights into the evolution of the Paleo-Pacific plate subduction.

Structural evolution and mechanism of Panyu 4 Sag, Pearl River Mouth Basin, South China Sea

Bowei Guo[1,2], Fusheng Yu[1,2*], Hui Li[1,2]
1. State Key Laboratory of Petroleum Resources and Prospecting, China University of Petroleum(Beijing), Beijing, CHINA
2. College of Geosciences, China University of Petroleum(Beijing), Beijing, CHINA
E-mail: fushengyu@cup.edu.cn

Keywords: Structural evolution, Analogue modelling, Formation mechanism, Panyu 4 Sag, Pearl River Mouth Basin

The Panyu 4 Sag is a relatively independent hydrocarbon-rich sub-unit that is located on the western side of the southeastern margin of the Zhuyi Depression, Pearl River Mouth Basin, South China Sea. In order to further understand the evolution of the Panyu 4 Sag, we present the results of seismic interpretation and analogue modelling to discuss the origin of the Panyu 4 Sag in this paper. Firstly, we describe the geological settings of the studied area based on literature. Secondly, we study the distribution and evolution of fault and sedimentation according to seismic interpretation and structural-sedimentary features of different members of the Wenchang Formation. Thirdly, for understanding the evolution of internal sub-structural units, we carried out analogue modelling to illustrate the formation in different periods to better constrain the evolution of the Panyu 4 Sag. Finally, a model for the formation of the Panyu 4 Sag was proposed. The Panyu 4 Sag can be divided into five parts (Northern, Central, Southern, Western, and Northwestern Sub-sags). The faults of the Panyu 4 Sag can be broadly divided into three fault assemblages that are oriented NE, NEE, and NWW. The NE-trending faults were mainly active during the deposition of members 6 to 2 of the Wenchang Formation, these faults had a significant controlling effect during the early deposition of sag. The NEE-trending faults are accommodation faults related to the NE-trending faults; they are short in extension and did not control deposition. The NWW-trending faults are primarily late-stage faults that were mainly active during the deposition of member 1 of the Wenchang Formation to Enping Formation; they controlled the distribution of late deposition. The Panyu 4 Sag has undergone three cycles of structural evolution—an early rift period (Wenchang Formation), a late rift period (Enping Formation), and a thermal subsidence period (Zhuhai Formation to Quaternary). Seismic interpretation and sandbox modelling results show that Panyu 4 Sag suffer two phases extension resulting in the superposition of structures of different generations during the Cenozoic. Influenced by the evolution of regional geological stresses, the stress field mainly exhibited a shift from NW-SE-trending tension to S-N-trending tension; the shift occurs in the upper Wenchang Formation. A combination of the above and the pre-existing basement fault systems controlled the transformation and superposition of the sedimentary features of the Panyu 4 Sag, resulting in the complex tectonic geomorphology of the present sag.

Spatio-temporal evolution and dynamic mechanism of lower Cretaceous volcanic-sedimentary strata in Songliao Basin, Northeast China: implications for regional tectonic evolution

chongyang chen[1*], youfeng gao[2]
1. College of Tourism and Geographical Science, Jilin Normal University, Siping, Jilin, CHINA
2. College of Earth Sciences, Jilin University, Changchun, Jilin, CHINA
E-mail: chency0337@163.com

Keywords: Lower Cretaceous, Volcanic-sedimentary strata, Tectonic evolution, Songliao Basin, Northeast China

The Early Cretaceous tectonic evolution in Northeast China may be affected by the Mongolia Okhotsk and the ancient Pacific tectonic domain, but the mode of action, scope of influence and transform time of the two tectonic region have been controversial. Early Cretaceous magmatic rocks are widely distributed in Northeast China. Their spatial and temporal distribution and geochemical characteristics do not clearly reflect the dynamic mechanism. The Xujiaweizi fault depressionSK-2 drilling area of the International Continental Scientific Drilling Program, located in the central part of Northeast China, is one of the large grabens in the Songliao Basin. It is mainly a set of thick volcanic-sedimentary strata formed in the Early Cretaceous (118-101 Ma). Its formation and evolution process may record the history of regional tectonic evolution in detail, and it is an important research area to solve the problem of regional tectonic evolution. In this study, the volcanic-sedimentary strata (114-101 Ma) of Yingcheng Formation of Lower Cretaceous in Xujiaweizi graben are divided and compared based on three-dimensional seismic profiles, boreholes and logging data. According to the geological and geophysical characteristics of lithology and interface, the volcanic-sedimentary strata are divided into three members, i.e. volcanic member I, sedimentary member II and volcanic member III, and the two volcanic members can be further divided into three volcanic eruption stages respectively. Combined with the characteristics of the main faults in the Xujiaweizi graben, the plane distribution maps of each stratigraphic sequencethree volcanic/sedimentary members and six volcanic eruption stagesare compiled. It is found from the plane maps that the volcanic-sedimentary strata of the Lower Cretaceous have the spatio-temporal evolution law of migration from southeast to northwest from early to late, accompanied by the NNW-SSE sinistral strike-slip deformation. According to the regional tectonic setting, the spatio-temporal evolution of the volcanic-sedimentary strata of the Lower Cretaceous should be related to the westward subduction of the paleo-Pacific. Therefore, during the period 114-101 Ma, the westward subduction of the paleo-Pacific plate had a significant influence on the tectonic evolution of Northeast China, and the scope of influence included at least the SB and its eastern region.

Analysis on Volcanic Development Model and Main Controlling Factors of Favorable Reservoir in the 3rd Member of Shahejie Formation in Zaoyuan Oilfield

Lei Bao[1], Yuming Liu[1*], Jiagen Hou[1], Zhentong Xia[1]
1. College of Geosciences, China University of Petroleum(Beijing), Beijing, CHINA
E-mail: liuym@cup.edu.cn

Keywords: volcanic reservoir, eruption mode, volcanic stage, volcanic lithofacies, main controlling factors

The volcanic oil reservoir of the third member of the Shahejie Formation in the Zao35 fault block of Dagang Oilfield is located in the Cangdong Sag of the Huanghua Depression, Bohai Bay Basin. It is a fracture-porous dual medium oil reservoir. Based on well logging, and 3D seismic data, the characteristics of volcanic rock reservoirs, volcanic eruption patterns and volcanic eruption stages were studied, and the influence of different volcanic rock factors on reservoir distribution was explored, which provided the geological basis for subsequent development of volcanic rock reservoirs. The research results show that there are two development modes of volcanoes in this area, the fractured eruption with the Litianmu fault as the channel and the string beaded central eruption. The volcanic rocks are divided into 3 main eruption cycles based on the comprehensive seismic response characteristics. Combined with the stable mudstone intervals drilled by wells, the volcano can be further subdivided into 8 eruption stages. Affected by the two eruption modes and the distribution of fractures, the favorable reservoirs in the volcanic rock are distributed between the Litianmu fault and the central eruption channel. Lithology is also the main reason for controlling volcanic rock reservoirs in this area. Basalt is developed on a large scale in this area, so it is more likely to be communicated by fractures to form favorable reservoirs. In addition, due to the different eruption stages, there are 3 different basalt reservoir types in the overflow facies reservoirs in each stage, namely thick and tight basalt without pores, basalt with pores develop at the top and dense at the bottom, and basalts with pores developed at the top and tight in the middle, so the oil reserves are mostly distributed on the top and bottom of the thick basalt, among which the volcanic rock reservoirs of stage III4 and III5 have the greatest oil reserves and development potential.

Structural styles and extension-strike slip fault system:A case from Nanpu sag, Bohai Bay Basin, NE China

Yuheng Wang[1,2], Fusheng Yu[1,2*]

1. State Key Laboratory of Petroleum Resources and Prospecting, China University of Petroleum (Beijing), Beijing, CHINA
2. Collage of geoscience, China university of Petroleum(Beijing), Beijing, CHINA

E-mail: fushengyu@cup.edu.cn

Keywords: Deformation genesis, Analogue modeling, Extension-strike slip fault system, Nanpu sag, Bohai bay basin

Nanpu sag is located in the northeast of Huanghua depression in the Bohai Bay Baisn (BBB), and the northern part is the first-order boundary fault of the depression: Baigezhuang fault (BGZ) and Xi'nanzhuang fault (XNZ) form the depression boundary together. It is a continental dustpan sag with the characteristics of north Fault and south superstructure. The research data show that the shallow reservoirs (Nm, Ng, Ed) in the Nanpu sag have the characteristics of shallow burial depth, good physical properties and high production capacity. In order to clarify the way in which the staged tectonic deformation affects the fracture spreading of hydrocarbons, this paper systematically summarizes the stress field transformation in the Nanpu sag region, the spatial spreading characteristics of the No.4 structure belt and the zonation characteristics of the main fracture of the shallow Cenozoic layer system through detailed interpretation of 3D seismic data, and clarifies the structure deformation mechanism of the No.4 belt. The established spatio-temporal evolution process combined with the paleotectonic geometry of the No.4 structure belt is then used to design physical analogue experiments to recover the deformation process and simulation results. Research shows that: (1) the Cenozoic No.4 structure belt and the surrounding areas mainly have the characteristics of superposition of anisotropic extensional deformation in phases, and there are several groups of NW and NE trending faults, which mainly form the style of strike-slip stacked fan and horst-ground combination in the plane, and the style of compound "y" combination, conjugate combination and negative flower combination in the section. (2) The Cenozoic No.4 structure belt has the deformation characteristics of planar zoning and sectional staging, forming a strong slip-weak extension zone at the southern section of the No.3-4 structure belt, and a conjugate strong extension-weak slip zone at the northwest end where the slip component gradually decreases. (3) The "strike-slip stacked fan structure" in the No. 4 structure belt is the result of the diagonal boundary extension due to the near north-south extension under the preexisting basement conditions, and there is no significant combination of pure strike-slip deformation, and specific boundary faults, basement inhomogeneity and preexisting fractures have a controlling effect on the tectonic pattern of the fault system. (4) The mudstone at the base of Ed3 is both the main hydrocarbon source rock and the controlling material factor in the formation of the extensional-slip transition zone in No.4 structure belt.

Influence of tectonism and volcanism on depositional system in south slope area of Lufeng Sag, Pearl River Mouth Basin, South China Sea

Xu Tang[1*], Yixin Yu[1], Yichao Li[1]
1. College of Geosciences, China University of Petroleum(Beijing), Beijing, CHINA
E-mail: tangxu0329@foxmail.com

Keywords: ancient gully, fault trough, volcanic eruption, braided river delta, Lufeng Sag

Lufeng Sag, located in the Pearl River Mouth Basin on the northern continental margin of the South China Sea, is one of the important sag with abundant oil and gas. The Paleogene Wenchang Formation was a continental sedimentary system with a large number of braided river deltas developed in the slope area. In this study, we adopted palaeogeomorphic map, seismic data, well data and the casting thin sections to clarify the impact of basement geomorphology, faulting and volcanism on sedimentary system in slope area.

Huilu low uplift in the south of Lufeng Sag was a continuous source in the Paleogene. Through the geomorphic highs and slope changes of the basement paleogeomorphic map, 13 ancient gullies supplying sources to the south of Lufeng sag were identified, including U-type, W-type and composite type. The U-type ancient gullies are formed in channel maturity, with strong sand transport capacity and long sediment transport distance. The seismic facies have a strong amplitude, a high frequency, a high continuity and a low angle progradation reflection, resulting in braided river delta deposits with large plane range, long extension and large vertical thickness. The W-type ancient gullies are formed in the late bifurcation of the channel, during which hydrodynamic force is weakened and sand transport capacity of the gully is weak. The seismic facies are medium amplitude, medium frequency and medium continuous forward reflection, forming the same type of the delta but with small plane range, short extension and small vertical thickness. The composite ancient gullies are formed by the superposition of U-type and W-type ancient gullies, with medium sand transport capacity. In addition, the Paleogene rifting was accompanied by numerous faults and local volcanic eruptions in the slope area. Volcanic eruption forms volcanic debris, crystal debris and volcanic ash, which do not affect the shape and size of the sand body, but alter the reservoir's physical properties of it, especially the tuffaceous filling will significantly reduce the reservoir permeability. Faults have an obvious influence on the size of the delta, some of which strike in the same direction as source injection, forming fault trough source channels. The fault trough controlled by a single fault has the characteristics of dustpan structure and wedge filling seismic phase in the vertical provenance direction seismic profile, whereas the fault trough controlled by two dip-faults has the characteristics of symmetrical structure and parallel-subparallel seismic phase in the vertical provenance direction seismic profile. When the fault activity is stronger, the sand transport capacity of the fault trough is stronger, and the scale of the delta is larger.

When the catchment area, width-depth ratio, and cross-sectional area of the ancient gully and fault trough are quantitatively analyzed and compared to the corresponding area of the delta, it can be seen that the catchment area and the multiplication of width depth ratio and cross-sectional area are both positively correlated with the area of the sedimentary sand body. These two parameters jointly determine the size of the sedimentary sand body.

Cenozoic Intermediate and Mafic Igneous Rocks in the Eastern Sag of Liaohe DepressionLithologyLithofaciesand Controlling Factors of Reservoirs

Bin Zhang[1*]
1. Research Institute of Exploration & Development, PetroChina Liaohe Oilfield Company, Panjin, Liaoning province, CHINA
E-mail: 64035164@qq.com

Keywords: Eastern sag, Cenozoic, volcanic, reservoirs

Abstract: On the basis of 110 wells with 1100 meters drilling cores and 500 wells with 107000 meters long sections of igneous rocks in the Eastern sag of Liaohe Depressionlithologic and lithofacies of the Cenozoic intermediate and mafic igneous rocks and controlling factors of reservoirs were studied by means of description and slice identification of cores, reservoirs physical property data and oil reservoirs analysis. Based on these data, 16 types of volcanic, intrusive rocks and volcanic sedimentary rocks are recognized, basaltic lava and basaltic volcanoclastic rocks have the greatest thickness and the most widely distributed91%. The volcanic lithofacies are mainly divied into 6 lithofacies and 16 subfaciesduring which Effusive lithofacies accounts for about 63%. The reservoirs space can be grouped into 4 types and 9 sub-types, secondary porosity and fracture are most developed in the study area. Trachytic lava and Trachytic volcanoclastic rocks, basaltic volcanoclastic rocks, extrusive dome facies, volcanic conduit faciesand explosive facies are the most favorable reservoirs. Three factors including Lithology, lithofacies and faults are thought related to the porosity and permeability of igneous rocks reservoirs. Lithology determines types and microscopic characteristics of reservoirs; lithofacies controls the development of primary pores and distribution of reservoirs; faults control the range of igneous rocks, position of vent lithofacies and proximal lithofacies, and effectiveness of reservoirs. The areas of favorable petroleum accumulation are near oil sources, structural highs adjacent to faults, and advantage of lithology and lithofacies.

An important tectonothermal event occurred in the middle and late Late Paleozoic in the Qinling Orogenic Belt

Ziwen Jiang[1], Jinglan Luo[2*], Zhengtao Zhang[3], Zhichao Li[3]

1. Department of Geological Engineering, Qinghai University , Xining, Qinghai, CHINA
2. State Key Laboratory of Continental Dynamics, Northwest University, Xi'an, Shannxi, CHINA
3. Research Institute of Petroleum Exploration and Development, PetroChina Changqing Oilfield Company, Xi'an, Shannxi, CHINA

E-mail: jlluo@nwu.edu.cn

Keywords: North Qinling Orogenic Belt, tectonothermal geochronology, tectonic event, provenance analysis, U-Pb geochronology

The Permian in the Liuyehe Basin of the North Qinling, the Lintan area of the West Qinling, the Zhen'an Basin of the South Qinling in the Qinling Orogenic Belt (QOB) and the Permian in the southern Ordos Basin on the north side of the QOB contain a large amount of ca.350~260Ma detrital zircons. Although the studies believe that the ca.350~260Ma detrital zircons come from the QOB, there are a few public reports of the magmatic/metamorphic age records of this period in the QOB. Only a small amount of reliable magmatic/metamorphic zircon age records of ca. 350–260 Ma have been found in the Jiangligou and Zhongchuan granites in the Western Qinling and the metamorphic rocks of the Wuguan Group in Danfeng County in the eastern North Qinling. Based on the existing work, we put forward the scientific hypothesis for the first time that "there is an important tectonothermal event that has not been fully revealed and recognized in the QOB during ca.350~260Ma". Through the research on the Jiangligou and Zhongchuan granites, and the metamorphic rocks of the Wuguan Group in Danfeng County (front side) by means of petrology, petrography, rock geochemistry, zircon U-Pb isotope dating and in situ Lu-Hf isotope. Through the study on the provenance, genesis and source area attribute of the ca.350~260Ma detrital zircons in the Permian of the southern Ordos Basin, the Liuyehe basin, the Lintan area, the Zhen'an basin (reverse side) by means of paleocurrent direction, sandstone composition, debris composition and heavy mineral characteristics analysis, sedimentary geochemical analysis, zircon U-Pb isotope dating and Lu-Hf isotope tracing. We combined with direct demonstration and indirect inversion, fully demonstrate the hypothesis from both pros and cons, and discuss the nature, tectonic evolution characteristic and tectonic setting of this tectonothermal event in the QOB during ca.350~260Ma. The research results are of great significance to further reveal the Late Paleozoic tectonic evolution history and plate tectonic attributes of the QOB, clarify the Qinling orogenic process and its control over the filling history of peripheral basins, and broaden the exploration fields and ideas of various mineral resources in the QOB and surrounding sedimentary basins.

The development characteristics, genesis and formation environment of igneous rocks in Nanpu Sag of Bohai Bay Basin

Jiafu YU[1], Fusheng Yu[1*]
1. College of Geosciences, China University of Petroleum-Beijing, Beijing, CHINA
E-mail: syfu1234@163.com

Keywords: igneous rocks in Nanpu Sag , developmental characteristics , petrogenesis , forming environment

Nanpu Sag is located in the northern end of Bohai Bay Basin. There are two types of volcanic rocks, intrusive rocks and exhalative rocks. The intrusive rocks include diabase, diabase porphyrite, quartz diorite, etc. Ejected rocks can be divided into volcanic lava and volcanic clastic rocks. The former mainly includes basalt, andesite, rhyolite, and the latter includes volcanic breccia, tuff, tuffaceous sandstone, etc.

Nanpu depression volcanic formation period can be divided into Shahejie, Dongying and Guantao three periods. The distribution characteristics of volcanic rocks : 1.Distribution direction deflection. In the early Shahejie period, the volcanic rocks were distributed in NE direction, and in the middle Dongying period, they were NW-SE direction, and in the late Guantao period, they were NE-SW direction, indicating that the regional stress changed. 2. Spatial distribution. The early volcanic rocks were distributed in the southwest of the sag, and the middle and late volcanic rocks extended to the middle and north. 3. Increased intensity of activities. From the early stage to the late stage, it is generally the expansion depression, and the expansion intensity increases.

The weighted average age of zircon U-Pb dating is 34.1 ± 0.5 Ma, so it is determined to be formed in Shahejie period. On the primitive mantle normalized spider diagram of trace elements, the curve generally tilts to the right, showing a zigzag jumping decreasing distribution , Enriched Rb, Ba, Sr and LREE, depleted Zr, Th ; in the REE distribution pattern map of chondrite, the curve was right-leaning, enriched LREE and depleted HREE ; the mean value of δEu is 0.97, indicating weak negative Eu anomaly.

The (Th / Ta) PM and (La / Nb) PM of the sample data are less than 1, suggesting no obvious crustal contamination. In the Huck plot with MgO as the abscissa, Ni, CaO and Al2O3 were positively correlated with MgO, TiO2 and P2O5 were negatively correlated with MgO. Sm-Sm / Yb diagram shows that the mantle source is composed of garnet , spinel and lherzolite, and 3 % ~ 16 % partial melting is speculated. The sample data have high Ta / Yb and Th / Yb values. The Th / Yb-Ta / Yb diagram, εNd-87Sr / 86Sr diagram and 208Pb / 204Pb-206Pb / 204Pb diagram show that the magma originates from the mixed source area of EMI and depleted mantle. In the 2Nb-Zr/4-Y diagram, TiO2-MnO-P2O5 diagram and Th / Hf-Ta / Hf discrimination diagram, it is shown that the formation environment is active rift expansion in continental plate.

Geochronology, Geochemisty, and Tectonic Significance of Carboniferous Andesites of Zhongguai Uplift in Northwestern Margin of Junggar Basin

Longfei Shao[1], Fusheng Yu[1*]
1. School of Earth Sciences, China University of Petroleum,Beijing, Beijing, CHINA
E-mail: fushengyu@cup.edu.cn

Keywords: northwestern margin of Junggar Basin, Zhongguai uplift, Carboniferous, andesite, chronology, geochemistry

In order to deepen the understanding of the Carboniferous tectonic background in the western part of the Central Asian orogenic belt, the core and samples of andesites in JinLong 10 well area of Zhongguai uplift in the northwest margin of Junggar basin have been studied in petrography, chronology and geochemistry. The results show that brown gray, grayish green and dark gray andesites are mostly developed in the study area andesites in the study and they are belong to low potassium to medium potassium calc alkaline rock series, and its REE diagram is slightly inclined to the right, with weak Eu negative anomaly. In the standardized spider diagram of the original mantle, The Pb and LILE(Rb, Ba)enrichments and HFSE (Nb, Ta, Zr) depletions resemble those of typical subduction-related arc volcanic rocks. The Th/La, Th/Ce and Lu/Yb ratios of andesites are below those of average continental crust, but similar to those of typical mantle-derived magmas. The andesites in the study area belong to the normal island arc volcanic rocks and atypical adakite, which are derived from the water rich mantle wedge and are formed by the partial melting of the fluid metasomatic mantle wedge produced by the dehydration of the subduction plate. The zircon U - Pb dating of andesites LA - ICP - MS shows that the crystallization age is 322.4 ± 1.1 Ma, which is in the Middle Carboniferous, in line with the time range of the first tectonic magmatic event of the extinction of the western Junggar residual ocean basin (329 ~ 320 Ma). Combined with regional geological background and comparison with magmatite in similar period, it is considered that the andesites in the study area was formed in the continental arc environment, and was the product of subduction of the residual oceanic basin in West Junggar, and the remnant ocean basin was not completely closed at 322.4 ± 1.1 Ma.

Eocene magmatic activity and its influence on the formation of lacustrine high-quality source rocks in the western Zhu I depression, Pearl River Mouth Basin

Xuanlong Shan[1*], Chuan Xu[1], Guoli Hao[1], Jian Yi[1], Mengrong Shen[1], Yalikun Rexiti[1], Kang Li[1]
1. College of Earth Sciences, Jilin University, Changchun, Jilin, CHINA
E-mail: shanxl@jlu.edu.cn

Keywords: South China, Pearl River Mouth Basin, Wenchang Formation, magmatic activity, source rocks

Following the collapse of the Yanshanian orogenic belt, mantle magma uplift, crustal stretching and thinning, and multiperiod strong magmatic activities widely developed during the Eocene in South China, especially in the western Zhu I depression, Pearl River Mouth Basin (PRMB). Moreover, the Eocene lacustrine mudstone of the Wenchang Formation has high OM abundance (total organic carbon (TOC): maximum of 3.20 wt%) and is an important source rock in the PRMB and in South China. Thus, the sedimentary records of the Eocene Wenchang Formation in the western Zhu I depression provide an interesting perspective for understanding the influence of magmatic activity on the formation of lacustrine high-quality source rocks. Based on detailed analysis of new three-dimensional seismic and drilling data and recent research results, using geophysical, basin analysis and geochemical means, this paper systematically analyzes the magmatic activity of Paleogene in Zhu I depression and its influence on the reconstruction of basin structure and the development of source rocks.

The results suggested that extensive magmatic underplating (mainly distributed in the depression) in the sedimentary period of Wenchang Formation of Zhu I depression, and the multi-stage magmatic underplating may be controlled by the rift of Zhuqiong movement and the tectonic transformation of Huilu movement. Under the joint influence of pre-existing faults and magmatic emplacement, Zhu I depression presents the complexity and diversity of structure. The preexisting detachment system controls the extension of the basin and forms many elliptical depressions with small aspect ratio. The synsedimentary magmatism promotes the tilt and rotation of the hanging wall of the detachment fault, resulting in the weakening of axial provenance, and the enhancement of gentle slope provenance and the development of large delta deposits. Meanwhile, the subsidence area in the fault depression forms an uncompensated deep lake environment, which provides excellent conditions for the formation of high-quality source rocks.

In addition, the detailed geochemical analysis of source rocks in the study area reveal that multiple hydrothermal activities occurred during Wenchang deposition, which is considered to be related to magmatic underplating in the same sedimentary period. During the hydrothermal activity period, regional tectonic activity caused the hydrothermal fluid to jet upward along the tensile fractures in the lake basin basement, thereby inputting abundant nutrients (Fe, Cu, Ni, P, Zn, etc.) and the common prosperity of lake microalgae and terrestrial plants greatly improved lake primary productivity. High lake level led to a reducing bottom water environment, and abundant reducing gases (H_2S, SO_2, and CH_4) were released into the lake along the hydrothermal overflow channel, which further influenced the anaerobic conditions of the bottom water. Therefore, the eugenic environment formed by magmatic hydrothermal activity (high biological productivity and reduction conditions) further promoted the development of high-quality source rocks of Wenchang Formation. The influence of magmatism on the formation of lacustrine high-quality source rocks will further enrich the organic matter accumulation mechanism of continental faulted lake basin, and provides useful enlightenment for oil and gas exploration in the PRMB and similar basins.

Discovery of the Late Jurassic-Early Cretaceous lamprophyres in western Songliao Basin of northeast China and their constraint on regional lithospheric evolution

Taiji Yu[1*], Pujun Wang[1], Yan Zhang[1], Youfeng Gao[1]
1. College of Earth Sciences, Jilin University, Changchun, Jilin Province, CHINA
E-mail: yutj1988@126.com

Keywords: Songliao Basin, Northeast Asia, Lamprophyre, Geochemistry, Lithospheric evolution, Jurassic and Cretaceous

Contradictory to common concept that the lithosphere in NE China was thinned from Late Jurassic through Early Cretaceous. We discovered, however, a thickening episode in the long-term thinning background. A series of lamprophyre dikes have been recently found in the Tuquan Basin of western Songliao Basin. They were subsequently dated at 156.0 ± 2.3 Ma, 132.9 ± 1.2 Ma, and 126.2 ± 2.5 Ma, respectively, using the zircon U–Pb technique. The lamprophyres are subdivided into Late Jurassic biotite orthoclase lamprophyre (BOL) and Early Cretaceous quartz magnetite lamprophyre (QML).The BOL and QMLs are shoshonite and calc-alkaline in series, characterized by high contents of FeOT, TiO2, MgO, and Mg# values, and are enriched in LREEs and LILEs but depleted in HREEs and HFSEs. They have high ratios of (La/Yb)N, La/Ta, La/Nb, Th/Y, Ba/Nb, Ba/Ta, and Ba/Th, and low ratios of Zr/Ba, La/Sm, and Nb/Zr. These features collectively point to the derivation of the dike magmas from the partial melting of enriched lithospheric mantle that had been previously metasomatized by subduction-related fluids. The BOL has high ratios of Rb/Sr (0.42) and K/Yb*1000 (28.3), and low ratios of Ba/Rb (13.5) and Dy/Yb (2.35), suggesting a magma derivation from high degree partial melting of phlogopite-bearing lherzolite mantle in the spinel–garnet transition zone at a depth about 60 km, the QMLs have low ratios of Rb/Sr (0.02–0.06) and K/Yb*1000 (8.13–19.73), and high ratios of Ba/Rb (17.6–42.6) and Dy/Yb (3.48–4.09), indicating that the magmas were derived by low degree partial melting of lherzolite mantle in the garnet zone at a depth of ca. 85 km, the younger QML (126.2 ± 2.5 Ma) has lower Dy/Yb ratio (3.48–3.92) than that of the older QML (132.9 ± 1.2 Ma) with Dy/Yb ratio of 4.09, implying that the younger magma was produced at a shallower mantle depth (85 km) than that of the older one. These indicate that in the period of 156–132 Ma, the lithosphere thickened by approximately 25 km at a rate of approximately 1.0 km/Myr. A new geodynamic evolution model of three stages was thus proposed.

E-mail: cbshen@cug.edu.cn

Keywords: volcanic edifice, volcanic sedimentation, Jurassic, Derbugan fault, Hailar basin

Derbugan and Erguna faults are the two important structures in the northeastern Asia. Recent studies suggest that the two fault belts control Jurassic volcanic eruptions, basin subsidence and sedimentary filling. The western Hailar Basin lies between the Derbugan and Erguna faults. Based on 2D/3D seismic data and field observation, this study aimed to characterize volcanic edifices, identify the lithofacies distribution of volcano-sedimentary rocks, and reconstruct volcanic paleogeography in the western Hailaer Basin. The volcanic rock belt distributed along the NNE-trending Derbugan and Erguna faults is about 50 km wide and hundreds of kilometers long. The volcanic edifices show multi-center eruption patterns as the typical features of composite volcanos, and they predominantly distribute along the NE-trending faults that are the secondary faults of the Derbugan and Erguna faults. The spatial distribution of the volcanoes is controlled by typical fault patterns, for example, parallel-fault assemblage, antithetical-fault assemblage, fault-transition zone and echelon-fault assemblage. Sedimentation usually takes place between volcanic edifices and the boundary faults of basin, and the fault-related structures and volcanic paleogeomorphology jointly impact the distribution of sedimentary rocks. The dip angle of boundary faults controls the range of sediment accommodation. The volcanic eruptions occur almost simultaneously with basin rifting and occupy a considerable part of the accommodation space. The sedimentary facies are developed in the accommodation space limited by volcanic edifices and faults. A detailed anatomy suggests that the volcanics in Bayanhushu depression mainly belong to effusive facies and explosive facies composed of tuffs. The Chagannuor depression is predominated by shallow lacustrine sediments, and the explosive facies and volcano-sedimentary facies mainly distribute in the south. Fan deltas and offshore sedimentary fans are generally developed in the gentle slope zone away from volcanic disturbance. The Derbugan and Erguna faults serve as a pathway for magma migration and affect the emplacement of volcanic edifices and the distribution of volcano-sedimentary rocks.

Characteristics of Volcano Stratigraphic Elements in Faulted Depression Basin and its Geologic Significance: A Case Analysis of Full Coring Well of Lower Cretaceous Yingcheng Formation in Jiutai, Jilin Province

Jingsong Hu[1], Huafeng Tang[1*]
1. College of Earth Sciences, Jilin University, Changchun, Jilin Province, CHINA
E-mail: tanghfhc@jlu.edu.cn

Keywords: Volcano stratigraphy, Yingcheng Formation, Deposit unit, Greenhouse gas, Songliao basin

Volcano stratigraphy has special temporal and spatial attributes and geological record characteristics, but it has not attracted enough attention in the analysis of basin filling. In order to further clarify the geological attributes of volcano stratigraphy, the characteristics and geologic significance of volcano stratigraphic elements of Lower Cretaceous Yingcheng Formation in Songliao Basin were studied by taking the full coring shallow drilling wells (Y1D1 and Y3D1) as examples. The results are described as follows: 3 eruptive interval unconformity boundaries and 10 eruptive conformity / unconformity boundaries are identified in the volcano stratigraphy of the first member of Yingcheng Formation in well Y1D1. 2 eruptive interval unconformity boundaries and 8 eruptive conformity / unconformity boundaries are identified in the volcano stratigraphy of the third member of Yingcheng Formation in well Y3D1. According to the attributes of eruptive interval unconformity boundary, the volcano stratigraphy of well Y1D1 can be divided into 4 volcano edifices, and the volcano stratigraphy of well Y3D1 can be divided into 3 volcano edifices. Rare earth and trace elements have a good response to the volcano edifice. There are 6 types of deposit unit: simple lava flow, braided lava flow, dome, pyroclastic flow, base surge and lahar. The emission intensity of volcano gas during the eruption of lava units is weaker than that of pyroclastic units. Volcano stratigraphy has the time attributes of short construction time and long eruptive interruption time, and the construction rate of volcano stratigraphy cannot be calculated simply by using the stratigraphy thickness and the time difference between the top and bottom of the test.

Development of extensional decollement structure and its petroleum implication in the Wushi east subsag, Beibuwan Basin.

Zheng Wang[1], Dianjun Tong[1*], Mingheng Gao[1], Jingyuan Yu[1]
1. College of Marine Science and Technology, China University of Geosciences(Wuhan), Wuhan, Hubei, CHINA
E-mail: djtong@cug.edu.cn

Keywords: Beibuwan Basin, Wushi Sag, Extensional decollement structure, Structural evolution, Oil and gas structure

Wushi Sag is located in the central part of the Beibuwan Basin, northwestern continental margin of the South China Sea. From the early Paleocene to the end of the Oligocene, it experienced multiple phases of extension. Based on the new high-quality 3-D seismic data obtained in the process of petroleum exploration, this study conducted an in-depth analysis of the extensional decollement faults in the Wushi east subsag, established the growth and linkage model of decollement faults and discussed the meaning to oil and gas exploration. The results show that there are 7 extensional decollement faults (Fa-Fg) in the Wushi east subsag, which are distributed in the near E-W or NE-SW direction. These decollement faults together with north-dipping No.7 boundary fault, controlled sedimentation from the 1st Member of Liushagang Formation to the 1st Member of Weizhou Formation, which formed a huge rollover anticline. In terms of evolution, during the Early-Middle Eocene, the basin is a graben or half-graben controlled by the NE-SW No.7 boundary fault and other local small basement faults. The 3rd member of Liushagang Formation strata are discretely distributed and were overlaid by thick layer of the 2nd member of Liushagang Formation. From the late Eocene to the late Oligocene, the basin deposited 1st Member of Liushagang Formation to the1st Member of Weizhou Formation , controlled by the oppositely dipping extensional decollement faults and the No.7 boundary fault. From the early Miocene to the present, the basin changed into a sag basin. This study depicted the geometry of extensional decollement structure which formed during the second rifting rift phase of Wushi east subsag, analyzed the growth and linkage pattern of decollement faults, proposed the decollement faults upslope-ward migration model, which has a great significance for solving the problems of oil and gas migration, storage and preservation.

E-mail: zhangjianguang108@126.com

Keywords: Botanical affinity, Palaeoenvironment, Palaeoclimate, Palaeoecology, Sporopollen database

The eco-group classification based on the growth-form of plants (Eco-Plant model) is widely used for extant, Cenozoic, Mesozoic, and Paleozoic palaeoenvironmental reconstructions. However, for most Mesozoic dispersed sporomorphs, the application of the Eco-Plant model is limited, because either their assignment to a specific eco-group remains uncertain or the botanical affinities to plant taxa are unclear. A new database Sporopollen (http://www.sporopollen.com) focused mainly on Mesozoic sporomorphs is created.

With the help of the database, 861 dispersed Mesozoic sporomorph genera of Bryophytes, Pteridophytes, and Gymnosperms are reviewed by comparing the unique outline and structure/sculpture of the sporomorph wall with that of modern plants and in situ fossil plants. The results show that 474 of them can be linked to their closest parent plants and Eco-Plant model at family or order level, but 387 of them cannot because of the lack of detailed ultrastructure descriptions. The use of a light microscope (LM) for determination is one of the main reasons that some dispersed sporomorphs cannot be linked precisely to their parent plants. The presented eco-groups for dispersed Mesozoic sporomorphs provide the possibility to identify detailed vegetation and palaeoenvironmental change in the Mesozoic, especially in the context of climate change.

A new interface (http://www.sporopollen.com/sporemesozoicsegs.php?opencode=paper1) was created based on the reviewed result to quickly link dispersed sporomorphs to past vegetation patterns and climatic changes. Users can upload their data to the database and in return get quick results. It can automatically link all of the Mesozoic and Cenozoic sporomorphs to their possible parent plants at phylum, order, or family level as well as all of the Triassic and Jurassic sporomorphs to the Eco-Plant model to assess the effects of humidity (EPH) and temperature (EPT).

As an example, samples from a lignite bed of the Upper Triassic Haojiagou Formation (Rhaetian) have been studied palynologically to reconstruct the palaeovegetation and palaeoenvironment of a peat-forming wetland near the Triassic-Jurassic boundary by using the Eco-Plant model. We analysed assemblages in terms of an Eco-Plant model, which assigns the parent plants of the palynomorphs into five groups based on humidity and four groups based on temperature and used multivariate statistical analyses to infer palaeoclimate and palaeoenvironmental conditions. Our results suggest that the palaeoclimate of the Rhaetian was generally wet and subtropical with short seasonal drought periods. The analysis shows that the Eco-Plant model is a useful tool to reveal past vegetation patterns and climate changes, applicable to other Mesozoic assemblages.

Volcanic activities usually disturb the environment and affect the palynological assemblages. Our database and the Eco-Plant model can be useful tools to detect the interaction between volcanism and environment.

Reservoir characteristics and differences of basement gas reservoirs in front of Altun Mountain, Qaidam Basin

yanli li[1*]
1. Northwest Branch, Research Institute of Petroleum Exploration and Development, PetroChina, Lanzhou 730020, China;, petrochina, lanzhou, gansusheng, CHINA
E-mail: li_yanli@petrochina.com.cn

Keywords: basement gas reservoir, lithologic, Reservoir characteristics, fracture characteristics, difference, Qaidam Basin

As a kind of unconventional oil and gas reservoirs, the basement reservoirs are widely distributed in the world. In recent years, breakthroughs have been made in exploration of basement buried hill gas reservoirs in front of Altun Mountain in Qaidam Basin. Three basement gas reservoirs (Dongping, Pingxi and Jianbei) have been discovered successively. They accumulated proven reserves of more than 100 billion cubic meters and is one of the most promising exploration fields in Qaidam Basin. The exploration proves that the differences of basement lithology and reservoir characteristics are related to the enrichment of natural gas. Therefore, it is of great geological significance to clarify the reservoir characteristics and differences of basement gas reservoir. Based on core observation, laboratory thin section identification, X-ray diffraction, ECS logging and electric imaging logging data, we made a comprehensive analysis and research. The results show that : There are various types of basement rock in front of Altun Mountain, and the reservoir lithology are mainly granite, granitic gneiss, granodiorite, crystalline limestone and slate. The mineral composition of different lithologies is different and shows obvious differences. The logging responses of different lithologies are different. The combination of ECS and conventional logging can distinguish lithologies. Different types of basement reservoirs have different reservoir space characteristics and physical properties. The reservoir spaces of magmatic and ortho-metamorphite are mainly dissolved pores and fractures, and the porosity is mainly distributed in the range of 2% ~ 7%. The reservoir space of para-metamorphic rock is mainly fracture, with a few dissolved micropores, and the porosity is mainly distributed in the range of 1% ~ 4%; The fracture characteristics of different lithologies are obviously different. The exploration practice shows that there are obvious differences in natural gas production due to different basement lithology, reservoir space and fracture development characteristics. The research results provide a certain reference for the exploration of basement reservoirs and have a guiding significance for the exploration of basement reservoirs in other areas.

Reference

As a kind of unconventional oil and gas reservoir, the total oil and gas reserves of basement reservoir are almost equal to 15% of the world's known oil and gas reserves (Yang and Xu, 2011), so it has attracted more and more experts' attention. Exploration practice shows that basement reservoirs are widely distributed in the world. 2017; Chen zhigang, 2016), White Tiger Oil Field in Vietnam (Chen et al,2009;Nguyen N T B et al, 2009; Nguyen T T et al, 2009; Dang C T Q et al, 2011), the Jatibarang oil and gas field in Indonesia (Ma et al,2006;Syarif M N et al,2015;), the Cupen Mahuida gas field in Argentina's Ueuquen Basin (Zubiri M and Silvestro J,2007;Luo Y Y et al.,2010) and so on are oil and gas reservoirs with reserves of hundreds of millions of tons. In China, there are such as the Bohai Bay Basin of Liaohe (Wang Xin et al., 2015; Hu Zhiwei, 2017), Songliao Basin (Song Borong, 2011; Zhu Yixiu, 2018), Kelameili Gas Field in Xinjiang (Hou Lianhua et al., 2012), Yaerxia Oilfield in Jiuquan Basin (Xie Gongjian et al., 1981), etc.

In recent years, great breakthroughs have been made in the exploration of basement reservoirs in Qaidam Basin. High-yielding oil flows have been obtained from basement in areas such as Kunbei (Li Jianming, 2011; Liu Guizhen, 2015), Dongping (Zhang Shenqin, 2014; Li Jiangtao, 2014; Cao Zhenglin, 2013; Li Yanli, 2019) and Jiandingshan and so on. Among them, Dongping Gas Field is considered to be a rare basement buried hill gas reservoir at home and abroad in recent years (Li Jiangtao, 2014). In recent years, the exploration of unconventional reservoirs has attracted much attention. With the deepening of exploration work, basement reservoirs will play an increasingly important role in the exploration and development of oil and gas. Therefore, the study of reservoir characteristics and accumulation law of basement reservoirs is of great significance for guiding the exploration and development of basement reservoirs.

Basement reservoirs are widely distributed all over the world. Most of the reservoir types are oil reservoirs, but a small number are gas reservoirs. Granite is the largest reservoir lithology, accounting for 32%, followed by igneous, metamorphic rocks and

limestone (Yang and Xu, 2011). strong heterogeneity of lithology and physical properties, the daily production of single well in basement reservoirs varies greatly. There are basement oil and gas reservoirs in almost all petroliferous basins. Some are oil and gas fields with geological reservoirs of up to 100 million tons, and some are only oil and gas shows. In recent years, the author has been devoted to the study of basement gas reservoirs in Dongping, Pingxi and Jianbei areas in front of the Altun mountains. The results show that different from the basement reservoirs in other basins, the basement reservoirs in the front of Altun of Qaidam Basin are mainly gas reservoirs. The basement rock types are complex and diverse, and the reservoir space types and characteristics of different lithologies are significantly different, leading to great differences in production. This paper aims to take the basement gas reservoir in this area as an example, through the analysis and research of the relationship between complex basement lithology, reservoir and fracture development difference and production, in order to provide inspiration and reference for the exploration of basement oil and gas reservoirs in Qaidam Basin and other areas.

Deformation Features and Genesis Simulation of Strike-Slip Faults in Junggar Basin, Northwest China

Jingqi Zhang[1,2], Fusheng Yu[1,2*]

1. State Key Laboratory of Petroleum Resources and Prospecting, China university of Petroleum (Beijing), Beijing, Beijing City, CHINA

2. College of Geosciences, China university of Petroleum (Beijing), Beijing, Beijing City, CHINA

E-mail: fushengyu@cup.edu.cn

Keywords: Junggar Basin, strike-slip structure, genetic model, tectonic evolution, physics simulation

The Junggar Basin located in the northwestern part of China, which is the second largest petroliferous basin of Chinese mainland. It has the pre-Carboniferous metamorphic rock basement, mainly depositing Carboniferous system to Quaternary system. The strike-slip fault structures of different properties and scales developed in the periphery and middle part of the basin were the result of the superposition of multi-stage tectonic evolution. Since the Late Paleozoic, the tectonic evolution of the Junggar Basin can be divided into four key stages, namely the Carboniferous-Permian extensional fault depression stage, the Triassic-Jurassic compressional depression stage, the Cretaceous equilibrium subsidence stage, Paleogene-Neogene squeeze and depression stage. Meanwhile, the Triassic-Jurassic compressional depression stage is the main period for the development of strike-slip structures. The different strike patterns of basement faults, various types of pre-existing structures, and compressional stress states of diverse directions are the main factors for the differences in strike-slip faults structural styles. Base on the field geological work, statistical analysis of fault occurrences and joint elements, interpretation of 3D seismic profiles, as well as tectonic physical simulation experiments, the deformation features and genetic mechanism of strike-slip structures in different areas of the Junggar Basin are discussed: (1) The Cenozoic NE strike-slip structure in the southern margin of Junggar Basin is a tear fault system formed by differential thrust in the northern part of Tianshan Mountain, which is controlled by dual factors of differential thrust velocity and basement properties. And a tear fault structure model has been established. (2) The structure system in the western margin of Junggar Basin is segmented in space and superimposed in time. It has experienced four stages: dextral extensional-shear in early Permian, dextral compressional-shear in middle and late Permian, sinistral compressional-shear in Triassic- Jurassic and dextral extensional-shear during Cenozoic. (3) The strike-slip fault system in the central Junggar Basin mainly overwent two evolutionary stages: Yanshanian compressional-shear and Himalayan extensional-shaer, which were controlled by the dual factors of basement properties and different shear modes. The strike-slip structure in the Zhong 3 block formed under the widely distributed right-lateral strike-slip mechanism jointly controlled by the basement pre-existing faults and Jurassic coal seams, and transformed during the thrusting process of the southern margin of the Himalayan period. The strike-slip structure in the Zhong 4 block is a combination of simple shear on both sides and pure shear at the thrust front caused by the displacement of the pre-existing basement uplift under the action of near-EW compressive stress in the Jurassic period.

Study on the evolutionary relationship of basement structure and Mesoproterozoic cover in Ordos Basin

Gang Tian[1,2], Minghui Yang[1,2*]

1. State Key Laboratory of Petroleum Resources and Prospecting, China University of Petroleum(Beijing), Beijing, CHINA
2. College of Geosciences, China University of Petroleum(Beijing), Beijing, CHINA

E-mail: 691561570@qq.com

Keywords: evolutionary relationship, early sedimentary cover, Basement structure, magnetic and seismic data, Ordos basin.

To understand the influence of the basement on the development and evolution of early sedimentary cover in Ordos Basin, using 1:200000 magnetic data, the latest drilling and seismic data, the characteristics including the basement structure and the Mesoproterozoic Changcheng-Jixian system tectonic-sedimentary formation are studied respectively, and the evolutionary relationship between basement structure and the early cover is discussed. The results show that the basement structure of the basin is controlled by four primary faults, which are divided into five secondary structural units, showing the characteristics of NE horizontal blocking. The early sedimentary cover mainly experienced the two stages of the Changcheng period NE trending intracontinental rift and Jixian period depression and was dominated by continental coastal-clastic rocks and marine carbonate rocks respectively. The primary faults that control the basement structure of the basin are revived differently in the form of main boundary faults in the Changcheng period, manifested in the structural style of graben and half-graben, and controlled the sedimentary framework of the Changcheng period in the form of three depressions and two uplifts. The Mesoproterozoic cover is controlled by basement structure, characterized by early strong and late weak, west strong and east weak.

Influence of multi-stages strata uplift and erosion on hydrocarbon charging time in Late Mesozoic of Hangjinqi area, northern Ordos Basin, China

Jingying LI[1], Minghui Yang[1*]
1. College of Geosciences, China University of Petrolumn, Beijing, Changping, CHINA
E-mail: yangmh@cup.edu.cn

Keywords: Erosion thickness, K-Ar dating, Hydrocarbon charging time, Tectonic evolution, Accumulation period

Ordos Basin had been subjected to multi-stages strata uplift and erosion in the late Mesozoic. How did this process affect the charging time of hydrocarbon? We selected the Hangjinqi area of northern Ordos Basin as the study area to discuss the question. This paper took the basin analysis system and thermochronology as the theoretical guidance. In the first, the late Mesozoic strata erosion thickness was calculated by acoustic time difference method, and then balanced cross-section technique and numerical simulation was been used for restored the strata uplift evolution process. Finally, the core samples of 16 sandstone reservoirs of Lower Shihezi Formation in the study area were measured and dated to restore the reservoir geothermal history and estimate the inflation time, which was based on the homogenization temperature of aqueous inclusions, thermal and burial history simulation and K-Ar dating of authigenic illite. The research results showed that the late Mesozoic strata in the study area experienced three stages of stratum uplift and denudation. The first stage occurred in the Middle Jurassic, caused the stratum had been eroded about 850 ~ 200 m, and the denudation thickness of the generally decreases from northwest to Southeast, meanwhile, the marching temperature variation range of sandstone reservoir inclusions was 140 ℃ ~ 30 ℃; In the second stage, it was the late Jurassic, the stratum suffered from uplift and denudation strongly with denudation thickness of about 920 ~ 200 m and decreasing from west to east. The temperature variation range of sandstone reservoir inclusion at this stage was 75 ℃ ~ 165 ℃; The third stage occurred in the late Cretaceous. Affected by fault activation, there was a significant difference in the erosion thickness between the north and south of the study area. The erosion thickness increased from 380 m to 730 m, and the temperature was 82 ℃ ~ 134 ℃. The time of three charging events were between 176 ~ 172 Ma, 166 ~ 154 Ma and 128 ~ 115 Ma respectively by K-Ar dating prior to the three stages of strata uplift and erosion. Due to the different erosion thickness of the strata in the north and south in the study area, the maturity and thermal evolution of the source rocks were different. In addition, the existence of the stratigraphic unconformity provided a channel for oil and gas migration, and the Middle Jurassic strata were uplifted and tilted, which became the dynamic factor of the second inflation event.

U-Pb dating of sandstone detrital zircons from Chert–Spilite and Sapulut Formation in Sabah, Malaysia and its geological significance

Zhiwen Tian[1], Youfeng Gao[1], Zhigang Zhao[2], Wu Tang[2], Huafeng Tang[1*], Pujun Wang[1], Kailun He[1], Chenxi Zhu[1]
1. College of Earth Sciences, Jilin University, Changchun, Jilin, CHINA
2. CNOOC Research Institute, China National Offshore Oil Corporation, Beijing, CHINA
E-mail: tanghfhc@jlu.edu.cn

Keywords: Sabah, Chert-Spilite Formation, Sapulut Formation, Detrital zircons, Tectonic evolution

The Sabah area has a complex tectonic setting. Many ophiolites are exposed in the Sabah area, and there are still some problems of previous studies[1-3]. Chert-spilite (Cs) and Sapulut (Sp) Formation as part of the Sabah ophiolite suites. These sediments may provide further evidence of the tectonic evolution of the Sabah.Through field samples test and analysis from the Cs and Sp Formation, the results are as follows. The minimum detrital zircons ages of three sandstone samples of the Cs Formation were 90 ± 2.0 Ma and 68 ± 2.0 Ma, the Sp Formation was 81 ± 2.0 Ma. The age spectrum of zircons of Cs Formation can be divided into four groups: 68~196 Ma (22%), 212~250 Ma (11%), 257~575 Ma (20%) and 618~3423 Ma (47%), respectively[4]. The discriminant diagrams of detrital zircon formation environment shows that most detrital zircons in Cs Formation were derived from continental crust rather than oceanic crust, indicating that zircons are not derived from Shaba basement. Dickinson diagram shows that Cs Formation sediments are mainly derived from the source area of cyclic orogenic belt. The Cs Formation zircon age spectrum of the sandstone samples is similar to those of sands in the drainage systems of South China and East Vietnam. This finding implies that the provenance of CS Formation and SP Formation was probably the South China block and/or the Sunda block. The Sp Formation sediment provenance was mainly derived from Schwaner Mountain in Southwest Borneo and Tin Belt in Malay Peninsula[5]. It indicates that the Sabah sediments source shifted from the northern to southern South China Sea during Late Cretaceous to Eocene. By comparing the tectonic evolution of Sabah and its adjacent areas, and combining with the analysis of detrital zircon age maps of sandstone in Cs and Sp Formation, it is inferred that Sabah was close to the northern South China Sea in Late Cretaceous.

Global typical basement boreholes comparation with the Songliao Basin

Zhuolong Yang[1*]
1. College of Earth Sciences, Jilin University, Changchun, Jilin, CHINA
E-mail: 673661121@qq.com

Keywords: basin, basement,sedimentary cover, Songliao Basin

Based on the available data both internet literature and new data unpublished, the author performed a new research of global comparation of the typical basement borehole. The writer finally selected 14 globally typical basins that have borehole constraint basement-cover sections and clearly show the main phases of the overlying basin fills. The basins are: Tarim Basin, China; Junggar Basin, China; Ordos Basin, China; Erlian Basin, China; Hailar Basin, China; Songliao Basin, China; West Siberian Basin, Russia; Alberta Basin, Canada; Molasse Basin, Germany; Cankiri–Corum Basin, Turkey; Olduvai Basin, Tanzania; Pairs Basin, France; Rennes Basin, France; Campos Basin, Brazil. By comparing basement and overlying sedimentary cover of the 14 globally typical basins, we found that the Songliao Basin should be a world unique basin.

Geological characteristics and controlling factors of bedrock gas reservoir in the eastern part of the Altun mountains in the Northwestern Qaidan Basin

Yanxiong Wu[1*], Jianqin Xue[1], Junlin L[1]

1. PetroChina Qinghai Oilfield Exploration and Development Research Institute, PetroChina Qinghai Oilfield Exploration and Development Research Institute, Dunhuang, Gansu, CHINA

E-mail: 150797673@qq.com

Keywords: Altun front, bedrock gas reservoir, weathering crust, geological features, controlling factors

The eastern section of the Altun Mountains starts from Crescent Mountain in the west and ends at Lenghu in the east, with an exploration area of nearly 8,000 km2. The whole has a structural pattern of alternating uplifts and sags, with a resource of 1.3 trillion cubic meters. Bedrock is the main exploration target layer. However, due to the complex factors controlling reservoirs and the strong differences in reservoir formation, it is necessary to carry out systematic comparative studies to identify favorable exploration targets for the next step.

The bedrock reservoirs are mainly developed into four categories: granite, granodiorite, granite gneiss and metamorphic rocks. The weathering leaching zone in the weathering crust of the bedrock is mainly composed of dissolved pores and fractures, with an average porosity of 4.3% and an average permeability of 0.66mD. The reservoir is the best. The average porosity is 2.4%, and the average permeability is 0.52mD, which is the same as the reservoir level.

The cracks in the piedmont developed in the late Caledonian, Indosinian, Yanshanian and Himalayan periods. Natural fractures were formed in the early stage, and high-angle and low-angle fractures developed; in the late Yanshanian-early Himalayan paleo-structural sites, weathering, leaching and denudation, the high-angle fractures provided infiltration channels for atmospheric water, and dissolved along dark minerals, forming a network of fractures-cavities system; the weathering leaching in the middle-late Himalayas was strengthened, and the weathering leaching zone formed a layered gas reservoir composed of a network of fracture-cavity systems, and the gas reservoir was relatively high-yield; the semi-weathered zone formed an isolated small-scale gas reservoir along high-angle fractures .

Through the analysis of the bedrock gas reservoirs, the accumulation law of "uplift-controlled accumulation, fault-cap controlled accumulation, and differential enrichment" is proposed, which clarifies the basis. The three main controlling factors of rock differential accumulation. Reservoir development characteristics are different. High-angle fractures and dissolution fractures along dark minerals are the main reservoir spaces of bedrock and control the physical properties of bedrock reservoirs. Differences in tectonic pattern. Controlled by faults from the piedmont to the basin, it can be divided into three tectonic steps: high fault step, middle slope, and sag middle uplift. Oil and gas first enter the second and third steps in the lower part, migrate upward along the fault, and continue to migrate to the higher part after being sealed by the caprock and charged with a certain amount. Differences in fault activity. The formation period of the piedmont faults controls the formation of bedrock structural traps, and the fault activity during the hydrocarbon accumulation period controls the migration and enrichment of natural gas. The low-fault steps and sag-middle uplifts located on the second and third steps are near-source and below-source accumulations, with superior reservoir-caprock assemblage and enriched lower assemblage. It is proposed that the bedrock structural traps in the Niuzhong slope belt are favorable practical breakthrough areas in the piedmont.

Characteristics and geological significance of calcarenaceous sandy conglomerate of Upper Cretaceous Quantou Formation based on the ICDP borehole SK3 in the Songliao Basin, NE China

Hang Gao[1], Pujun Wang[1], Yongkang Yin[1], Jingsong Hu[1], Zheng Zheng[1], Youfeng Gao[1,2*]
1. College of Earth Sciences, Jilin University, Changchun, Jilin Province, CHINA
2. Research Center of Palaeontology and Stratigraphy, Jilin University, Changchun, Jilin province, CHINA
E-mail: gaoyoufeng@jlu.edu.cn

Keywords: Songliao Basin, SK3, Quantou Formation, calcareous concretions, calcarenaceous sandy conglomerate

Borehole SK3 is the last borehole of International Continental Scientific Drilling Program (ICDP) in the Songliao Basin consisting of "three wells and four holes". Together with well SK1(consists of north borehole and south borehole) and borehole SK2, borehole SK3 has realized the scientific goal of drilling through the Cretaceous strata of the Songliao Basin, which provides an important basis for the study of paleoenvironment, paleoclimate, paleogeography during Cretaceous and tectonic evolution of the Songliao basin. 1592.35m cores of Upper Cretaceous Quantou Formation and Lower Cretaceous Denglouku Formation has been collected by borehole SK3. Through the fine description of cores of borehole SK3, several calcarenaceous sandy conglomerate layers with calcareous concretions debris as the main clastic components (i.e. calcareous concretions debris more than 50%) was found at the depths of 1001.54m, 1002.29m and 1083.00m of the third member of Quantou Formation and 1344.80m of the second member of Quantou Formation, thickness of which ranging from 4cm to 1.3m.

Calcarenaceous sandy conglomerates develop massive structures and grain texture, with grain size ranging from 0.5mm to 5mm, roundness ranging from sub angular to sub circular and medium clastic separation. Gravels of calcarenaceous sandy conglomerates are mainly composed of calcarenaceous(calcareous concretions debris), with proportions of about 70% and small amounts of torn mud gravels. Gravels of calcarenaceous sandy conglomerates cemented by sand grains, amount which quartz fragments accounts for about 15%, feldspar fragments account for about 10% and lithic fragments account for about 5%. Through fine core description and sedimentary facies analysis, sedimentary model of calcarenaceous sandy conglomerates of Quantou Formation revealed by SK3 is preliminarily summarized. The flood plain and natural levee are exposed to the surface during the drought. A large number of calcareous concretions are precipitated because of strong evaporation. Calcareous concretions with large granularity are transported and broken in the subsequent flood period. Finally, a set of calcarenaceous sandy conglomerate is developed on the point bar and riverbed. The scale of calcarenaceous sandy conglomerate is affected by length of pre-diagenetic drought period, strength of weathering and denudation, strength of hydrodynamic force in flood period and duration.

The development of calcarenaceous sandy conglomerate in the second and the third member of Quantou Formation in SK3 suggests a new diagenetic model of terrigenous clastic rocks in the Songliao basin. The development of calcarenaceous sandy conglomerate indicates that the climate of the diagenetic stage of the parent rock is dry and hot, with strong evaporation, accompanied by weathering and denudation, which gradually weakens with the deepening of river water depth and the strengthening of hydrodynamic force. The reservoir space of calcarenaceous sandy conglomerate is dominated by intergranular pores, intragranular dissolved pores and fractures, and the measured porosity can reach up to 12.9%. If this kind of reservoirs with large thickness and scale were found in the basin, it would have the potential to form high-quality lithologic reservoirs.

Early Carboniferous volcanic-sedimentary filling pattern in the northeastern margin of Junggar Basin

Sheng Zhu Wang[1*], Sheng Li Ni[1], Zhong Cai Bai[1], Zheng Rong Xiong[1], Wei Hua Bian[2], Hong Zhou Yu[1]
1. Research Institute of Exploration and Development, Shengli Oilfield, Dongying city, Shandong Province, CHINA
2. College of Earth Sciences, Jilin University, Changchun City, Jilin Province, CHINA
E-mail: wangshengzhu.slyt@sinopec.com

Keywords: Carboniferous, volcanic arc, interarc basin, backarc basin, volcanic-sedimentary filling pattern

Carboniferous strata in the northeast margin of Junggar basin are important targets for oil and gas exploration. The detailed volcanic-sedimentary filling pattern is key to the research of source and reservoir relationships and hydrocarbon exploration. Based on outcrops, drilling, seismic and non-seismic data, the Carboniferous basin filling pattern was characterized by lithologic association, sedimentary facies sequences, geochemical and tectonic settings, and proofs of gravity-magnetic-electric-seismic inversion, etc. The northeastern margin of Junggar Basin in the early Carboniferous was a multi-arc and basin system. A NW-SE volcanic island arc belt formed along Luliang-Kelamei area, and isolated aquatic volcanic arcs formed in Sangequan and Shiyingtan, respectively. Interarc basins developed in Shixi, Shibei, and Dishuiquan. Lapilli and lava were dominating in beaded volcanic edifices. Pyroclastic and fan-delta terrigenous coarse clasts were deposited in the proximal island arc region. Deep water fine grained argillaceous material precipitated in the distal island arc region. The configurations of source rocks with volcanic rocks are overlapping or inter-finger in vertical, and centered to volcanic rock as a ring in plane view. Wulungu area was a backarc basin where accepted sediments from northern Altay ancient land and southern Luliang-Kelamaili island arc. Influenced by the two side sedimentary provenances, the sedimentary filling within the Wulungu area is stripped from the north Zhaheba-Chakurt district, the center Well Wucan1 district, to the south Well Zhunbei 1- Quan 1 district. Fan delta coarse clastic deposits were developed in the north under the control of the northern terrigenous sedimentary provenance. Tuffaceous mudstone, mudstone, intercalated tuff and volcanic rock were developed in the center in the backarc deep-water environment under the co-influence of dual provenances. Volcanic rocks and tuffaceous sandstone mixed with tuffaceous mudstone deposits were developed in the south in the shallow backarc environment influenced obviously by volcanism. The deep water areas of interarc and backarc basins are favorable for source rock development. Volcanic lapilli and lava in the island arc area are favorable for reservoir development. Pyroclastic rocks and fan delta tuffaceous sandstone in the flank of the island arc area are favorable for tight reservoir development. Fine grained argillaceous rocks in the deep water area of backarc and inter-arc basins are favorable for shale oil and gas reservoir development. The source-reservoir (trap) configuration styles of overlap and lateral contact under the complex configuration of volcanic-sedimentary rocks in the multi-island arc basin system are attractive hydrocarbon exploration targets.

Practice And Enlightenment Of Efficient Development In Complex Oilfield Under The Influence Of Igneous Rock

MINGZHE CUI[1*], SHAOPENG WANG[1], CHUNXIN WU[1], XUETONG LIU[1], ZHUO LI[1]
1. Bohai Oilfield Research Institute, Tianjin Branch of CNOOC Ltd, TIANJIN, CHINA
E-mail: cuimzh2@cnooc.com.cn

Keywords: Igneous rock, Evolution of igneous rock, Spatio-temporal coupling relationship, Lateral plugging mode, tap potential of oilfield

Bozhong 34-9 oilfield is located in the southern part of Bohai Sea and the regional structure is in the Huanghekou sag in the southeast of Bohai Bay Basin. This area is rich in oil and gas resources, relatively active oil and gas migration, which is a favorable zone in Bohai Bay Basin, more importantly, it's the first Cenozoic sandstone reservoir which is most affected by igneous rock discovered in Bohai Sea during these years. It is worth noting that this kind of oilfield is put into development for the first time in China, so the practical experience of oilfield exploration and development is quite important. The main oil-bearing strata (Paleogene) of the oilfield is affected by multi-period superimposed volcanic eruption, the spatial distribution of reservoir is quite complicated. At the same time, as the igneous rocks interpenetrate and cut reservoir, the understanding of the evolution law of igneous rocks and the spatial configuration relationship between igneous rocks and sandstone are still vague, they seriously restrict the implementation of development Wells. This paper makes full use of the core, the micro chip, drilling and logging information, also 3D seismic forward modeling data, detailed analysis the characteristics of basalt, diabase, andesite and tuff, summarise the identification templates of various igneous rocks in the aspects of pattern characteristics, drilling characteristics, lithologic assemblage and seismic response characteristics, discuss the temporal and spatial evolution law of igneous facies, at the same time, the lateral sealing mode of igneous rock, the matching relationship between igneous rock and sandstone and the oil and gas potential area are explored. Under the influence of volcanism, the longitudinal alternating superposition degree of igneous rocks in the formation of E3d1 and E3d2 is much greater than that in E3d3 and Shahejie Formation in Cenozoic, it mainly develops Volcanic channel facies, intrusive facies and overflow facies igneous rocks. Based on the identification of various igneous facies, combined with actual drilling data and well-seismic matching relationship, Bozhong 34-9 oilfield is dominated by igneous rock/sandstone matching relationship of volcanic channel lateral occlusion and intrusion lateral occlusion, also the spatial and temporal distribution relationships of three kinds such as multi-rock facies, namely, lateral plugging of rock wall, lateral plugging of layered igneous rock mass and lateral not plugging of layered igneous rock mass are clarified. On the basis of abundant data, volcanic channel facies or intrusive facies with quite well matching relationship with target layer can be regarded as better hydrocarbon potential areas. It can effectively guides the development plan of oilfield and provides sufficient geological basis for the implementation of development Wells and rolling tapping potential of the oilfield. During two years of development and adjustment, a total of 78 development Wells including evaluation Wells were drilled, alse 4 wells drilling more than 100 meters oil reservoir, which successfully avoiding the risk of igneous rock drilling and achieving good implementation effect, more importantly, it provides a good reference for the exploration and development of Bohai Sea or similar oil fields at home and abroad.

Research on Sedimentary, geochemical characteristics and isotope tracer study of Permian transitional shale in the Lower Yangtze region, China

Min Dong[1*], Zongxiu Wang[1], Hui Dong[2], Xingqiang Feng[1], Licheng Ma[1], Linyan Zhang[1]
1. Energy Research Lab, Institute of Geomechanics, Chinese Academy of Geological Sciences, Beijing, CHINA
2. Laboratory Test Center, Xi'an Center, China Geological Survey, Ministry of Natural Resources, Xi'an , Shanxi, CHINA
E-mail: dongminyf@sina.com

Keywords: marine-continental transitional facies, shale gas accumulation, Permian, Lower Yangtze region

ABSTRACT: Starting from the major needs of the investigation of shale gas resources in China, this paper studies the sedimentary of marine-continental transitional facies shale layers, the geochemical characteristics of reservoirs, the evolution of process and preservation conditions of shale gas in this area. In order to study the sedimentary characteristics and reservoir geochemical characteristics of shale gas in this area, this paper obtained the data of reservoir organic and petrographic characteristics, experimental test analysis and regional data comparison. Combined with the actual drilling data of wells JY1, WJD1 and WJD2, the geochemical tracer method, the comprehensive analysis of the formation and preservation conditions of shale gas in this area finally completed. The results show that marine-continental transitional facies shale in the Lower Yangtze region have higher in the southeast and thin in the northwest. The organic carbon content of shale is 0.37-2.90%, the kerogen is mainly type II and type III, and the shale organic matter maturity has entered the dry gas generation stage, and the degree of thermal evolution is in a higher mature stage, which was distributed in the range of 0.55~2.66%. Drilling revealed that the area has good shale gas accumulation, which shows the shale gas enrichment mode under syncline controlled reservoir, stable structure conditions is beneficial for the preservation of shale gas. Considering the shale of the Permian transitional facies in the Lower Yangtze region are often interlayered with coaltight sandstone and limestone, it is indicated that shale gascoalbed methane and tight sandstone gas could be developed in a collective manner, so as to become a favorable area for increasing shale gas reserves and production in China.

Keywords: Sichuan Basin,Late Permian,Mantle plume,Volcano-sedimentary succession description,Basin filling characteristics

As a product of mantle plume activity, Permian Emeishan Large igneous province is widely distributed in Sichuan Basin. Compared with the extensive research on volcanic rocks around the world, the research on volcanic rocks in Sichuan Basin is still in its infancy. Previous studies have shown that uplifting mantle plumes can usually cause large-scale crustal uplift and the formation of dome-like uplift features, and control regional paleogeographic pattern and sedimentary facies distribution. The surface uplift caused by mantle plume uplift, differential denudation of existing sediments, changes of sedimentary facies and lithofacies paleogeography must profoundly affect the paleogeomorphology and eruption mechanism of volcanic rocks in Permian Emeishan Large igneous province before eruption. This study constrains the temporal sequence of different regions and types of volcanic rocks in the Permian Emeishan Large Igneous Province, combines the spatial distribution patterns of different types of volcanic rocks, paleogeomorphology and eruption environment before eruption, reduction of volcanic eruption to build process, established above the cycle and lower cycle of 2 major eruption cycle of 4 stages of the volcano-sedimentary succession description, The filling characteristics of Permian basin in Sichuan Basin are also discussed.

The Permian volcanoes in Sichuan Basin underwent four stages and two major eruption cycles. From bottom to top, the mantle plume in stage 1 began to rise, and the tectonic pattern of uplift and depression was formed by the geofissure movement. The uplift area suffered weathering and denudation, and the deep-water area and depression area were covered by sea water. Stage 2 early intense volcanic eruption and overflow interaction, the formation of underwater pillow lava and pyroclastic rock interbedded or underwater pyroclastic rock. In the late stage of stage 2, massive quiet overflow was carried out to build a huge thickness of basalt. The early stage 3 was characterized by localized ephemeral submerged volcanic eruptions in Jianyang and other areas; Stage 3 late locally onshore neutral volcanic debris accumulation with minor basalt development. Stage 4 tuffs are widespread, continuously exposed to dissolution, forming weathering crusts and laying the material basis for the formation of volcanic reservoirs.

The transition mechanism of continental rifting to seafloor spreading: Insights from the SW South China Sea

Yuanyuan Gao[1*], Jianye Ren[1], Peng Chao[1]

1. College of Marine Science and Technology, China University of Geosciences,Wuhan, Wuhan, Hubei Province, CHINA

E-mail: 2717065291@qq.com

Keywords: South-western South China Sea,Detachment fault,Continental rifting,Breakup,Seafloor spreading

The South China Sea (SCS) is the largest marginal sea in the western Pacific region that is surrounded by three major tectonic plates, namely the Pacific, Eurasian, and Indian-Australian plates. The margins of the SCS are wide and rifting affected a hot and weak post-orogenic crust during a relatively short syn-rift interval in comparison with the Atlantic-type margins. Based on detailed observations of high-quality reflection seismic and wells data, we describe and interpret the characteristic structures of the SW-South China Sea Ocean Continent Transition (OCT) and their relationship with overlying syn rifting to syn breakup phase sediments and magma. Using the seismic lines imaging the complete sedimentary and magmatic architecture of conjugate rifted margin, we: (1) provide a detailed description of the crustal architecture; (2) define extensional rifting margin domains; (3) determine the tectono-stratigraphic-magmatic evolution linked to rifting and breakup. We discuss the link between the kinematic evolution and the sedimentary and magmatic record and illustrate it in a Wheeler Diagram. Relying on the identification and characterization of distinct stratal patterns and crustal architectures, we show that the OCT displays a transition from fault dominated rifting to magma dominated seafloor spreading. On its continent-ward side, the OCT is made of hybrid crust where tectonic thinning of continental crust is compensated by syn-extensional magmatic thickening; oceanward, the hybrid crust evolves into a fully magmatic. This study differs from previous interpretations of correlative surfaces in the distinction between: (1) different types of top basement and (2) syn-and post-tectonic packages within the syn-rift record. This study propose new interpretations of the tectono-stratigraphic-magmatic evolution and kinematic restoration of the breakup phase of the SW South China Sea.

Permeability-porosity relationship and the impacts of heterogeneous pore-structures of volcanic rocks affecting fluid-flow

Hanfei Wang[1*]
1. School of Earth and Environment, , University of Canterbury, Christchurch, Canterbury, NEW ZEALAND
E-mail: hfwang1988@gmail.com

Keywords: Permeability-porosity relationship, volcanic rocks, fluid-flow, pore-structures

In this paper, we investigate the relationship between permeability and porosity of 787 rock samples from the Yingcheng formation, aiming to understand factors controlling the migration and accumulation of hydrocarbons in volcanic rocks.

We use information from a range of techniques, including analysis of thin section and mercury injection capillary pressure (MIP) tests to characterize the pore structure of these volcanic rocks. Our research shows a counterintuitive result that under 2500 m depth in Songliao Basin, coherent volcanic rock, e.g., lava and welded pyroclastic rocks, present higher porosity and permeability than volcaniclastic rocks e.g. unwelded pyroclastic rocks, volcanic epiclastic rocks, volcanic breccia. For coherent volcanic rock, we find fractures are the key factors providing permeability, while porosity is mainly provided by complicated combination of primary (vesicles) and secondary (dissolution and devitrification) pores in coherent matrix.

The permeability porosity relation of coherent volcanic rock is mutually controlled by fractures and coherent matrix pore system. The entry pressure of coherent volcanic rock is mainly controlled by fractures. For volcaniclastic rocks, porosity and permeability is mainly provided by intergranular pore network. Permeability porosity relation is mainly controlled by grain size of volcaniclastic rocks. Large grain size (>2 mm) volcaniclastic rocks provide better reservoir quality than small grain size volcaniclastic rocks.

Analysis of spatial distribution of volcanic rocks in fault depression based on the characteristics of pathway and magma chamber: taking Cretaceous Yingcheng Formation of Changling fault depression in Songliao Basin as a case study

Tang Huafeng[1*]
1. College of Earth Science, Jilin University, Changchun, Jilin Province, CHINA
E-mail: tanghfhc@jlu.edu.cn

Keywords: Volcanic rocks, spatial distribution, controlling factors, Cretaceous Yingchen Formation, Songliao Basin

Volcanic rock is an important part of the filling in faulted depression. Volcanic rocks provide important clues for studying the genesis, age and evolution of basins. It is also an important target for oil and gas exploration in the deep part of basin. There have been extensive studies about petrology, chronology, filling sequence and reservoir geology of the volcanic rocks in the basin. It is recognized that volcanic rocks are unevenly distributed in faulted basins. But the reason of the uneven distribution is not clear. The distribution of volcanic rocks in the fault depression is unevenly. In the study of the distribution of volcanic rocks in the basin, the deep structure has not attracted enough attention. To further understanding the spatial distribution of volcanic rocks in faulted depression, the relationships between volcanic rocks and faults, volcanic rocks and deep structure characteristics are analyzed by using drilling data, seismic data, and existing research results of electrical structure for magma chamber interpretation. The followings are the results. In totally, the volcanic rocks divisions are along north-south ward. Then they are divided into blocks along the north-south ward. The central belt of faulted depression accumulates the most volcanic rocks. Horizontal throw of fault is more sensitive for volcanic rock existing, and the vertical throw of fault is more sensitive for volcanic rock thickness. The fault is only a necessary condition for the volcanic rocks existing, not a sufficient one. The distribution of volcanic rocks is also constrained by the magma chamber that can be characterized by the electrical data. The uplift of asthenosphere is the necessary condition. So, the spatial distribution of volcanic rocks can be inferred by the uplift of asthenosphere and the thinning region of extension crust. The filling of volcanic rocks in faulted depression usually corresponds to the subsidence and sedimentary centers. It can form good source-reservoir association with fine-grained rocks when the volume of volcanic rocks is small, and it can also reduce the proportion of fine-grained sedimentary rocks when the volume of volcanic rocks is large. So, the volcanic rock in the faulted depression is a double-edged sword for the oil and gas reservoirs.

Middle Permian seamount sequences within the central Yarlung Zangbo suture zone: Implications for the opening of the eastern Neo-Tethys Ocean

Xiaolong Fan[1], Xianghui Li[1*], Zhen Wei[1], Jingyu Wang[1], Min Zhou[1]
1. School of Earth Sciences and Engineering, Nanjing University, Nanjing, Jiangsu, CHINA
E-mail: leeschhui@126.com

Keywords: Neo-Tethys Ocean, Yarlung Zangbo suture zone, Middle Permian (Guadalupian) seamount, Early Permian (Cisuralian) opening of the Neo-Tethys Ocean

The opening of the Neo-Tethys Ocean is an important geological event in the paleoceanographic and paleotectonic evolution through the Phanerozoic. However, when the Neo-Tethys Ocean began to open has been dispute due to the scarcity of contemporary oceanic crust and sedimentary records. This work presents multiple sequences of basaltic rocks + sedimentary covers of the Middle Permian (Guadalupian) preserved in the central Yarlung Zangbo suture zone, to provide an insight for the initiation of the Neo-Tethys Ocean. We conducted field investigation, lithological observation, and geochronological and geochemical analyses for a bundle of basalt + carbonate assemblages in north of Lang Co (Buma of Ngamring county), southwestern Tibet, China. Mapping and stratigraphic sections show multiple sequences of basement rocks upwards to sedimentary covers. Petrography and lithofacies indicate basement rocks are chiefly eruptional basalts and sedimentary covers are dominantly thick carbonate rocks with a few siliceous and calcareous mudrocks that deposited in the pelagic environment. Geochemical data demonstrate that the basalts are tholeiite series, closely identified as the OIB-type, very similar to Hawaiian oceanic island basalt. We have recognized at least eight sets of seamount sequences and four types of seamounts, in which part of seamounts have experienced a stage of island caused by the sea level falling. According to the stratigraphic texture and OIB-type basalts, we propose that sequences of the basalt basement + carbonate cover are probably relicts of seamounts, indicating the Middle Permian oceanic crust record of the eastern Neo-Tethys Ocean and implying an incipient opening already took place in the Early Permian (Cisuralian).

U-Pb isotope geochronology and geochemistry of granites in Songnan low uplift, Qiongdongnan BasinConstraints on Mesozoic tectonic evolution of the South China Sea

Yanan Liu[1], Yan Zhang[1*], Weihua Bian[1], Hongming Li[1], Pujun Wang[1]
1. College of Earth Sciences, Jilin University, Changchun, Jilin province, CHINA
E-mail: yan_zhang@jlu.edu.cn

Keywords: South China Sea, Songnan low uplift, Mesozoic, Zircon U-Pb ages, Geochemistry, Tectonic evolution

The South China SeaSCSwas located in the transitional zone between the Paleo-Tethys ocean and the Paleo-Pacific ocean during the Mesozoic. There is no convincing conclusion on the transformation process of its tectonic regime yet. In this study, we take granites from deep water area of the Songnan low uplift in Qiongdongnan Basin as objects, and reconstruct the Mesozoic tectonic evolution of the SCS based on chronological and geochemical data. The granites in Y8-1 district of Songnan low uplift are high-K calc-alkaline series, with A/CNK values ranging from 0.97 to 1.18. The rocks are featured by distinctive enrichment in the RbUKPb depletion in BaPTiNbfractionated REEs (LREE / HREE = 3.03~9.02) , and moderate to weak negative Eu anomalies (0.30~0.71). They are highly differentiated S-type granites related to syncollision. Taking into account the zircon U-Pb age of 239.7±3.1Ma, the granites are the products of the collision between the Indosinian and South China blocks during middle Triassic. The granites in Y8-3 district of Songnan low uplift are high-K calc-alkaline series, with A/CNK ranging from 1.06 to 1.40. The rocks show distinctive enrichment in the RbKPbdepletion in NbTiP fractionated REEs (LREE / HREE = 4.98~10.58), and moderate to weak negative Eu anomalies ((0.48~0.74). They belong to the highly differentiated granites with arc affinity. Taking into account the zircon U-Pb age of 220.2±2.0Ma, the granites are related to the westward subduction of the ancient Pacific Ocean in late Triassic. Combined with the works of predecessors around the SCS, we establish the Mesozoic tectonic evolution model of the SCS region : (a) Late Permian~Early Triassic (272-247.2Ma), the branch of the Paleo-Tethys ocean northward subducted to the South China block. (b) Middle Triassic (247.2-237Ma), the branch of the Paleo-Tethys ocean closed, and the Indosinian collided with the South China block. (c) Late Triassic~early Late Cretaceous (237Ma-90Ma), the Paleo-Pacific subducted westward beneath the Indosinian-south China blocks, and the Andean-type continental arc developed.

Characteristics and Main Controlling Factors of Bedrock Buried Hill Natural Gas Reservoir in Central Paleouplift Belt in Northern Songliao Basin

Xuefeng Bai[1], Jiamin Lu[1*], Jiajun Liu[1]
1. Exploration and Develoment Research Institute, Daqing Oilfield Company, Daqing, Heiongjiang, CHINA
E-mail: lujm@petrochina.com.cn

Keywords: northern Songliao Basin,central paleouplift zone,bedrock buried hill,dual porosity gas reservoir,weathering crust, transportation system

The bedrock buried hill in central paleouplift belt in Northern Songliao basin is an important target for deep natural gas exploration in Daqing Oilfield. Although gas reservoirs have been found in many bulges, the degree of exploration is low with unclear gas reservoir characteristics ,vague main controlling factors and uncertain exploration direction. Based on data related core, experiment, well logging, high-precision three-dimensional seismic and gas production test, the characteristics of bedrock buried hill gas reservoir and the main controlling factors of reservoir are studied. The results show that the type of bedrock buried hill gas reservoir in central paleouplift belt is pore fracture dual porous medium gas reservoir. Its formation is mainly controlled by the following factors:The paleotectonic background that has been developing during the reservoir formation period is a favorable target area for natural gas to accumulae; Wih the influence of tectonism, weathering,leaching and dominant lithology, the netted pore fracture weathering crust reservoir with good connectivity is formed on the top of the bedrock buried hill; The natural gas generated by high-quality source rocks during the fault depression period around the buried hillmigrated and accumulated along the “ternary” lateral transportation system composed of faults, fractures and unconformity;The stable regional mudstone caprock of Denglouku formation formed during the period transformed from fault depression to sag provides sealing conditions. On this basis, the favorable zones determined by comprehensive research guided the exploration discovery of bedrock buried hill in the central paleouplift belt in northern Songliao basin, which will provide theoretical guidance and exploration case reference for bedrock buried hill exploration.

Differential evolution process and dynamic mechanism of Cenozoic prototype basins in the southwest margin of South China Sea

Dianjun Tong[1*], Jianye Ren[1], Yuantao Liao[1], Hui Liu[1]
1. College of Marine Science and Technology, China University of Geosciences, Wuhan, Hubei, CHINA
E-mail: djtong@cug.edu.cn

Keywords: Prototype basin, Differential evolution, Tectonic-stratigraphic framework, Tectonic event, South China Sea

The southwestern margin of the South China Sea (SCS) is located at the tectonic junction region of continental blocks collision and subduction leading edge zones. By using recently collected 2D seismic profiles, drilling wells and outcrop data from onland Borneo to offshore Zengmu and Beikang basins, we identify three tectonic key interfaces in the Cenozoic basins, namely the basement unconformity (T_{100}, ca. 65Ma), Sarawak Orogeny (T_{80}, ca. 38Ma) and Sabah Orogeny (T_{50}, ca. 16Ma). On this basis, the Cenozoic tectonic-stratigraphic framework and prototype basins are determined. The result shows that the West Baram line (WBL) is not only an important basement fault boundary separating Zengmu basin and Beikang basin, but also an important dynamic deformation boundary in Cenozoic. The Beikang basin in the northeast of WBL has developed two prototype basins of rifting basin (T_{100}-T_{50}) and depression (T_{50} to present), while the Zengmu basin in the southwest has experienced the superposition evolution from rifting basin (T_{100}-T_{80}), foreland basin (T_{80}-T_{50}) to passive margin basin (T_{50} to present). Consequently, the formation and evolution of Zengmu and Beikang basins show remarkable differences. We proposed the dynamic mechanism of differential evolution for the prototype basin in the southwestern margin of SCS, through the tectonic movement events of the surrounding plates/blocks, combing with the results of basin tectonic-stratigraphic interpretation, prototype basin analysis, subsidence history and depth-dependent lithosphere stretching modelling. During the Late Cretaceous to Early Cenozoic, slab roll-back of the subducted paleo-Pacific plate contributed to the developing of continental rifting in the early stage. While the Late Eocene Sarawak Orogeny led to the collision between the Zengmu continental block and Borneo, on which a peripheral foreland basin was formed. Afterwards, the subduction of the Proto-SCS oceanic crust migrated to the east of the WBL and triggered the sustaining extension rifting of Beikang basin until the Sabah Orogeny. Since the Middle Miocene, Zengmu basin and Beikang basin have entered the evolution stage of passive continental margin basin and peripheral foreland basin respectively.

Reservoir characteristics and controlling factors of deep sedimentary pyroclastic rocks in the basin——a case study of Yingtai fault depression, southern Songliao Basin

Xu Xiao[1], Zhao Ran Lei[1*]
1. College of petroleum and natural gas engineering, Liaoning Petrochemical University, Fushun, Liaoning Province, CHINA
E-mail: zhaoranlei@foxmail.com

Keywords: Deep basin, Volcaniclastic sedimentary rocks, Reservoir controlling factors, Anomalously high porosity and high permeability zone, Clastic composition,

The reservoir characteristics and controlling factors of deep sedimentary pyroclastic rocks in basins have always been the focus of petroleum exploration research. Based on core, thin section, SEM, logging and reservoir physical properties, the reservoir controlling factors of volcaniclastic sedimentary rocks in deep basin is carried out on the relationship between reservoir and characteristics, sedimentary microfacies and diagenesis, so as to analyze the contributing factor of anomalously high porosity and high permeability zone. The physical property of the volcaniclastic sedimentary rocks in deep basin is gradually decreased with the increase of the buried depth, and there are several anomalously high porosity and high permeability zones were developed. The lithology characteristics and diagenesis of the volcaniclastic sedimentary rocks are closely related to the formation of the reservoir. The reservoir's physical properties of volcaniclastic sedimentary rocks with large volcanic clastic particles is better than that with small clastic particles, and volcaniclastic sedimentary rocks with unstable clastic particles (feldspar, debris) are more easy to form the high quality reservoir than the rocks with high quartz content. The dissolution is the most important and direct reason for the formation of the anomalously high porosity and high permeability zone of the volcaniclastic sedimentary rocks in the deep basin. It is shows that the size and composition of the clastic particles in the volcaniclastic sedimentary rocks are the internal controlling factors of the effective reservoir, while the diagenetic fluid and the burial process are the external controlling factors for the formation of the effective reservoir.

Keywords: Mesozoic, extension, subduction, lacustrine, basin

The convergence between the paleo-pacific plate (Izanagi and Kula plates) and the Eurasian continent caused the complicated subduction and strike-slip tectonics in Northeast China from the Middle Jurassic to the end of the Cretaceous. The tectonic convergences acted in multiple directions during the Jurassic in eastern Asian, and then broadly and intensely extension and rifting during the Early Cretaceous. This transition of the tectonic system that occurred around the Jurassic/Cretaceous boundary is also equivalent to the second orogenic episode (episode B) of the Yanshanian Movement. During the Early cretaceous, exactly from 137 Ma to 131 Ma, along the tectonic line of Nenjiang - Balihan Fault and Kalaqin Metamorphic Core Complex (NBF-KMCC), the area of western side relative decline, and a series of volcano-graben basins formed in northern Hebei, the Greater Khingan Mountains and Arguna to Chita of eastern Russia, with lacustrine strata yielding the early fossil assemblage of the Jehol biota; at the same time, the Western Liaoning - Songliao area is a relatively uplifted broad tectonic plateau, which is subjected to denudation. During the period from 130 Ma to 110 Ma, the volcanic-rifting system extended to most parts of northeast Asia, and the volcanic basins formed on the eastern side of NBF-KMCC, with the middle and late assemblages of the Jehol biota spread around. The basin history and biogeographic evolution indicated that the Early Cretaceus volcanic-rifting system had migrated easternward in Northeast China, and this should be induced by the subduction of the paleo-pacific plates.

Sedimentary characteristics of the Early Cretaceous volcanic intermittent period in the Songliao Basin, data from the Shahezi Formation of ICDP borehole SK2

haibo liu[1*], Pujun Wang[1], Youfeng Gao[1], Honghao Li[1]
1. College of Earth Sciences, Jilin University, Changchun, Jilin, CHINA
E-mail: liuhaibo918@126.com

Keywords: Early Cretaceous, Songliao Basin, Sedimentary characteristics, Shahezi Formation, ICDP borehole SK2

The Shahezi Formation in the Songliao Basin is a sedimentary cycle between two volcanic cycles, Yingcheng Formation and Huoshiling Formation[1]. It is significant for research on initial basin history restoration, global continental–marine stratigraphic correlation, climate during the age of dinosaurs[2]. As the first set of sedimentary sequence in the basin[3], it has irreplaceable research significance.

In our research, 6 categories and 12 kinds of lithology were identified from the Shahezi Formation, mainly sedimentary rocks, in accordance with the thickness ratio from high to low are mudstone, grit stones, siltstone, conglomerate, fine sandstone, medium sandstone and lithology containing volcano material, including tuffaceous sandstone, sedimentary breccia tuff, tuffaceous siltstone,sedimentary tuff, tuff and tuffaceous mudstone.

In the Shahezi Formation period, sedimentary process is dominant, sedimentary rocks of fan delta facies are developed, with 3 subfacies: fan delta plain, fan delta front, profane delta, 6 microfacies: braided channel, subaqueous distributary channel, inter subaqueous distributary channel, subaqueous mouth bar, sand sheet, mudstone of still water, showing a fining-upwards sequence.

According to the lithology combination, the Shahezi Formation was divided into 6 cycles which all of them are fining-upwards sequence. However, according to the sediment granularity, the particle size of cycle I with conglomerate mainly developed is maximum, that of cycle III with pebbly grit stone widely developed is second, and that of cycle VI with mudstone and silty mudstone mainly developed is minimum.

Segmentation and Linkage of a Basin Boundary Fault System: Insights from the Early Paleocene Evolution of the Lishui Sag, East China Sea Shelf Basin

Jian Li[1], Qi Li[1*], Zhenjun Zhu[1], Hehe Chen[1]
1. School of Ocean Sciences, China University of GeosciencesBeijing (CUGB), Beijing, CHINA
E-mail: liqi@cugb.edu.cn

Keywords: Fault segmentation and linkage, Syn-rift sedimentation, Lingfeng fault; Lishui Sag, East China Sea Shelf Basin

The Lishuui Sag located on the southwest margin of the East China Sea Shelf Basin, which is a typical back-arc rift basin, is considered to be a one of the most prospecting oil and gas exploration zones. Fault superposition and linkage exert a significant influence on basin evolutionary history. A detailed stratigraphic and structural analysis of the three-dimensional (3-D) seismic survey on the Lishui Sag with throw backstripping and time thickness maps has illustrated the segmentation and linkage of the boundary Lingfeng Fault. We report that the fault system consisted of at least 7 segments, which were ca. 20–40 km long, during the initial 4.5 My of early Paleocene rifting(E1y). Throw backstripping indicates that fault segments were hard-linked or soft-linked during the succeeding 3.3My of syn-rift stage(E1l), and finally formed a single 180 km long fault zone during the last 1.2My of post-rift stage(E1y). Fault linkage has resulted in an obvious redistribution of displacement, with the locus of faulting initially locating on the center of each paleo-segment during the E1y, then being shifted from the south segments to the north segments during the E1l, and finally reached to the center of the through going fault during the E1y. The most redistribution occurred during the E1l, the main fault activities transferred from the south fault segments to the north fault segments. The average growth rate of the south faults segments was 450ms/My which was approximately 1.5 times of that of the north faults segments during the lower E1l(60.5Ma-60Ma), however the average growth rate of the north faults segments was 320ms/My which was approximately 1.6 times of that of the south faults segments during the upper E1l(60Ma-57.2Ma). The incised valleys crossing faults provide additional information on the geomorphological responses to fault growth. Early isolated fault growth is proved by the occurrence of major valley incisions at the fault linkage zones outlining the extent of the individual fault segments during the initiation of rifting. And the deterioration of the scale and amount of incised valleys of the south sections of the Lishui seg illustrated the weakness of fault growth in the south fault segments and the strengthening of that in the north fault segments during the late stage of syn-rift (upper E1l). The results identified that fault linkage exerted considerable control on sedimentation and evolution of the basin. This study demonstrates the importance of integrating stratigraphic and structural observations to reconstruct the temporal and spatial evolution of normal fault zones in the Lishui sag, as well as rift basins development in eastern China and similar areas throughout the world.

Quantitative analysis of structural evolution difference between East and West in Wushi Sag

Mingheng Gao[1], Dianjun Tong[1*], Jingyuan Yu[1], Hui Liu[1], Zheng Wang[1]
1. College of Marine Science and Technology, China University of geosciences, Wuhan, Hubei,CHINA, Wuhan, Hubei Province, CHINA
E-mail: djtong@cug.edu.cn

Keywords: Wushi sag,Differential evolution, Tectonic-stratigraphic framework, Tectonic event

Taking the Wushi Sag in Beibu Gulf Basin as the research object, four representative sections controlling the formation of the sag are selected from west to East. Use 2D move software to restore the equilibrium profile of the four profiles, and calculate the extension amount, extension rate and extension rate of each profile in different stages; EBM is used to calculate the fault subsidence activities of the East and West depressions. On this basis, the structural evolution process of Wushi sag and its east-west regional differences are quantitatively studied from the horizontal and vertical directions. The research shows that there are differences in time and space and intensity in the structural evolution of East-West sag: in the early stage of t100-83 sag, the overall activity of the early stage of West Sag is weak, but there are also sections with strong local activity. The overall activity of east sag is strong, and its extensional activity and subsidence activity reach the peak period of activity. After T80, the activity of dongwa tends to weaken, and the activity of Xiwa begins to strengthen gradually. T80-60 stage is the main stage of Xiwa activity, and the extensional activity and subsidence activity reach their peak at this stage. It shows the characteristics of early in the West and late in the East. In terms of tectonic activity intensity, the extensional activity of the west depression is stronger than that of the East depression, but the early subsidence activity of the East depression is stronger than that of the west depression, and the subsidence rate decreases gradually after T80. After T80 enters the peak period of dongwa activity, the extension rate and settlement rate of dongwa are stronger than those of Xiwa.

Influence of Eocene Regional Tectonic Stress Field Change on Beibu Gulf Basin Structure

Jingyuan Yu[1], Dianjun Tong[1*], Chen Hu[1], Mingheng Gao[1], Zheng Wang[1]
1. College of Marine Science and Technology, China University of Geosciences, Wuhan, Hubei, CHINA
E-mail: djtong@cug.edu.cn

Keywords: strike-slip fault,Tectonic-stratigraphic framework,South China Sea

Clarifying the basin structure is an important part of the basin tectonic research, and it is an important precondition for further detailed research on the basin as well. Before and after the formation of the T_{83} structural interface, the structural style and fault distribution of the Beibu Gulf Basin were significantly different, and the subsidence center also moved from the edge of the basin to the center. The main reason for this series of changes is the subduction of the Pacific plate to the Eurasian plate before and after 40.4Ma, resulting in a clockwise rotation of the stress field in the Beibu Gulf Basin. Under the influence of this regional tectonic movement, the stress in the Beibu Gulf Basin was The original single tensile stress was transformed into the superposition of two stresses, and a series of right strike-slip faults began to develop in the basin. At the same time, the activity of the sag-controlling faults weakened, then the subsidence center began to migrate to the center of the sag. During the same period, the lakes in the basin shrunk greatly. The change of the depositional environment and the change of the stress field resulted in the formation of the T_{83} interface. Above this interface, strike-slip structure was superimposed on the original simple half-graben structure. T_{83} interface marks the transition of the basin structure, and also marks the transition of the basin from the rift episode II to the rift episode III.

Volcano - Sedimentary Stratigraphic Sequence and Tectonic Significance of Laiyang Group in Taolin Area, Ri-Qing-Wei Basin

Sunyi Li[1], Yaoqi Zhou[1*], Tengfei Zhou[1]
1. School of Geosciences, China University of Petroleum, Qingdao, Shandong Province, CHINA
E-mail: zhouyq@upc.edu.cn

Keywords: volcanic-sedimentary squence, basalt, siliceous rocks, volcanism, Ri-Qing-Wei basin, Laiyang Group

Ri-Qing-Wei basin is a late Mesozoic rift basin in the central Sulu orogenic belt, which developed at the junction of North China plate and Yangtze craton. Taolin area is located in the southwestern margin of the basin, and the filling sequence is developed from sedimentary strata (Laiyang Group) to volcanic strata (Qingshan Group). The strata of Laiyang Group is divided into three sections from bottom to top: the bottom of the lower section consists of glutenite, the sandstone with interbedded gray siltstone and black siliceous rock, showing the characteristics of deep-water turbidite channel microfacies. The middle section is thick grey-white,grey siltstone interbedded with black siliceous shale, and several layers of mudstone. The upper section transits from the turbiditic siltstone-mudstone interbeds to siltstone and sandstone, indicating a incised valley developed in this period. Moreover, a layer of basalt developed at the top of the stratum. The overlying layer is the white rhyolite of Qingshan Group. The sedimentary facies evolved from alluvial fan -fan delta facies-subaqueous fan facies-turbidite fan facies-fan delta facies-volcanic effusive facies. The basin filling sequence shows the characteristics of transgression-regression, indicating that the evolution of the basin in Laiyang period experienced a rift basin evolution process of rifting-subsidence-closure. The siliceous rocks widely developed in Laiyang Group have the characteristics of mixed deposition of hot water and terrigenous clastic rocks, indicate deep magmatic activity. The rapid deposition of the massive thick sandstone of the middle section may be the response in shallow lithosphere tothe lithosphere thinning event caused by the delamination. The basalt in the top section owes the geochemical features of low SiO_2 (46.86 % -48.11 %), high ALK content (4.50 % -4.94 %) and high Mg# (75-87), indicating that it is high calc-alkaline series basalt. The trace elements enriched inthe large ion lithophile elements (Ba , K , Pb) and light rare earth elements, while depleted inof the high field strength elements (Ta and Nb) and heavy rare earth elements. The ratio of Th/Yb(average value of 2.90) and the tectonic environment discrimination diagrams (Y-Zr , Th / Ta-La / Yb) show that the geochemical characteristics of this basalt is similar to the arc volcanic rocks, which are related to the subduction of the oceanic plate, indicating that Ri-Qing-Wei Basin evlolved from rift basin into volcanic arc basin in the late Laiyang period. Above all, the evolution process of Ri-Qing-Wei Basin was co-affected by the delamination of lithospheric root and the subduction of thePaleo-Pacific plate (Zhou et al., 2022). The influence of the magmatic activities on the sedimentary rocks in shallow lithosphere also changed from early indirect participation to late intrusive transformation.

Buried hill types and genetic mechanism in Baiyun Sag, Pearl River Mouth Basin, northern margin of the South China Sea

wei Guan[1*], Lei Huang[1], Chi- yang Liu[1], dong xu wang[2], li li zhang[2], zhe wu[2]
1. department of geology, Northwest University, Xi'an, Shaanxi, CHINA
2. Shenzhen Branch, China National Offshore Oil Corporation, Shenzhen, Guangdong, CHINA
E-mail: cupgw@qq.com

Keywords: South China Sea, Pearl River Mouth Basin, Type of buried hill, detachment fault, Magmatism,Pre-existing fault

The Pearl River Mouth Basin (PRMB) in the northern continental margin of the South China Sea (SCS) is unique and different from the orderly rifted structure of the typical passive continental margin of the Atlantic type. In terms of lithospheric structure and basin structure, the northern SCS is a continental margin with dual properties of poor magma and rich magma. The PRMB was formed and evolved under the background of plate subduction. Affected by the late extension and detachment, magma underplating coupling and strike-slip transformation, the basin structure and buried hill types are diverse.

In this study, based on the interpretation of large-scale contiguous high-resolution 3D seismic reflection volume in the Baiyun Sag, the sag tectonic system and evolution stages are studied. Considering the genetic mechanism and evolution of buried hills, it is divided into three categories: primary type, intermittent transformation type and continuous transformation type, with a total of 15 sub-categories. It is found that detachment, basement pre-existing structure, multi-stage magmatism and late strike slip faults play an important role in controlling and transforming the buried hills.

The geometric and kinematic characteristics of the detachment fault in the eastern Baiyun Sag are revealed for the first time, and the strong amplitude continuous S-reflection structure of the detachment fault is displayed through 3D imaging. The imaging results show that surface has a corrugated structure, which is the sliding track of the overlying block, and the detachment can transform the buried hill reservoir. In addition, the fluctuation of the fault plane was observed along the fault strike, forming a special type of buried hill formed by the detachment of the fault ridge.

Pre-existing structures, especially Pre-Cenozoic faults, have a controlling effect on the formation of buried hills. The influence of preexisting fault activation on the formation and evolution of buried hills is mainly reflected in two aspects. One is the activation of preexisting faults to form low-angle normal faults, which control the types of relay high and clamping block on the detachment fault. The other is differential subsidence caused by multi-phase fault activation, forming horst-type buried hills. The multi-stage activity of fault reversal can form fractured reservoirs of granite on both sides of the fault zone.

Previous studies have found that there are 3 to 4 stages of magmatism in the Baiyun Sag, and multi-stage magmatism forms a new type of volcanic cone. It also has a transformation effect on early buried hills. In addition to causing the early buried hill to be arched again, it will also cause the fault block to rotate and denudate, and even metamorphic core complexes will appear. Multi-stage magmatism enriches the types and evolution of buried hills. For granite buried-hill reservoirs with insufficient exposure weathering and leaching, the extrusion deformation, heat transfer and hydrothermal action caused by magma arching have a transformative effect on buried-hill granite reservoirs.

This study enriches the types of buried hills in extensional fault-depression basins, and provides a basis for the prediction of favorable buried hill areas in deep-water exploration.

Lithology Identification of Volcanic Lava Based on K-means Clustering Algorithm Optimized by Simulated Annealing

Ma Wentao[1], Zhao Ranlei[1*]
1. College of Petroleum and Natural Gas Engineering, LiaoNing Petrochemical University, Fushun city, Liaoning province, CHINA
E-mail: zhaoranlei@foxmail.com

Keywords: Lithologic identification,Optimized K-Means,Simulated annealing algorithm, Volcanic lava,Songliao Basin

Lithologic identification is the basis of volcanic reservoir research, which is affected by diagenetic environment and heterogeneity, logging curve is crossed obviously, the distribution between data sets is uneven, so the commonly used methods of lithologic identification such as K-Means clustering are not precise. This paper proposes an improved method: optimize K-Means clustering by simulated annealing, in view of the fact that K-Means clustering depends on the initial clustering center to easily produce local optimal solutions and simulated annealing has the characteristics of global search. The method is used to train and study 430 groups of logging data (core and rock ore identification data are complete) in Songliao Basin, and the actual logging data of a well in the study area are compared with the traditional K-Means clustering. The results show that the traditional K-Means algorithm has a recognition rate of 70.00%, while the optimized K-Means algorithm has a high lithologic recognition rate of 93.94% and It is significantly higher than the traditional K-means algorithm. In this paper, this method is innovatively applied to the lithology identification of volcanic lava, and the recognition effect is good. It can be used as a new volcanic lithology discrimination method.

The Mesozoic and Cenozoic Structural Characteristics and Genesis of the Gissar foreland thrust belt, in the Eastern Amu Darya Basin

Xin Wang[1*], Xiaoxing Gong[1], Boyong Liao[1], HongXi Li[1], Huiping Xia[1]
1. Research Center for Reservoir Evaluation, CCDC Geological Exploration and Development Research Institute, Chengdu, Sichuan Province, CHINA
E-mail: wangxin_dyy@cnpc.com.cn

Keywords: Gissar thrust belt, structural characteristics, basal detachment, decollement deformation

The Jurassic subsalt carbonate assemblage in the Gissar thrust belt in the eastern Amu Darya Basin is an important hydrocarbon exploration target. The tectonic origin in this area is unclear and complex, which restricts the discovery of hydrocarbon.By comparing regional seismic profiles and analyzing the basement structure of the Gissar thrust belt, the tectonic evolution and genesis of this area are discussed in this paper, on the basis of the description of the Mesozoic and Cenozoic structure frameworks.

The research results show that Gissar thrust belt can be generally described as detachment of shallow basement from southeast to northwest, and decollement - deformation of gypsum-salt layers in Kimmeridgian-Tithonian. In addition, some deformation characteristics , such as basement detachment, subsalt uplifting, and suprasalt passive decollement and deformation are presented as well.Gissar Mountain to the northwest(west-Joramergen structure) structral belt can be divided into root belt→middle belt→frontal belt→hedging belt→recoil belt. Correspondingly the structural style from southeast to northwest can be divided into basement involvement anticline → basement detachment double faulted anticline → basement detachment imbricate anticline → hedging syncline → basement decollement recoil fault anticline.The area has experienced two main tectonic compression since the Late Jurassic. The first compressions, "Middle Gypsum Movement", occured in Kimmeridgian, Late Jurassic. In this tectonic movement, faults in basement and faults formed by Early-Middle Jurassic extension were reversed due to the early response of Late Cimmerian or Neo Cimmerian in western central Asia. The second compressions which constituted the main Gissar thrust belt occurred in Middle Miocene due to the crustal convergence, crustal thickening and lateral flow deformation in Pamir on the east. In this tectonic movement, Gissar thrust belt undergone 4 progressive deformation stages consisting of basal detachment, subsalt uplifting, suprasalt decollement and deformation and finally formed. The detachment between the deep-shallow basement and the slipping adjustment of gypsum-salt layer of the Kimmeridgian-Tithonian vertically, are the two essential controlling factors of the complex structural deformation and transformation of the Mesozoic and Cenozoic in the Gissar thrust belt.

Reservoir Characteristics and formation mechanisms of basement granite from the central uplift of Songliao basin

Weihua Bian[1*], Yuanzhe Li[1], Jinjiao Ji[1], Ningyuan Sun[1], Huafeng Tang[1]
1. College of Earth Sciences, Jilin University, Changchun, Jilin Province, CHINA
E-mail: WeihuaBian@jlu.edu.cn

Keywords: Buried-hill reservoir, Granite, Basin basement, Songliao Basin

The granite buried-hill hydrocarbon accumulation has been discovered worldwide as an unconventional accumulation in recent years. As one of the most important deep accumulation types, the granite buried-hill accumulation has been found in ocean margin basins and some continental basins, and has shown significant hydrocarbon potential in China.The granite is a major lithological component of the basement of Songliao basin. Understanding the reservoir characteristics and formation mechanism is critical for the basement granite to evaluate its potential as a new exploration field. In order to characterize the reservoir features in multi-scales, granite samples were collected from different well cores of the basement, analyzed by thin section, SEM, zircon U-Pb dating, HPMI, NMR, and Micro CT, etc.

The basement granite of the central uplift had crystalized in the Late Jurassic. The lithology is dominated by monzogranite with less plagiogranite. Affected by dynamic metamorphism, mylonitization and schistization are locally serious. Primary pores in granite are limited. The effective reservoir spaces are dominated by secondary pores, including micro-nano erosional pores in feldspar crystals and micro tectonic fractures. The reservoir potential of granite is closely related to the secondary alternation and the types of feldspar. Weathered crust reservoir is more common than internal massif reservoir of granite. The subtype of weathered crust reservoir is dependent on its tectonic position as well as the weathering processes. Due to severe surface erosion and down-slope migration of weathered loose materials, reservoirs on local tectonic highs are fracture dominating reservoirs. Reservoirs on local depressions are featured by fracture and pore dominating reservoir spaces. Fault activity plays an indispensable role in the formation of an internal massif reservoir. Granites close to faults are prone to generate fractures and secondary erosional pores, thus, improving their reservoir capability and enlarging their reservoir potential.

New views of basement and Early Cretaceous strata based on the Continental Scientific Drilling Project-SK2 borehole in Songliao Basin

Youfeng Gao[1*], Pujun Wang[1], Yongkang Yin[1], Haibo Liu[1], Xuejiao Qu[2]
1. College of Earth Science, Jilin University, Changchun, Jilin Province, CHINA
2. School of Petroleum Engineering, Chongqing University of Science and Technology, Chongqing, CHINA
E-mail: gaoyoufeng@jlu.edu.cn

Keywords: Songliao Basin, SK2 borehole, Early Cretaceous, Triassicbasement, volcanic-sedimentary strata

The Songliao Basin (SB) is one of the largest non-marine petroliferous basin and contains nearly complete Cretaceous sedimentary records. The International Continental Scientific Drilling Project of the SB includes the SK1 boreholes (south borehole and north borehole) (Wang et al. 2016), SK2 borehole and SK3 borehole. The SK2 borehole is to obtain continuous terrestrial geological records for the study of greenhouse climate change and basin development. The target strata are the Lower Cretaceous Shahezi, Yingcheng formations, and the basement of the SB (Wang et al. 2017). The depth of the SK2 borehole is 7,018 m. The length of the drilling core is 4,134.8 m, with a core recovery rate of 96.61%.

The lithology of basement in SK2 borehole is mainly andesitic volcanic rocks interbedded with sandstone and conglomerate. The isotopic age of andesite is 242.6 ± 1.5Ma, and the youngest peak age of sandstone is 242.2Ma (Yin et al. 2019); Shahezi Formation is mainly composed of lacustrine clastic rocks intercalated with volcanic ash layer. The age of volcanic ash at the bottom is 118.2 ± 1.5Ma (Liu et al., 2021), and the upper is 113.9 ± 0.9Ma (Yu et al. 2020); The lithology of the lower part of Yingcheng Formation is rhyolite, and the upper part is sandy conglomerate. The age of rhyolite is 112.078 ± 0.067Ma (Wang et al., 2022).

Based on the lithostratigraphy and chronostratigraphy research results of SK2 borehole, there are two new views on the basement and overlying sedimentary rocks of SB. (1) Previous studies indicated the absence of Triassic to Lower and Middle Jurassic strata in northeastern China because of uplift and erosion events associated with the return of geo-synclinal folds and orogenic movement during the Late Permian–Early Jurassic. To date, geochronological studies of intrusive and metamorphic rocks in the basement of the SB have also confirmed Carboniferous and Permian ages for the basement in general (Gao et al., 2007; Pei et al., 2007; Wu et al., 2000). Radiometric dating has been carried out for the entire drilling core of the SK2 borehole. As a result, we have discovered Triassic volcanic-sedimentary strata in the basement. These Triassic strata provide new clues for studying the basin origin and development, and a new target for oil and gas exploration in the SB. (2) A large number of zircon U-Pb ages of volcanic rocks from Yingcheng Formation are distributed in two ranges, 102-108 Ma and 110-121 Ma (Chen et al., 2017). We also dated ages in the volcanic ash and rhyolite of Yingcheng Formation in Xushen 22 borehole. The results are 112.2 ± 1.3Ma and 113.9 ± 1.4Ma, which are equivalent to the ages at the bottom of Yingcheng Formation and the upper part of Shahezi Formation in SK2. It indicates that the Shahezi Formation partially overlaps with the Yingcheng Formation, which is a sedimentary rock stratum that did not receive volcanic material accumulation during the volcanic eruption. This new view is of important guiding significance for oil and gas exploration in the fault depression of SB.

Geochemical characteristics of marble in the Ailaoshan Group and its constrain to the nature of crystalline basement in the Ailaoshan metamorphic complex belt, SW China

Xiaoli Shen[1,2*], Huhu Su[1], Qingxiang Du[1,2]
1. College of Earth Science and Engineering, Shandong University of Science and Technology, Qingdao, Shandong, CHINA
2. Key Laboratory of Depositional Mineralization & Sedimentary Mineral of Shandong Province, Shandong University of Science and Technology, Qingdao, Shandong, CHINA
E-mail: shenxiaolili@126.com

Keywords: Ailaoshan metamorphic complex belt, Yangtze Block, crystalline basement, marble, Paleo-Tethys Ocean

The Ailaoshan metamorphic complex belt, located in SW China, is sandwiched between the Amojiang fault and Red River fault on southwestern margin of the Yangtze Block. The nature of crystalline basement in the Ailaoshan metamorphic complex has been controversial for a long time[1-3]. The Ailaoshan Group in the metamorphic complex belt considered as Neoproterozoic in age contains biotite hornblende gneiss, amphibole plagiogneiss, granite gneiss, augen migmatite, granulite and marble, and it can be divided into four units, including the Xiaoyangjie Formation, Along Formation, Fenggang Formation and Wudukeng Formation from bottom to top. The study on geological and geotectonic property of marble can provide constraints on the nature of crystalline basement[3-5]. The major and trace elements and C-O isotope compositions of marble samples in the Wudukeng Formation were analyzed to constrain the genesis and tectonic significance of the Ailaoshan Group. The major elements show the protoliths of marble samples are dolomite and dolomitic limestone. The marble samples are obviously enriched in large ion lithophile elements, such as Sr and Ba elements, and they have weak depletion of high field strength elements, such as Nb, Ta, Zr, Hf and Th elements with negative Eu anomaly. The chondrite normalized REE diagram and the LREE/HREE ratios ranging from 5.31 to 9.48 suggest the fractionation of LREE and HREE. The δ^{13}CPDB and δ^{18}OSMOW of marbles range from 1.36‰ to -1.43‰ and 17.45‰ to 23.94‰, respectively, indicating that the marble samples are marine carbonate rocks instead of igneous carbonatites suggested by previous studies. The salinity formula $Z=2.048 \times (\delta^{13}CPDB + 50)+0.498 \times (\delta^{18}OPDB + 50)$ was widely used to determine the sedimentary facies, and the Z data in the study area ranges from 117.19 to 126.59, indicating that marine carbonate rocks experienced weathering, leaching and metamorphism. Previous studies showed that the main peak ages of detrital zircons from marbles from the Along Formation in the Gasa-Mosha area in the Ailaoshan metamorphic complex zone concentrate at 424-550 Ma and 700-876 Ma[3-5], which indicated that some of the sediments were sourced from the Paleo-Tethys Ocean in the Paleozoic. The identification of marine sedimentary strata suggests that the Ailaoshan Group not only witnessed the assembly and breakup of the Rodinia supercontinent in Neoproterozoic [1-2], but also was affected by the Paleo- Tethys Ocean in the Paleozoic. Therefore, the Ailaoshan Group, whose protoliths contain Neoproterozoic magmatic rocks and Paleozoic sedimentary rocks, has obvious pro-Yangtze tectonic properties, rather than be considered as Precambrian crystalline basement of the Yangtze Block.

Micropore characteristics of pyroclastic lava of Yingcheng Formation in the Yingshan Fault Depression in the Songliao Basin

JinJiao Ji[1], Weihua Bian[1,2*], Yuanzhe Li[1], Pujun Wang[1,2]

1. College of Earth Sciences, Jilin University, Changchun, Jilin province, CHINA

2. Key Laboratory of Mineral Resources Evaluation in Northeast Asia, Ministry of Natural Resources, Changchun, Jilin Province, CHINA

E-mail: WeihuaBian@jlu.edu.cn

Keywords: pyroclastic lava,tight reservoir,microstructure,pore type, Yingcheng Formation, Yingshan Fault Depression

The Yingshan fault depression is one of the most proliferous depocenters of the Songliao Basin, which is the main supplementary area for deep natural gas exploration to Xujiaweizi fault depression. Industrial gas flow has been discovered in the volcanic reservoir of early Cretaceous Yingcheng Formation. The volcanic reservoirs are mostly tight reservoirs with low porosity and low permeability. The lag in the research on their pore structure and influencing factors has affected the effective exploration and development. In order to qualitatively and quantitatively characterize micropore characteristics, the pyroclastic lava samples which are tuff lava but physical properties are obviously different from Yingcheng Formatio have been analyzed based on core observation, thin section identification, FE-SEM, LTNA, constant-rate mercury intrusion, HPMI, NMR, and micro-nano CT. The pyroclastic lava is mainly welded tuff, which has the characteristics of ultra-low porosity and permeability and complex pore structure. The reservoir space types are mainly devitrification pore, feldspar dissolved pore, and illite intercrystalline pore. The devitrification pore provides about 66.8% total pore volume, its shape is mostly honeycomb, evenly distributed, and its pore diameter is 1 ~ 10 μ m. It shows good spatial connectivity in three-dimensional space. The feldspar dissolved pore has the potential as storage space for oil and gas, but it is too isolated to establish an effective communication network. The main performance of illite is filling pores to damage the physical properties of the reservoir. The complete filling of macropores or sudden shrinkage of pore size in the illite-enriched part leads to an "ink bottle " pore combination. The intercrystalline pores of illite provide an additional 13.5% total porosity as a specific compensation for pore filling. The devitrification is vital to improving the reservoir's physical properties of tuff lavas. The vitric-dominated acid tuff lavas is prone to devitrification due to the high content of SiO_2 and glassiness, thus, it has a better micropore structure. The entire micron-nano scale quantitative characterization of pore structure of tuff lava reservoir has been preliminarily realized, which will benefit the further research on pyroclastic hydrocarbon reservoir.

Stages of the sediment cover formation in the Canada Basin, Arctic Ocean

Georgii Ovanesyan[1,2*], Alexey Piskarev[1,2], Vasily Savin[1]
1. Department of the Marine Seismic Exploration, Gramberg All-Russian State Research Institute for Geology and Mineral Resources of the Ocean (VNIIOkeangeologia), St. Petersburg, RUSSIA
2. Institute of Earth Sciences, St. Petersburg State University, St. Petersburg, RUSSIA
E-mail: goshovan@gmail.com

Keywords: Arctic, Canada Basin, seismic velocity distribution, 3d geophysical modelling, tectonics

The data of 145 refraction soundings obtained in the course of the American-Canadian studies of the Canada Basin in 2007-2011 were analyzed. The data were published (Chian, Lebedeva-Ivanova) as a digital atlas in 2015.

The analysis of the sedimentary cover is based on the dependence of the P-wave velocity in clastic rocks on the depth and age (Faust, 1951). A database has been compiled, in which for each of 145 buoys the depth and thickness of sediments of the Miocene, Oligocene, Paleogene (Paleocene-Eocene), Cretaceous and Jurassic ages are determined. The calculated data show that the reference horizons of the sedimentary cover of the Canada Basin have an age of: R10 – about 12 Ma; R30 – 23-25 Ma; R40 – 56-65 Ma. Note that our estimation of the R30 horizon age differs significantly from the generally accepted age (41 Ma).

An analysis of the thickness and velocity distribution in the crystalline part of the Earth's crust and the subsequent joint analysis of seismic and gravity data made it possible to construct a 3D model of the earth's crust in the Canada Basin. With the exception of the southwestern part, the crust of the Canada Basin is represented by oceanic-type crust formed in several stages. The area characterized by magnetic anomalies of the northwest direction, apparently, is part of the Paleopacific Ocean (Izanagi Plate), cut off from the Pacific Ocean in the Early Cretaceous. Sediments attributable to the Jurassic age occur everywhere at the base of the sedimentary cover in this extensive area. And only in the southeastern part of the basin, which at the Jurassic/Cretaceous time boundary was located closer to the spreading axis between the Izanagi and Farallon plates, there are no Jurassic sediments at the base of the sediment sequences.

In the central part of the Canada Basin, a Cretaceous zone of rifting and limited spreading is determined. Its axial zone is marked by an extended along 140 W gravity minimum.

In the northern part of the Canada Basin, in a number of buoys sediments older than the Cenozoic are not identified in the sequences. The upper part of the crystalline crust has low P-wave velocities, and a thick crust-mantle layer is noted in the lower part. All this is characteristic of the oceanic crust whose age is not older than the Paleogene.

Sedimentary strata and the rift valley position along Gakkel Ridge's segments

Georgii Ovanesyan[1,2*], Alexey Piskarev[1,2], Valery Kaminsky[1], Victor Poselov[1], Artem Kireev[1], Vasily Savin[1], Oleg Smirnov[1], Daria Elkina[1], Dmitry Bezumov[1]

1. Department of the Marine Seismic Exploration, Gramberg All-Russian State Research Institute for Geology and Mineral Resources of the Ocean (VNIIOkeangeologia), St. Petersburg, RUSSIA
2. Institute of Earth Sciences, St. Petersburg State University, St. Petersburg, RUSSIA
E-mail: goshovan@gmail.com

Keywords: Arctic, Gakkel Ridge, rift valley, bathymetry, seismic surveys

Many cross-sections of the Gakkel Ridge and its rift valley were made using a profiler and seismoacoustic profiling during 2019-2020 expeditions. New data, coupled with the results of seismic surveys in 2011-2015 made it possible to reveal the features of the morphology of various parts of the ridge and its rift valley.

The slope gradients and seismic data reflect the subdivision of the Gakkel Ridge and its rift valley into three segments. In the western part, west of 75° E, the width of the ridge is 180-210 km. The rift valley runs approximately in the middle of the Gakkel Ridge. The relief of the ridge looks strongly dissected. The small areas of the seabed, on which the presence of sedimentary strata with a thickness of more than 10 meters, were recorded.

East of 75° E the rift valley is shifted to the southwestern margin of the ridge. The area of ocean floor with gentle slopes increases, occupying more than half of the total area of this segment of the Gakkel Ridge, the width of which varies within 105-130 km. Sedimentary strata are recorded in extended sections of the section, and in some places their thickness reaches more than 1 km.

Finally, a sharp change in the nature of the rift valley occurs south of the giant caldera (Piskarev and Elkina, 2017) located on the continuation of the Gakkel Ridge near the point with coordinates 81° N, 120° E. The rift valley turns to a graben of several hundred meters depth verging towards the Laptev Sea shelf. Faults forming the graben's walls are traceable deep into the thick (up to 4-5 km) sedimentary sequence, and, according to the data, the Cretaceous sediments constitute the lower layers.

Structure of the sedimentary strata in transition zone Laptev Sea shelf – Eurasian Basin

Georgii Ovanesyan[1,2*], Alexey Piskarev[1,2], Artem Kireev[1], Vasily Savin[1], Daria Elkina[1]
1. Department of the Marine Seismic Exploration, Gramberg All-Russian State Research Institute for Geology and Mineral Resources of the Ocean (VNIIOkeangeologia), St. Petersburg, RUSSIA
2. Institute of Earth Sciences, St. Petersburg State University, St. Petersburg, RUSSIA
E-mail: goshovan@gmail.com

Keywords: Arctic, Laptev Sea, Eurasian Basin, 3d geophysical modelling, gravity anomalies, earth crust structure

Over the past decade, a number of expeditions have collected data, that greatly detailed our knowledge of magnetic and gravity anomalies, structure of the sedimentary cover and basement of the region located south of 81°N, where the rift valley is interrupted by such a specific formation as a giant (80x45 km) caldera.
A poor quality of aeromagnetic observations does not allow to reliably correlate magnetic anomalies in the region. At the same time, a two-dimensional Fourier analysis of magnetic anomalies in the Eurasian Basin termination area shows that, with the exception of a narrow zone along the line of the present-day axis of the rift graben, the predominant direction of magnetic anomalies is east-northeast, parallel to the shelf margin.
Analysis of the probable age of seismic horizons, correlation with sections of the sedimentary strata of the Laptev Sea and the Taimyr shelf, analysis of the distribution of velocities in sedimentary strata with depth shows that Cretaceous, and, probably, Late Jurassic sequences occur at the base of the sections of sedimentary strata in the termination areas of the Nansen and Amundsen Basins.
The most important features of the new 3D geophysical model are the extension of the West Laptev Basin to the northwest into the Nansen Basin, continuation of the East Laptev horst to the north to the junction with the Gakkel ridge and the presence of a basement uplift in the termination area of the Amundsen Basin, overlain by Neogene deposits. On the map of the thickness of the Earth's crust blocks with a typical continental crust with a thickness of more than 30 km are clearly distinguished. In the southeast, this is the Kotelny massif, where the total thickness of the Earth's crust of 32-33 km was established according to the analysis of converted earthquake waves. An increased thickness of the earth's crust is observed on the Taimyr shelf and on the southern margin of the Laptev Sea, near the northern boundary of the Siberian Platform. The entire shelf area within the West Laptev Basin, where the thickness of the sedimentary cover reaches 14 km, is characterized by an extended thinned continental crust up to 20–22 km thick.

Study on tectonic regime change and sedimentary environment of Late Paleozoic in Junggar Basin

Bang An[1*], Weifeng Wang[1], Baogang Li[1], YIfei Sun[1], Xin Li[1]
1. School of Geosciences, China University of Petroleum(East China), Qingdao, Shandong Province, CHINA
E-mail: baan4717@163.com

Keywords: tectonic regime change, sedimentary environment, Late Paleozoic, Junggar Basin

The late Paleozoic in Junggar Basin mainly experienced two periods of tectonic regime change, including compression-extension type at the end of Carboniferous and extension-compression type at the end of Early Permian. The basin entered the post collisional extensional tectonic environment in the Late Carboniferous, and the water body in the basin is relatively shallow, mainly composed of marine land transitional facies and shallow marine facies. The tectonic regime change at the end of Carboniferous made the basin complete the ocean continent transformation process and enter the intraplate tectonic environment. The regional tectonic unconformity (C / P) formed between the Carboniferous and the overlying Permian is the stratigraphic response of this tectonic regime change, and an obvious thrust structure was formed around the basin. The tectonic regime change at the end of the early Permian brought the basin into a compressive tectonic environment. From the perspective of stratigraphic filling characteristics, the lower part of the lower Permian is generally characterized by volcanic rock coarse clastic rock assemblage, and the upper part is dominated by dolomitic rock fine clastic rock assemblage. This change in sedimentary sequence reflects the transition of the basin from a strongly extended fault depression to a relatively stable fault depression; The middle and Upper Permian changed from fine clastic rock to coarse clastic rock in the upper part. This reverse cycle sedimentary sequence with grain size from fine to coarse from bottom to top represents the process of compression uplift in which the water body gradually becomes shallower.

Diachronous accretionary history of East Junggar arc: insights from petrographic and geochronological studies of the Permian-Lower Triassic sandstones from southern and northern Bogda Mountains, NW China

Sixuan Wu[1*], Wan Yang[1]

1. Geosciences and Geological and Petroleum Engineering Department, Missouri University of Science and Technology, Rolla, Missouri, UNITED STATES

E-mail: swtxb@mst.edu

Keywords: Central Asian Orogenic Belt, provenance, detrital zircon, petrography

North Tianshan Arc has been suggested to contribute sediments to the greater Turpan-Junggar basin since the late Paleozoic. However, the timing of the amalgamation of the Central Asian Orogenic Belt is constrained to late Carboniferous – middle Permian, implying that the other adjacent terranes have the potential to provide detritus. We conducted high-resolution petrographic and detrital zircon geochronological studies of Permian-Lower Triassic sandstones from measured sections in Zhaobishan (ZBS) and Dalongkou (DLK) in the south and north Bogda Mountains, respectively. Kungurian samples from ZBS have a main peak at 290-310 Ma of detrital zircon ages, suggesting North Tianshan (NTS) arc is the source. Guadalupian samples in both areas have the main peak from 310-330 Ma, indicating a common NTS provenance. Additionally, the ZBS sample has unique peaks at 390-500 Ma and 1.5-2.0 and 2.6-3.0 Ga that suggest the East Junggar arc to the east is a source, and age spectra of the Wuchiapingian-mid Olenekian samples are similar with that of Guadalupian sample. Age signature of the East Junggar arc is recorded in the DLK Wuchiapingian-mid Olenekian samples, suggesting the East Junggar source appeared in the late Permian in DLK. Besides, increasing volcanic lithics in DLK's late Permian-Lower Triassic sandstones suggest a magmatic arc signature for the source area, which is consistent with the detrital zircon results. This study confirms that the NTS has been a persistent source since Permian and proposes that the East Junggar accreted to the Junggar block diachronously by the northward closure of Kelameili Ocean. It provides constraints on the timing of amalgamation of the southern CAOB from a sedimentary perspective.

Control of tectonic-paleogeomorphology on deposition in the South Lufeng area of the Pearl River Mouth Basin

Mengya Jiang[1,2], Dongxia Chen[1,2*]

1. State Key Laboratory of Petroleum Resources and Prospecting, China University of Petroleum (Beijing), Beijing, CHINA

E-mail: lindachen@cup.edu.cn

Keywords: Fault activity, paleogeomorphology, sedimentary system, Paleogene, Lufeng Sag, Pearl River Mouth Basin

The Paleocene in the Lufeng South area has a complex spatial distribution of depositional systems, influenced by pre-depositional paleogeomorphology and multi-period tectonic activities. To clarify the role of tectonic and palaeomorphic control on the sedimentary body and effectively guide the lower oil and gas exploration. The Paleogene paleogeomorphic pattern in the southern Lufeng area was restored by the impression method, and the temporal and spatial evolution laws of the main faults were clarified. The results show that the supply capacity of the source area and the accommodated space of the lake basin are coupled to control the deposition scale. The slope controlled by the combination of paleogeomorphic assemblage and the activity of the main fault determines the sedimentary type. Braided river deltas developed stably in the long-axis gentle slope belt of the lake basin, while the short-axis sedimentary system changed from fan delta to braided river delta in response to the change of dominant fault strength from strong to weak. The tectonic slope fold zone controls the spreading pattern of the sedimentary sands. The cliff type of the single-fault steep slope zone is controlled by the boundary fault, with large fault throw and steep section, and develops wedge-shaped sand bodies. The multi-level fault-step zone provides the driving force for the advancement of the sedimentary system, and the sand body extends for a long distance.

Upper Jurassic-Lower Cretaceous Clastic Dykes in southern Tibet: Characteristics and Paleogeographic Significance

Huifang Guo[1], Xi Chen[1*]
1. School of Earth Sciences and Resources, China University of Geosciences, Beijing, CHINA
E-mail: xichen@cugb.edu.cn

Keywords: Jurassic-Lower Cretaceous, Clastic dykes, Southern Tibet, Northern Indian margin, Earthquakes

A clastic dyke is a tabular body of clastic sediments that fills open fissures across strata, and may provide important information on regional depositional processes and tectonic activity. Clastic dyke swarms are widely exposed in the Jurassic-Lower Cretaceous sedmentary strata in the Gucuo, Wölong and Jixiog areas of the Tethyan Himalaya in southern Tibet.

The Jurassic clastic dykes are composed of medium to coarse-grained quartz sandstones, which are sub-vertical. The length and width range from 5 to 50 m and from 10 to 50 cm, respectively. The U-Pb age spectra of zircon grains are similar to those in Upper Jurassic sandstones (Menkadun Formation). Petrographic analyses show that the dykes are similar to the overlying strata and the quartz grains are more than 90%, indicating that the dykes were derived from overlying strata and formed by passive deposition of unconsolidated clastic material into pre-existing fissures from above. We conclude that the clastic dykes may be related to a large-scale contemporaneous fractures formed during the Jurassic.

The Lower Cretaceous clastic dykes are composed of fine to medium-grained volcaniclastic sandstone and distributed along a series of normal faults. The length and width of clastic dykes range from 5 to 50 m and from 20 to 150 cm, respectively. The U-Pb age spectra of zircon grains are similar to those in Lower Cretaceous sandstones (i.e., Wölong vocaniclastics) and display a youngest peak at 124.3±2 Ma. Petrographic analyses show that the dykes contain more volcanic lithic fragments and less feldspar grains than the overlying strata, indicating that the dykes were derived from underlying strata and injected upward along faults. Their formation may be explained by a fault-induced clastic-dyke model: normal faults provided conduits for clastic material injected from the underlying unlithified sandstones which were undergoing re-fluidization owing to over-pressure. We infer that the liquefaction of underlying strata was induced by earthquakes associated with the extensive magmatic activity and regional extension that affected the Indian passive margin of Neotethys during the Early Cretaceous.

We thus infer that the Tethyan Himalaya had been in the regional extension during the Jurassic-Early cretaceous. The Kerguelen plume was likely suitably placed to cause weakening of the basal Indian continental lithosphere since the Late Jurassic. In the Late Jurassic, the farther from the Kerguelen plume resulted in a lower intensity of plate extension, and only a large number of contemporaneous fractures in the surrounding rocks to form the neptunian dykes. Until the Early cretaceous (~120Ma), the Kerguelen plume activity reached its peak, and the plate extension was of high intensity, leading to a large number of volcanic and seismic activities, forming the injection dykes.

Tectonic setting and evolution of granite basement in Qiongdongnan basin, northern margin of South China sea: evidence from geochronology, geochemistry and apatite fission track

Wang Yan Quan[1], Wu Qi Lin[1*], Yu Jun Feng[1], Hou Ying Ling[1]
1. School of Petroleum Engineering, Guangdong University of Petrochemical Technology, Maoming, Guangdong, CHINA
E-mail: 86800051@qq.com

Keywords: granite basement, geochronology, geochemistry, tectonic setting, apatite fission track, Qiongdongnan basin

The lithofacies, zircon chronology, geochemical and tectonic environment of the Songnan low uplift granite in Qiongdongnan basin, northern South China Sea are analyzed. The results show that the buried hill lithology is mainly composed of granodiorite and monzonitic granite. The zircon U-Pb dating results of LA-ICP-MS are 228.6 and 243.7 Ma, which is the product of Triassic magmatic activity. The rock mass belongs to high-k calc alkaline series, with high content of SiO2(54.94%-79.71%), moderate alkali (3.53%-6.43%), Al2O3(9.82%-18.23%), CaO(1.24%-9.55%) and MgO(0.37%-2.28%). The A/CNK values range from 1.09 to 2.13, which are both aluminum and peraluminous granites. The rocks are generally rich in large ion lithophile elements such as K, Rb and Th, depleted in high field strength elements such as Ta, Nb, Ti, and show moderate to weak negative Eu anomalies (δ Eu= 0.50~0.85). Petrographic and geochemical characteristics show that the granodiorite is aluminum I-type granite, and the monzogranite is peraluminous S-type granite, which was formed by partial melting of sediments in the crust. On the other hand, comprehensive analysis indicates that the granite has the characteristics of post-collisional granite, formed in extensional tectonic environment. It is related to roll back or the reverse extension after collision between South China and Indosinian blocks. In order to further study the regional tectonic evolution, cryogenic thermochronology, especially apatite fission track is used to restore the thermal history of the granite basement. The subsidence history is simulated by the thermal history with the fission track data. The multiple annealing model of Ketcham et al. (2007) is used for simulation. The inversion results are realized by HeFTy software (version 1.9.1). The results show that there were three subsidence and three uplift under the background of regional extensional tectonics since the late Cretaceous. The three episodes of subsidence were late Cretaceous subsidence (100-80 Ma), late Eocene-Oligocene subsidence (55-45 Ma) and Late Oligocene-early Miocene subsidence (32-20 Ma). All the three episodes of subsidence were rapid ones. The three uplift periods were late Cretaceous to Eocene (85 ~ 55Ma), middle Oligocene (45 ~ 32Ma) and middle Miocene to present (20Ma-). The first two were rapid subsidence, the last one can be divided into two periods, (20-10Ma) is the slow uplift period, and the uplift speed has accelerated since 10Ma.

Evolution of tectonic geomorphology and provenance-sedimentary response of Cretaceous Qingshuihe Formation in central Junggar Basin

ZhenJun Zhu[1*]
1. School of Ocean Sciences, China University of Geosciences, Beijing, Beijing, CHINA
E-mail: 3011200003@cugb.edu.cn

Keywords: Junggar Basin, Qingshuihe Formation, Che-Mo paleo-uplift, Tectono-geomorphology, Provenance, Depositional systems

Provenance-sedimentary filling varies in different sites of basins corresponding to the evolution of tectonic geomorphology. Taking the Lower Cretaceous Qingshuihe Formation (K_1q) in the Moxizhuang-Yongjin area of the Junggar Basin as an example, we analyzed the sequence stratigraphy, provenance, depositional system, and the geomorphic evolution via integrated 3-D seismic data, outcrop, well logging, core, thin section and heavy mineral analysis. The results show that K_1q develops a 3rd order sequence in which the 1st member of K1q (K_1q^1) develops lowstand system tract (LST) and lacustrine transgressive system tract (TST), and the 2nd member (K_1q^2) develops high-stand system tract (HST). In the late Jurassic, the Chepaizi-Mosuowan (Che-Mo) paleo-uplift, in the centre of the study area, was strongly eroded, resulting in local topographic highs that attribute sediments to Paleo-Hammock. The Yanshan II movement resulted in the rapid subsidence of the basin and the study area submerged under the water and started to receive sediments. During the LST period, influenced by the residual Che-Mo paleo-uplift, the sediments from the northeast and northwest were deposited in the topographic lows, developing shallow braided river deltas, with successive underwater distributary channels developed. The earlier stage of continuous sedimentation of braided river deltas gradually reduced the residual rough topography, resulting in a wide and gentle slope which tilting to the south. During the TST period, rapid lacustrine transgression occurred from the southeast to the north, resulting in the deposition of shallow lacustrine that mainly featured mudstone and locally developed beach-bar sandstone. During the HST period, the climate gradually changed from arid to humid and the study area mainly deposited shoal-water meandering river delta which featured limited subaqueous distributary channels in the inner front of the delta and successive sheet sand in the outer front of the delta. The evolution of tectono-geomorphology controlled the provenance changes and the sedimentary filling, which provide an excellent example for similar basins worldwide.

Volcanic-sedimentary succession and reservoir-seal assemblage in Junggar Basin : A case study of Carboniferous volcanic reservoir in Zhongguai uplift

Jianing Xie[1], Zhonghong Chen[1,2*]
1. School of Geosciences, China University of Petroleum, Qing Dao, Shan Dong, CHINA
2. College of Resources and Environment, Yangtze University, Wu Han, Hu Bei, CHINA
E-mail: hongczh@163.com

Keywords: Junggar basin, Carboniferous, Volcanic sedimentary sequence, reservoir-seal assemblage

The Junggar basin, located in northern Xinjiang, is a large petroliferous basin and a major field of volcanic petroleum development. This paper reveals the characteristics of the volcanic sedimentary sequence and petroleum reservoir-seal assemblage in the north of the Zhongguai uplift and defines the petroleum potential in this area based on data from outcrop investigation, drilling and logging comparison, core observation, and seismic interpretation. The results show that the Carboniferous volcanic activity in this location was intense, with multi-stage eruptions forming the volcanic rocks. The lithology consists primarily of medium-basic volcanic lava and pyroclastic rocks that range in pH from basic to acidic, but are primarily medium-basic. Rock types mainly include volcanic breccia, tuffaceous sandy conglomerate, andesite, basaltic andesite, and dacite. In this area, typical volcanic sedimentary sequences have formed. The lower part of the sequence is volcanic rock, and the upper part is sedimentary rock, which is characterized by the interbedding of volcanic rock and sedimentary rock. The sand-mud interbedding (primarily mudstone)–glutenite–mudstone–medium basic volcanic rock succession is mostly developed. Volcanic reservoirs come in a variety of shapes and sizes, with the most common lithologic reservoirs being “pyroclastic rock, lava, and tuffaceous sandy conglomerate”. Dissolution pores, pores, and microfractures make up the reservoir pores, forming a fractured pore dual medium reservoir dominated by pores. The reservoir has low physical qualities, falling into the medium porosity and low permeability categories. Porosity and permeability range from 5.0% to 18.1% and 0.011mD to 477mD, respectively, with an average of 9.6% and 0.477 mD. The Triassic Karamay lower formation, the Permian upper Urhe formation, and the Jiamuhe Formation from west to east are the carboniferous overlaying layers in the north of the area in terms of caprock. Among them, a set of stable lacustrine mudstones has developed in the third member of the Permian Urhe formation, which is an important regional caprock in the area. Due to the obvious enormous mudstone thickness and thin sand layer in the sand mud interbedding of the second member of the Urhe formation and the Triassic Karamay formation, it can also be used as local caprock. As a result, several well-configured reservoir cap assemblages in the Carboniferous can be found in the northern part of the area, including andesite–volcanic breccia–tuff assemblages in the overflow facies area, mudstone–tuff glutenite–fused breccia assemblages in the volcanic sedimentary facies area, and mudstone–tuff glutenite–tuff assemblages in the volcanic sedimentary facies area. And the sand–mud interbedded (mainly mudstone)–dacite–tuff assemblage, among which the mudstone–volcanic breccia–tuff assemblage is the most favorable in the overflow facies development area.

Study on the Geochemical Characteristics of Highly Differentiated Granites in the Xiaozhushan, Qingdao, Shandong Province

Ruiyang Liu[1], Yaoqi Zhou[1*]
1. School of geoscience, China university of petroleum, Qingdao, Shandong, CHINA
E-mail: zhouyq@upc.edu.cn

Keywords: Xiaozhushan, Petrogeochemistry, Highly differentiated granite, Laoshan period

The Xiaozhushan is located in the northern Jiaonan Uplift of the Sulu orogenic belt`s eastern extension in eastern Shandong Province, adjoining the Wulian-Qingdao fault. The Late Yanshan Cretaceous Qingshan stage igneous rocks are widely exposed in this area, appearing in rock stock, laccolite and batholite. The Xiaozhushan rock are mainly composed of Laoshan granite, similar to the Laoshan potassium granite. The sample rocks are dense, solid and light in colour. The rock types are alkaline granite, syenogranite and granite porphyry with clear contact zone with the surrounding rock and mafic inclusion. Based on the previous study, researching granite in the Lingzhushan National Forest Park, typical samples were obtained for the whole rock major elements, trace elements and rare-earth elements, U-Pb zircon dating, X-ray diffraction analysis and X-ray fluorescence spectrum analysis. The results are as follows: feldspar veins were found on granite, and the minerals in rocks are plagioclase, potash feldspar, cordierite and aragonite. Automorphic quartz, muscovite, sericitization and chloritization are developed under the microscope. The alteration is obvious and speculating that it may be the late hydrothermal transformation. As for the geochemical characteristics, the samples are all high-silica granites (SiO2>75%), with high total alkali content (Na2O+k2O>8.5), belonging to the high-potassium calc-alkaline series. The negative Eu anomaly is obvious (δEu=0.4-0.5), and the aluminim saturation index (A/CNK>1.2) reflects the characteristics of high differentiation. According to the calculation of CIPW standard minerals, the differentiation index (DI) is above 90, and the saturation temperature of zircon is between 832 °C to 875 °C. Zircon trace elements show the ore-bearing property of highly differentiated rocks (Eu/Eu*=0.03-0.27; Ce/Ce*=1.1-149). Geochronology shows that the granite age is 117±3 Ma, which is a typical Early Cretaceous Laoshan granite. Different types of granites have different geochemical characteristics. Combined with the diagram of 10000Ga / Al-Zr, it can be indicated that the granites in this area are mixed granites of type I and type S. It provides a basis for studying geochemical characteristics of Late Yanshanian high differentiated granites in eastern Shandong province.

Keywords: Junggar basin, Deep oil and gas exploration, Carboniferous, volcanic islands and reefs

Carboniferous volcanic eruptive rocks, basalt, pyroclastic rocks, tuff and sedimentary tuff are widely distributed in the deep layer of Junggar basin. However, limestone lenses or limestone intercalations of different sizes often appear in the strata dominated by pyroclastic rocks of Upper Carboniferous, with a thickness of more than 10-100 meters and an area of 0.1-tens of km^2, which are discontinuous. Predecessors explained that they represent a kind of marine carbonate bioclastic beach deposition. These limestone bodies do contain a large number of shell biological fragments, coral fragments, various calcareous bioclasts, and complete brachiopod shells. The field observation is indeed similar to bioclastic beach facies, represented by Shiqiantan formation and Qijiagou formation.

In recent years, through continuous observation and reinterpretation of several similar stratigraphic groups and sections, we found that the construction of volcanic rocks with limestone with similar sedimentary characteristics has the sedimentary characteristics of volcanic islands and reefs: one of the most remarkable features is that collapsed volcanic breccia and blocks are found in reef limestone, the contact boundary between limestone and volcanic rock is very irregular, and limestone and volcanic rock are irregular and interbedded with unequal thickness, The spatial shape is complex, which is completely different from the characteristics of normal carbonate platform, platform margin beach or platform inner beach.

Combined with the structure characteristics of its seismic profile, it is identified that it may be volcanic islands and reefs in the rift valley on the continental margin of marine facies. Various volcanic rocks and pyroclastic rocks controlled by ancient volcanic cones are developed in the stage of intense volcanic activity. In the quiet period of volcanic activity, the volcanic islands are denuded, collapsed, submerged near the sea level, and coral reefs are developed on them. The growth and transformation of reefs are controlled by the rise and fall of sea level and waves, or collapsed, or spread out, The formation of bioclastic beach is more consistent with the model of volcanic islands and reefs. The macro reservoir physical properties are excellent. It is very similar to volcanic islands and reefs and volcanic atolls in modern tropical ocean, but the Junggar basin was unlikely to be a far ocean environment at that time. The biological reef limestone of Carboniferous-Permian system is of great significance for oil and gas exploration all over the world, and there are many examples of large and giant reef limestone oil fields. At present, several possible volcanic islands reef structures with good preservation conditions have been preliminarily identified.

Alteration products and diagenetic evolution characteristics of tuffaceous clastic rocks in Paleogene Wenchang Formation in Lufeng and Huizhou area

ding lin[1*]

1. RESEARCH INSTITUTION OF CNOOC. LTD. SHENZHEN BRANCH, CNOOC.LTD SHENZHEN BRANCH, SHENZHEN, GUANG DONG, CHINA

E-mail: dinglin@cnooc.com.cn

Keywords: Lufeng and Huizhou area, Wenchang Formation, Tuffaceous clastic rock, Alteration products, Apatite

Different authigenic minerals precipitated during the alteration of tuffaceous components in clastic rocks can significantly improve or destroy the reservoir space.The authigenic mineral types, characteristics and diagenetic evolution process of tuffaceous alteration in clastic rock oil and gas reservoirs in different structural zones in the study area are deeply analyzed by comprehensively using the technical means of core analysis, microscopic observation (cast thin section, scanning electron microscope, cathodoluminescence,et al), lithogeochemical analysis and testing in Lufeng and Huizhou area.The results show that 1) the tuffaceous alteration products that have an important impact on the reservoir space of Wenchang Formation in the study area are mainly chlorite, laumontite, kaolinite, apatite and authigenic quartz, and the types of alteration products are closely related to the properties of synsedimentary volcanoes; 2) There are three types of tuffaceous in the study area: acidic, medium basic, P/Ca
-rich alkaline. The acidic tuffaceous is mainly in-situ alteration, which can produce authigenic kaolinite and authigenic quartz; Medium basic tuffaceous is prone to in-situ Laumontite, and the precipitation of authigenic chlorite and authigenic quartz may occur at the same time of dissolution and pore formation; For alkaline tuffaceous matter rich in P and Ca, on the one hand, it is eroded into plate columnar apatite in situ. In the process of further dissolution, apatite will also dissolve and precipitate to form plate strip or fibrous apatite; 3) The early chlorite rim structure can protect the primary pores, and the laumontite cement can destroy the primary pores in the early stage, but the dissolution pores generated by later dissolution can improve the physical properties of the reservoir. Apatite authigenic minerals retain a large number of intergranular pores, and secondary dissolution can occur to form a large number of intergranular dissolution pores, while authigenic kaolinite and quartz are mostly filled in feldspar and tuffaceous dissolution pores to destroy the reservoir pores.Studying the alteration products and diagenetic process of tuffaceous clastic rocks in Wenchang Formation in different structural zones in Lufeng and Huizhou area can clarify the quality difference mechanism of tuffaceous oil and gas reservoirs and provide a scientific basis for high-quality reservoir prediction.

The Research on Control Factors of Sedimentary System by Metamorphic Core Complex Tectonism in Kaiping Sag of Pearl River Mouth Basin

Ning Jiang[1*], Zhaoming Chen[1], Shuiming Yu[1], Jianyao Wu[1], Zhongliang Gao[1], Chujing Zhang[1]
1. Shenzhen Branch of China National Offshore Oil Company, China National Offshore Oil Company, Shenzhen, Guangdong, CHINA
E-mail: jiangning@cnooc.com.cn

Keywords: Kaiping, metamorphic core complex,sedimentary systems,Paleogene

Kaiping sag, located in the Pearl River Mouth basin, is the emerging hot spot of exploration in recent years, which developed rich types of continental sedimentary system in Paleogene. It is difficult to accurately identify the morphology and distribution characteristics of favorable source rocks and reservoirs for deep Paleogene, due to multiple tectonic periods, rapid changes of sedimentary systems, multi-periods of volcanic rock development and low-exploration area. The analysis of regional seismic data and limited Paleogene drilling data, shows that the uplift of the middle (lower) crust caused by the metamorphic core complex, controls the evolution of the fault system in the Kaiping Sag. The Wenchang Formation can be divided into two stages: the tensile fracture stage and the detachment fracture stage. During the tensile stage, in response to the regional extension of NW-SE trending, the faults are mostly NE direction and cease to be active at a later stage; during the detachment stage, in response to the uplift of metamorphic core complex, the faults are mainly rootless near EW direction and most faults are continuously active in Enping stage. In the depositional period of Wenchang Formation, due to the uplift of metamorphic core complex, the terrain became gentle, the valley-slope break zone was developed visibly in the northern sag. A series of developed paleo-valleys, indicating that the provenance has entered the middle of the sag from the steep slope zone. In the south and southeast of the depression, the topographic relief becomes slow, the scale of basement gullies become smaller, and the southeast is mainly supplied by scattered small gullies. Influenced by detachment faults, large fan deltas were in the northern sag and braided river deltas formed in the south slope of Kaiping sag, which were favorable zones for reservoir rocks formation.

Evolution of Mesoproterozoic continental rift : Evidence from Volcanic-sedimentary cycles of the Xiong 'er Group in southern North China Plate

Jie Chen[1,2], Minghui Yang[1,2*]

1. State Key Laboratory of Petroleum Resources and Prospecting, China University of Petroleum, Beijing, BeiJing, CHINA
2. College of Geosciences, China University of Petroleum(Beijing), BeiJing, CHINA

E-mail: 280251512@qq.com

Keywords: Mesoproterozoic, North China Craton, Continental Rift, Xiong'er Group, Volcanic-sedimentary cycles

The Mesoproterozoic rifting event is one of the hot topics in the study of Precambrian tectonics. As the first volcanic-sedimentary formation in the North China Craton, reconstruction of the tectonic-sedimentary evolution sequence of the Xiong'er Group is of vital significance for understanding the early Mesoproroterozoic rifting and even Columbia supercontinent breakup. Based on the geological survey, petrology, and geochemistry data of the Xiong'er Group in the Ruyang region, the sedimentary facies, filling sequence, and tectonic environment of the volcanic-sedimentary rocks of this Group were determined, and the early tectonic-sedimentary evolution processes were discussed. The results show that the Xiong'er Group was formed in a continental rift environment. From early to late, it included three volcanic activities of the Xushan Formation with a gap-type volcanic eruption, the Upper Jidanping Formation with a central volcanic eruption, and the Upper Majiahe Formation with a gap-type fissure-type volcanic eruption, and the intermittent subsidence of clastic rocks in fluvial or lacustrine facies of the Dagushi Formation, the Mid-Jidanping Formation, the Mid-Majiahe Formation, and the Gaoshanhe Group. The Xiong'er Group generally reflects three volcanic-sedimentary cycles, in which the volcanic activity shows a weak-strong-weak evolutionary trend and the sedimentary source shows the evolution process of terrigenous clastic river facies-volcanic clastic river facies-volcanic clastic lake facies. This characteristic of intermittent volcanic activity associated with regional continuous extension and subsidence reflects the type of early tectonic-sedimentary filling of typical intracontinental rifts and represents the onset of the early Mesoproterozoic extension-breakup event in the North China Craton.

E-mail: sunqiliang@cug.edu.cn

Keywords: Hydrothermal vent, fluid migration, gas chimney, pockmark, shallow gas, Great South Basin

Structures that facilitate sub-vertical fluid migration are common in sedimentary basins. In this study, we used high-resolution 3D seismic data document several hydrothermal vents located above the Tuatara Volcanic Field in the Great South Basin of New Zealand. Four hydrothermal vents have been identified and three of them are vertically stacked, indicating episodic re-use of the same vertical fluid migration pathway between ~75 Ma to ~58 Ma. A gas chimney and pockmark has been observed above the hydrothermal vents. The pockmark dated to ~49 Ma and was filled with free gas. A small amount of free gas above the pockmark is recognized as developing at the Horizon H2 which is indicated that the hydrothermal pathway still can focus fluid flow upward after 28 Myr. The spatial association of the vents, pockmark, and free gas may suggest continued re-use of a fluid migration pathway for over 54 Myr. Our results imply reutilization of fluid flow pathways may affect the distribution of fluids within basins, potentially impacting hydrocarbon/geothermal exploration and geohazard assessment. Therefore, reassessment of the hydrothermal pathway' role on fluid flow should be pained where the hydrothermal vent occurs.

A millimeter-scale insight into formation mechanism of lacustrine black shale in tephra deposition background

Senhu Lin[1*], Xia Luo[1]
1. Department of Oil and Gas Geology, Research Institute of Petroleum Exploration & Development, Beijing, CHINA
E-mail: lsh2012@petrochina.com.cn

Keywords: Tephra, Black shale, Organic carbon, Formation mechanism

To reveal the role of tephra in the deposition of black shale during periods of volcanic activity, we performed lithostratigraphic and geochemical analyses on 14 horizontally sliced samples drilled from a 2-cm-thick black shale interval in the lower Ch7 Member of the Upper Triassic Yanchang Formation, southern Ordos Basin. Results indicate that fewer plankton are preserved during tephra deposition than during periods of volcanic quiescence. With the decrease of volcanic activities and tephra deposition, the abundance of redox-sensitive trace elements (RSTEs) and biolimiting elements increases, while terrigenous elements gradually decrease, resulting in the improvement of organic matter (OM) preservation. Paleoenvironmental proxies suggest that the climate during the Late Triassic was generally warm and humid with freshwater. However, subsequent intense volcanic eruptions may have caused climatic cooling that affected the water column, resulting in enhanced salinity, primary production, water stratification, and bottom water anoxia, leading to enhanced organic carbon production and preservation. Primary productivity and redox conditions controlled the accumulation of organic carbon. Although physical and chemical reactions relating to the deposition of tephra into water are short-lived, climate change induced by volcanic eruptions is the critical cause of black shale formation.

Origin and diagenesis in volcanic matrix-rich sandstones: A case example from the Shanxi and Shihezi formations (Permian), Southwest of the Ordos Basin, China

Hang Cui[1,2], Shifa Zhu[1,2*], Huan Tong[1,2]
1. State Key Laboratory of Petroleum Resources and Prospecting, China University of Petroleum (Beijing), Beijing, CHINA
2. College of Geosciences, China University of Petroleum (Beijing), Beijing, CHINA
E-mail: sfzhu@cup.edu.cn

Keywords: Volcanic matrix-rich sandstones, Provenance attribute, Hyperpycnal flow, Diagenetic processes, Ordos Basin.

Complex interrelationships may exist between topography, depositional systems and volcanic activity in the volcanically active regions[1]. Additionally, volcanic eruptions can provide large amounts of sedimentary materials[2] and expose fluvial valleys or lakes to catastrophic hyperpycnal flood events. The Permian ancient fluvio-deltaic system in the Longdong Region (southwest of the Ordos Basin), which reveals evidence for abundant synsedimentary volcanism linked to the tectonic evolution of orogenic belt around the basin, provides a “natural laboratory” for volcanism-related hyperpycnal flows.

In this study, volcanic matrix-rich sandstone samples have been analyzed for petrology, mineralogy and geochemistry in order to explain the volcanogenic material provenance attribute, depositional and diagenetic processes. Discussion on detrital zircon geochronology and geochemical characteristics indicates that volcanogenic materials were not derived from the Yinshan-Yanshan Orogenic Belt as previously thoughts, but favors the southwestern origin from the North Qinling Orogenic Belt. Combined with the mapped distribution characteristics of volcanogenic materials and the tectonic setting around the basin, the crater may be located in the west or south of Longdong Region. Volcanogenic materials retained in the provenance area during frequent volcanic eruptions were transported to the basin via fluvial system shortly after eruption. According to the color, sedimentary structure and grain size characteristics of volcanic matrix-rich sandstones, thirteen lithofacies were recognized through detailed core observations, and five principal facies association in the Shanxi and Shihezi formations were identified and delineated. These deposits have met the criterion for hyperpycnites according to conceptual schema proposed by Zavala et al., 2011.[3], which suggests the occurrence of hyperpycnal flows during the deposition of volcanic matrix-rich sandstones. During the subsequent burial stage, three types of volcanic matrix-rich sandstones divided by the volcanic matrix content have similar paragenetic sequences but different diagenetic intensities. The cementation strength of authigenic minerals, however, was closely related to pore structure characteristics and the migration trend of volcanic-matrix alteration materials.

Within this study, it is proposed the possible tectonothermal events in the North Qinling Orogenic Belt during the Permian, which has been previously unidentified, and validates and reinforces theoretical work of volcanism-related hyperpycnal flow. This contribution provides new insights to the understanding of the depositional and diagenetic processes of lacustrine basins with similar tectonic settings.

Mechanism of Rhyolitic ash Promoting organic matter enrichment in a shallow carbonate platform: A case study of the Maokou Formation in eastern Sichuan Basin

Qian Pang[1], Guang Hu[1*]
1. School of Geosciences and Technology, Southwest Petroleum University, Chengdu, Sichuan, CHINA
E-mail: guanghu1198119@163.com

Keywords: volcanic ash, organic matter, productivity, bio-precursor, hydrocarbon generation, Sichuan Baisn

Erupted volcanic ash improve the amount of nutritive elements in the lake and ocean (Uematsu et al., 2004; Duggen et al., 2010; Hoffmann et al., 2012; Liu et al., 2019), but it is not fully understood how volcanic ash influences the total organic matter content (TOC) and bio-precursor, and the scope of influence. A volcanic layer, measuring 5cm in thickness, was examined using electron microscopy scanning, TOC/TS, pyrolytic, and inorganic geochemical analyses. The study of TOC and inorganic elements shows that the TOC content in the overlying shales increases by 18 wt.% on average, and the vertical scope of influence on shales is twice as thick as the volcanic layer. Organic matter enrichment is attributed to the fact that the volcanic layer provides nutritive elements and meanwhile changes the oxidation-reduction condition. Large variations of hydrogen index (HI) and oxygen index (OI) in the lower and upper parts of the volcanic layer is related to terrestrial organic matter vanishing, due to volcanic eruption and subsequently more terrigenous organic matter migrating into the ocean. Little change of the source organisms in the overlying and underlying shales may be related to the fast restoration within the ocean and land ecosystems after a volcanic eruption. The decrease in terrigenous sediments indicated by Rb/Sr, Zr/Y, and ∑REE after a volcanic eruption indirectly reflects fast restoration of terrestrial vegetation boom. These results may offer fundamental data support in the study of volcanic ash influence on source rocks.

Study of late Carboniferous tuffaceous sandstone and related manganese deposits in the Maerkansu manganese belt, western Kunlun, Xinjiang Province, Northwest China.

Chen Denghui[1*]
1. Mineral geology Department, Xi'an Center of China Geological Survey, China Geological Survey,, Xi'an, Shaanxi, CHINA
E-mail: 47134454@qq.com

Keywords: Maerkansu manganese belt, late Carboniferous, tuffaceous sandstone,zircon U-Pb dating, Hf isotope

The Maerkansu ore-cluser district in western Kunlun Metallogenic Belt hosts extensive Mn deposits including Aoertokaneshen, Muhu, Maekantu, etc, mainly for rhodochrosite, and the average grade is about 30%. The deposits are mostly associated with the late Carboniferous pyroclastic-carbonate formation, which have received lots of study and exploration. However, the genesis of the manganese and metallogenic relationship between pyroclastic rocks and manganese deposits have not been well constrained. In this study, we report new zircon U-Pb ages, Hf isotopic and geochemical of tuffaceous sandstone, orebody and host rock in the Maerkansu regoin. Two LA-ICP-MS U-Pb ages of tuffaceous sandstone in the Muhu deposit are 309.9±3.7Ma and 309.5±3.5Ma. Hf isotopic ratios are ƐHft=15.29~19.76 and 15.53~20.26, and Hf crustal model ages are 0.98 to 1.26 Ga and 0.92 to 1.29 Ga (average=1.09 Ga). Their model ages are similar to the ancient crustal basement in the West Kunlun area. Thus, we suggest that the magma is mainly derived from the anatexis of the Proterozoic crustal material. Based on our analysis, tuffaceous sandstone and manganese ore share similar distribution modes of rare earth elements and trace elements. Combined with volcanic hydrothermal sources of manganese are revealed by the geochemical characteristics, the manganese metallogenic materials are mainly derived from submarine volcanic activity.

A tail of orogenic cycle from syncollisional crust thinking to post collisional subaerial uplift for the Mesozoic Qinling Orogen

Rong Chai[1], Hai Jiang Yang[2*]
1. School of Earth Sciences and Resources, China University of Geosicece(Beijing, Beijing, CHINA
2. School of Earth Sciences , China University of Geosicece(Wuhan, Wuhan, HUBEI, CHINA
E-mail: yangjh@cug.edu.cn

Keywords: Qinling orogen,foreland basin,crustal thicking,denudation

Through the study of typical orogenic belts in the world (such as the Himalayas and the Andes), it is found that there is a decoupling relationship between crustal thickening, surface uplift and erosion (Mulch and Chamberlain, 2006; Garzione et al., 2008; Govin et al., 2018; Fang et al., 2020). The tectonic evolution history of the Qinling orogenic belt in the early Mesozoic has always been the focus of debate (Dong et al., 2016; Wu and Zheng, 2013). Based on the provenance analysis of the foreland basin on the periphery of the orogenic belt, it is inferred that the North China plate and the South China plate had initially collided at the beginning of the Middle Triassic (Ma et al., 2021). Deformation structure and thermochronology show that after the closure of the ocean in the Late Triassic ca. 50 m.y., the continental-continent fusion continued, resulting in a reduction of at least 400-500 km in the crust. (Shi et al., 2012; Dong et al., 2013). The relationship between the geochemical characteristics of magmatic rocks in the Qinling orogenic belt and the thickness of the earth shows that the Moho depth of the South Qinling increased rapidly in the early Late Triassic (~230 ~ 220 Ma), reaching a maximum of ~60km-70km at ~220 ~ 210 Ma. After about 10 Ma, the depth of the Moho surface decreased rapidly (Hu et al., 2020). Thermochronology shows that from the early Middle Triassic to the Jurassic, the South Qinling region experienced multiple stages of lifting and cooling histories (Li et al., 2013; Wang et al., 2014; Wang et al., 2019). Although multiple evidences show that the basement of the Qinling orogenic belt in the Late Triassic was uplifted to varying degrees and the crustal thickness increased significantly, but at the same time, the orogenic belt did not undergo surface uplift and denudation. In this paper, by studying the trace geochemical data of detrital zircon in the foreland basin of the southern margin of the Qinling orogenic belt, it is speculated that the orogenic belt experienced a syn-collisional orogenic process in the Middle Triassic, and the crust at the end of the Late Triassic (~210 Ma) The thickness reaches the thickest (~76 km), and finally experienced a rapid denudation process in the Early Jurassic.

Characteristics of the volcanic lithofacies of Cretaceous Qingshan Group in Jiaodong uplift

Tingyue Li[1], Shikuo Lu[1*], Yachao Wang[1], Xuetao Wang[1]
1. School of Earth Science and Technology, China University of Petroleum, Qingdao, Shandong, CHINA
E-mail: 809924204@qq.com

Keywords: volcanic lithofacies, Qingshan Group, Jiaodong uplift, pyroclastic current deposit

The voluminous intermediate-acid volcanic rocks developed in Jiaodong Area in Cretaceous. Much work carried out are mainly about their petrologic, geochemical and chronological features. However, there are few studies about their lithofacies, at least out of proportion to their size. Here, we systematically analyse the characteristics of the volcanic lithofacies of Bamudi and Shiqianzhuang Formations, Qingshan Group, in Jiaodong area via better outcrop sections, which contributes to understand the volcanism process, and their genetic mechanism.

The volcanic rocks' lithologies of Bamudi Formation are mainly basaltic andesite, andesite and trachyandesite, whereas those of Shiqianzhuang Formation being dacite and rhyolite. They all belong to calc-alkalic series. In term of the volcanic facies, in Jiaozhou area, being close to the southeastern margin of Jiaolai basin, the explosive and effusive facies coexist in Bamudi Formation as well as in Shiqianzhuangzu. However, as a whole, the proportion of explosive facies is much greater than that of effusive ones, though the proportion of the effusive facies in Banudi Formation is a little higher than that in Shiqianzhuangzu Formation. Field outcrop sections in this area show that there were many episodes' volcanic eruption in these two sets of strata. In Bamudi Formation, each eruptive cycle is mainly comprised of pyroclastic flow subfacies, which sometimes being overlain by thin lava flow and occasionally overlying on the pumice fall deposit. The fine ash deposit is hardly seen. The pyroclastic current deposits(ignimbrites) mainly consist of ash-rich lapilli tuff, being poorly sorted, matrix-supported and often reversely graded. Some lithic fragments usually existed in the lower part of pyroclastic deposit sequence. Under the influence of the emplacement temperature and the lithostatic load, the pyroclastic current deposits are usually shown as welded ignimbrite with fiamme and eutaxitic textures. Additionally, the block and ash flow deposit also developed in Bamudi Formation, which showed a chaotic jumble of lava blocks of various sizes in an ashy matrix, a large block being about twenty meters in diameter, whose distinctive prismatic joints proving the high temperature origin of the deposit. In Jiaozhou area, the overall characteristics of volcanic lithofacies of Shiqianzhuang Formation are similar to those of Bamudi Formation, except that the lava flow became more less developed, only being occasionally found on the top of some sections.

The volcanic rocks of the Shiqianzhuang Formation also extensively developed in the interior of Sulu orogen zone. Based on the outcrop section in Huangdao area, their volcanic lithofacies were apparently different from those in Jiaozhou area and mainly consisted of effusive facies, though the pyroclastic current subfacies also developed in some volcanic cycle sequence. Intriguingly, the base surge deposit can be seen in the bottom of a certain cycle, with poorly sorted and cross-laminated ash beds, possibly implying the hydrovolcanic eruption style. Additionally, spherulites and lithophysae texture developed well in the thick lava sequence, indicating the high-temperature devitrification of some initial glassy lava. The variable volcanic lithofacies of Shiqianzhuang Formation in the various areas possibly suggest that they have the different origin.

Keywords: Permian, ashfall, volcanism, anoxia, bentonite, Zaysan basin

Permian sedimentary deposits are well exposed in the Kenderlyk trough (Eastern Kazakhstan) which was structurally detached from the Zaysan basin in the Late Cenozoic. These deposits are underlain by thick Devonian-Carboniferous flow basalts and conformably overlain by Triassic clastic deposits. The formation of accommodation space and sedimentation during the Permian was largely controlled by the collision of Kazakhstan and Siberian plates. As a result of the associated dynamic interplay of thrusting, magmatism, and sedimentation, the Permian terrestrial and lacustrine clastic deposits are interbedded with numerous variably thick (centi- to multi-meter scale) volcanic ash deposits and scarce small lava creeks. Our field sedimentological studies coupled with pyrolysis [RockEval] results from black shale strata of Kenderlyk (C3-P1), Karaungur (P1), Tarancha (P1) and Maychat (P2) formations are characterized by thicknesses of up to 50 m and organic richness averaging 5-10% of total organic carbon (TOC). The correlation between volcanic ashfalls beds and organic richness suggests that ashfalls had both positive and negative effects on paleo-bioproductivity and organic matter preservation. The positive effect, evidenced by increased TOC above thin ashfall beds is in line with the concept that mineral nutrients introduced to seas and lakes by ashfalls may increase bioproductivity and cause algal blooms, which then deplete oxygen and form anoxia needed for the preservation of organic matter. The negative effect, evidenced by the absence of organic rich strata in the proximity of thick (2-5m) lacustrine bentonites, implies that water column anoxia caused by long-lasting volcanic activity significantly reduces and/or terminates bioproductivity.

The absence of macroscopically noticeable ash deposits in the bottom 30m of organic rich (10-12% TOC) Tarancha formation black shales may imply a long-lasting high bioproductivity and anoxia in a stratified lake water column that may have existed in the Zaysan basin without the interference of ashfalls. However, considering the tectonic setting, it is more likely that the ashfalls were present, but had a lower preservation potential in deeper parts of the basin. The above interpretations may serve as a proxy for identifying intervals of interest for source rock and/or unconventional resource characterization, and as a predictive and/or a risk assessment tool during basin analysis for exploration in frontier basins. The former is feasible because of an easy recognition of ashfalls in cores and logs, but the latter requires well-established paleo-volcanic age databases as well as the source of these ashes. A higher resolution sampling in cm scale intervals would shed more insights into the bioproductivity during and shortly after ashfalls. Future studies may focus on establishing the relationship between bioproductivity and compositionally different ashes as the amount of mineral nutrients and/or toxic elements may greatly vary depending on sources.

This paper is dedicated in memory of Dr. Erzhan Sapargaliev who took us to the field and introduced us to the magnificent geology of the Eastern Kazakhstan. This project is supported by Nazarbayev University Grant No 080420FD1905 and supplemented by the IAS Postgraduate Research Grant of the second author.

Volcanic activities pacing gravity flows deposition process during the Late Carboniferous in the southern margin of Jungar Basin, China

Shixin Li[1], Tingshan Zhang[1,2*]
1. School of Geoscience and Technology, Southwest Petroleum University, Chengdu, SIchuan, CHINA
2. Natural Gas Geology Key Laboratory of Sichuan Province, Sothwest Petroleum University, Chengdu, Sichuan, CHINA

Keywords: Volcanic activities, Collapse, Gravity flows deposits, NTS volcanic island-arc, Upper Carboniferous Qianxia Formation

The North Tianshan (NTS) is an important tectonic unit of the Central Asian Orogenic Belt in Xinjiang, China. During the Late Carboniferous, a large number of volcanical-sedimentary rocks which were regarded as turbidites were deposited, which recorded the paleogeographic evolution of the Paleo-Asian Ocean. Understanding the space-time evolution of deep-water gravity flows, and how the deep-water gravity flows responds to the changes of sedimentary and tectonic setting, are a key research focus for gravity flow sedimentology. Based on field outcrop investigation, through the analysis methods of petrology, isotope chronology and geochemistry, the co-evolution of Late Carboniferous volcanic activity and deep-water gravity flow deposition in the southern margin of Junggar Basin is discussed. Research shows that volcanic activities not only lead to instability of slope sediments, triggers sediment collapse, and forms slump-type deep-water gravity flow deposition, but also provides important material sources for gravity flow deposition. The occurrence of volcanic beds in the slump deposits confirms that synchronous volcanic activity accelerates the sediments instability and triggers the gravity flow slump. The Upper Carboniferous Qianxia Formation's structural environment indicators of the volcanic rocks, such as Th / Yb, Ta / Yb, and Th / Ta; the U-Pb age of sandstone detrital zircons, the directional arrangement of pebbles and the paleocurrent direction indicated by the trough model all indicate that the volcanic island-arc of the NTS Mountains provides sources for the gravity flow deposition area. In addition, through the statistics of pyroclastics components in the gravity flow deposition process, the intensity index of volcanic activity is established. The index shows that the coupling relationship between volcanic activity and gravity flow deposition process is good, and volcanic activity controls the type and distribution of gravity flow deposition. From eruption period to intermittent period of volcanic activity, the sedimentary type of gravity flow transits from imported pebbly debris flow to slump-sandy debris flow. Based on the above research, the sedimentary evolution model of volcanic-triggered deep-water gravity flow is established, which provides reference for the prediction of Paleozoic deep-water gravity flow reservoirs in Junggar Basin.

Carboniferous structure, sedimentary environment and the filling evolution in Junggar Basin

Juanjuan Guo[1*]

1. Research Institute of Petroleum Exploration & Development-Northwest,PetroChina, Lanzhou, Lanzhou, Gansu, CHINA
E-mail: 165421654@qq.com

Keywords: Carboniferous structure, sedimentary environment, filling evolution

The Junggar Basin belongs to the paleo-Asian Ocean tectonic domain, which records the dynamic processes of the Central Asia accretionary Orogenic Belt from subduction-accretion-collision to later intracontinental reformation. Carboniferous is the key period from subduction to closure of the paleo-Asian Ocean. The complex ocean-continent evolution in this period created the hydrocarbon accumulation examples of Carboniferous in Junggar basin. However, the study of Carboniferous prototype basins is still relatively weak, which restrains the evaluation of Carboniferous source and reservoir conditions and favorable zones. Therefore, the study of Carboniferous tectonic framework and filling evolution in Junggar area can not only enrich the understanding of the structural evolution of the Central Asia accretive Orogenic Belt, but also play an important role in promoting the oil and gas exploration process of deep volcanic basins. In this paper, structural geology, geophysics, isotopic geochronology and geochemical methods are systematically applied to systematically analyze and study the Carboniferous chronostratigraphic framework, geological structure, geotectonic environment and sedimentary filling sequence in Junggar Basin and its adjacent areas by comprehensively using drilling, field outcrop, seismic and gravity and magnetism data. On this basis, the structural framework of Carboniferous in Junggar Basin and its adjacent areas, as well as the evolution characteristics of structural sedimentary environment under the background of multi-stage structure, are revealed.

The geochronological results of volcanic rocks drilled in the basin show that there are five stages of volcanic activity in Carboniferous in Junggar area. The regional unconformity boundary divides the Carboniferous system into two structural stratigraphic sequences: upper and lower Carboniferous. The lower Carboniferous is dominated by compressional structural deformation, with a large number of calc alkaline basalt, andesite, dacite and rhyolite developed. However, the upper Carboniferous is mainly controlled by extensional faults. The volcanic rocks are mainly middle basic volcanic rocks, and there are bimodal volcanic rock assemblages in some areas. Based on the analysis results of volcanic tectonic environment and the study of structural deformation, combined with the division scheme of Carboniferous structural belt in Junggar Basin and its adjacent areas, four Carboniferous arc basin belts are determined. There are many types of basins are also identified. Based on the establishment of the structural framework and the analysis of the sedimentary filling sequence of the Carboniferous basin, the evolution process of the Carboniferous structural sedimentary environment in Junggar Basin and its adjacent areas is divided into three stages, i.e. the compressional flexure stage related to the early Middle Carboniferous subduction, the extensional rifting stage related to the late Early Carboniferous Middle Carboniferous subduction and the intracontinental fault stage related to the Late Carboniferous Depression stage. The results not only reveal that the basement of young continental crust lies in the Junggar basin, but also indicate that the Junggar basin, its adjacent area and even the whole Central Asia accretive orogenic belt are formed in the process of multiple rows of South accretive arc basin systems colliding and splicing in turn to the north.

Keywords: cyclostratigraphy,obliquity,δ13C,CIA,thermohaline circulation,volcanic ash

Astronomical and volcanic forcing organic-carbon during Later Ordovician – Early Silurian in the Upper Yangtze area, China was studied by cyclostratigraphic and geochemical methods. δ13C and CIA were used to filter the astronomical orbit parameters recorded in sediments. Orbital drving climate change controls the fluction of sea level changes at different scale. Obliquity forcing climate changes drives thermohaline circulation (THC) of the ocean, and THC-induced bottom current transports nutrient-laden water from high latitude regions to the surface water of low-latitude area. THC is the main dynamic mechanism of organic-carbon supply. In late Hirnantian (E4), the marine paleoproductivity from index of Ba/Al and Ni/Al indicates that volcanic activities have limited effect. However, volcanisms have great influences on organic carbon preservation efficiency. Paleo-environmental indicators(Th/U, V/Cr and V/ (V+Ni) show that there is a significant relationship between volcanisms and oxygen content in Paleo-ocean. Volcanisms control the organic carbon preservation efficiency by regulating oxygen content in Paleo-ocean. The difference of Volcanisms intensity in different areas is an important factor for the differential preservation. The organic carbon input of orbital driving and the preservation efficiency affected by volcanisms are coupled to control the enrichment of organic carbon in the middle-upper Yangtze region.

Keywords: Gravity flow, Carboniferous , Remnant ocean basin, West Junggar

We conducted a study of the types, spatial distribution, and evolution of Carboniferous deep-water sediment gravity flows and their associated deposits in the West Junggar region of northwestern China.Combining information obtained from outcrop sections and cores and seismic profiles, nine lithofacies associated with sediment gravity flows were identified and attributed to formation by slide-slump,turbidity currents, detrital flows, hyperpycnal flows. The characteristics of these gravity flow sediments are mainly controlled by the tectonic processes of the subduction of the West Junggar remnant ocean basin and volcanic activity.From the analysis of petrological and paleogeographical features, it is known that the early Carboniferous and Late Carboniferous gravity flow sediments have great differences in material sources and genetic mechanisms.We have identified 5 typical vertical lithofacies assemblages.Subduction-related tectonic activity and volcanism and earthquakes are the main triggering mechanisms for the development of sediment gravity flow. The influence of volcanism on gravity flow sediments is directly reflected in the content of pyroclastics in coarse-grained sediments and tuffaceous matter in fine-grained sediments.

In the Early Carboniferous, the West Junggar remnant ocean basin was in the early stage of subduction and demise. The basin had a relatively large accommodation space, and the gravity flow sediments had sufficient migration distance to complete the fluid transformation process of slump-detrital flow-turbidity current. During this period, there was relatively little terrigenous input, and the material sources of gravity flow sediments were mostly products of the unstable continental slopes. In the Late Carboniferous, with the shrinking and filling of the ocean basin, the accommodating space of the basin became smaller rapidly. At this time, debris flow sediments and slump sediments were the main types of gravity flow sediments. In addition, along with changes in paleoclimatic conditions, flood-related hyperpycnal flow deposits are extremely developed during the late Carboniferous.

Keywords: Paleosol, Deccan volcanic province, Pedogenesis

The Late Cretaceous interbasaltic paleosols of Deccan volcanic province present a unique opportunity to understand the paleoenvironmental condition during the volcanism. The interbasaltic paleosols are named as bole beds [2,7,8,9]. This study presents a combined field, petrographical, mineralogical and spectroscopic characterization of different types of Deccan bole beds for reconstructing paleoenvironmental conditions during a lull in volcanism. These bole beds may vary in thickness from a few cm to a few meters. The bole may be either massive or bedded, and they exhibit variable geometry. The bole bed shows both sharp and gradational contacts with underlying lava flow . However, the upper contact of bole beds with overlying lava flow is always sharp [8,9]. Petrographic investigation of red boles shows gradation in texture and constituents from incipiently pedogenised red bole to moderately pedogenised red bole. The red bole with incipient pedogenesis contains volcanic lithic fragments (lathwork, microlitic and vitric), scoria, pyrogenic particles or monomineralic grains (plagioclase, pyroxene) as essential phase along with accessory iddingsite, zircon, quartz, opaque phases [8,9]. The vitric particles are variably altered to palagonite, clay and zeolite [4]. Moderately pedogenised red bole reveals the presence of highly altered basaltic clasts (100 µm to 5 mm), iron glaebules, alteromorph and oxidized fragments set in the groundmass of homogeneous red ferruginous, clayey material showing b-striations under cross nicol [8,9]. The presence of 2.21 µm, 2.24 µm and 2.29 µm absorption features in reflectance spectra of VNIR spectroscopy indicates a mixture of Al smectite (montmorillonite) and Fe-smectite as the clay mineral constituents in red bole [3,5,8,9]. X-ray diffraction confirms the presence of montmorillonite as the dominant clay in red bole [6]. Green boles, in contrast, are only incipiently pedogenised. They contain volcanic lithic fragments, plagioclase, pyroxene and green clay as an essential phase. Red clay, zeolite, apatite and opaques occur as an accessory phase. The green clay occurs as dissolution and alteration of plagioclase, volcanic glass, mafic minerals and pore-filling cement. Celadonite in green bole shows variation in composition with K_2O ranging from 7 to 9 wt%, Fe_2O_3 from 14 to 19 wt%, MgO from 4 to 6 wt% and Al_2O_3 from 9 to12 wt %. The random and oriented X-ray diffraction mounts of <2 µm clay confirm the presence of celadonite along with Fe-smectite as major clay in green bole [6,8,9]. Characteristic absorptions of equal strengths at ~2.30 µm ($Fe^{3+}Fe^{3+}$–OH combination) and 2.35 µm (Mg_3–OH combination) and a strong slope between 1.00 µm and ~2.10 µm under VNIR spectroscopy [3,5,8,9] and a sharp band at 3558–3560 cm^{-1} (Fe(III)OHMg or AlOHFe(II), 3581–3583 cm^{-1} (MgOHMg), 3604 cm^{-1} (AlOHMg), and a shoulder near 3539 cm^{-1} (Fe(III)OHFe(III) in FTIR spectra confirms the presence of celadonite [10]. Although both red and green boles form during the pedogenesis of basaltic detritus in subaerial conditions, the former represents oxic while the latter represents dysoxic depositional conditions [1,8,9] during the soil-forming process.

Volcanic-sedimentary stratigraphy and facies architecture of the early Cretaceous volcanism on Lingshan Island in eastern China and its implication on basin system

Tengfei Zhou[1*], Yaoqi Zhou[1]
1. School of Geosciences, China University of Petroleum (East China), Qingdao, Shandong, CHINA
E-mail: zhoutfgeoscience@126.com

Keywords: Volcanic-Sedimentary Stratigraphy, Volcanic facies architecture, Lingshan Island, Basin system

Understanding the volcanism in sedimentary basin is crucial for unraveling the evolution, sedimentary environment and tectonic setting of basin system. In this study, volcanic depotion on Lingshan Island are reported based on the newest Scientific Drilling (well LK-1) and typical field outcrops. The Lower Cretaceous stratigraphy sequence consists of two main groups: Laiyang Group and Qingshan Group. The former one represents a typical passive-rifting sequence which was divided in four units (stages) from the bottom to the top: fan delta (initial rifting), subaqueous fan (basin expansion), turbidite fan (deep rifting) and delta (uplifting) *(Yuan et al., 2019; Zhou et al., 2022)*. While the Qingshan Group represents a crustal doming stage in a volcanic arc environment *(Zhou et al., 2022)*. There isn't any volcanic deposits developed in the stages of initial rifting and basin expansion, while in the deep rifting stage, a suite of volcanic rocks were developed as the interlayers in deep-water sediments. Additionally, large amounts and various types of volcanic deposition developed in the Qingshan Group, including rhyolitic tuff, trachyandesitic lava and volcanic breccia, lamprophyre lava and sill. Based on the fieldwork description, different volcaniclastic lithofacies were identified: mLT, mLTf, mLBr, mscAg, sLT and fpoorT. The facies architectures of volcanic deposits in the whole strata were composed by the different combination between those lithofacies above. In Laiyang Group, the volcanic deposits are mainly single thin layer of mLT, which indicates they were the products of pyroclastic flow from nearby onshore volcanic eruption. While in Qingshan Group, lithofacies combinations varied a lot and changed frequently, which indicates that the sedimentary environment also changed frequently. Combining with the results of grain-size analysis, the volcanic deposits are products of pyroclastic flow, pyroclastic surge and fallout depositsand the explosive activities involve phreatomagmatic explosions and phreatic explosions. For distinguishing the participation of water in volcanic eruption, Laser-Raman analysis was used to ensure the type of feldspar of volcanic deposits in different volcanic phases. Sanidine were only found in the pyroclastic flow deposits in lower Qingshan Group which indicates that there was a short subsidence stage during the crustal doming period. This stage may be the subsidence stage of the passive-rifting in Laiyang period, suggesting a complete passive-rifting sequence was developed, which has not been proven before *(Zhou et al., 2022)*. It is very complex to distinguish the different geological event products during the tectonic transformation of the basin evolution because many processes are synchronous, while the volcanic facies analysis could be a very useful tool.

Note: The terminology used for the lithofacies follows *Branney and Kokelaar (2002)*.

The effect of volcanic activity on carbonate deposition

1*

1. , , , , CHINA
E-mail: 3254078989@qq.com

Keywords: Key words: volcanic activity, carbonate deposition, lithologic assemblage, diagenesis, biological succession

Abstract: Volcanism is the phenomenon in which lava (magma), pyroclasts, and volcanic gases are ejected to the Earth's surface through craters. Volcanic activity and volcanic substances have certain influences on the formation process of carbonate rocks and their depositional environment: (1) Lithologic assemblages. Due to the influence of pyroclastic materials, the composition, content and structure of carbonate rocks will change, and different lithofacies combinations and combinations (lenses, interlayers or interlayers) will be formed during the deposition process. (2) Diagenesis. Under the action of fluids rich in carbon dioxide and silica, siliceous metasomatism and cementation, dolomitization, and dissolution are prone to occur in carbonate rocks, resulting in the formation of authigenic minerals such as dolomite, calcite, and siderite, and "nodules", "clumps", "bands" and other geological phenomena. (3) Biological succession. The effects of volcanism on organisms and their growth conditions are divided into destructive and constructive effects. The volcanic eruption caused a large increase in carbon dioxide , which caused the ecosystem to be affected by acidification, resulting in the inability of some organisms to survive. In the early stage, some organisms died and were quickly buried. In the later stage, the pyroclastic sediments were redistributed, and the volcanic ash dissolved and released phosphate, silica, iron and manganese plasma to promote biological growth. (4) Sedimentary environment. Gases and volcanic ash erupted during volcanic eruptions can cause increased sunlight penetration, increased water temperature, water turbidity, changes in chemical properties (salinity, pH, etc.) and water eutrophication,which will ffect the deposition of carbonate rocks.

Keywords: rift basin, volcanism, depositional systems, sediment supply, landscape, Bohai Bay Basin

Although volcanism is an important process in the evolution of rift basins, current tectono-sedimentary models largely neglect its impact on sediment supply, transport pathways, and depositional systems. In this paper, we integrate core, well-logs, and 3D seismic data from the Palaeogene-Neogene Shaleitian (SLT) uplift and surrounding sub-basins, Bohai Bay Basin, China, to investigate the sedimentology and geomorphology of a volcanic rift basin. Results of this study show that the spatial distribution of extrusive centres was strongly controlled by basement-involved intra-basin normal faults. During the early part of the syn-rift stage, the SLT uplift supplied sediments to transverse fan deltas and braided-river deltas that fringed the adjacent syn-rift depocentres. Volcanic deposits mainly occurred as relatively thin lava-flow and pyroclastic facies that partially filled fault-controlled topographic lows, reducing topographic rugosity, and enhanced breaching of basement highs between syn-rift depocentres. Integration of drainage to the syn-rift depocentres and development of through-flowing axial depositional systems was enhanced. During the later part of syn-rift and in early post-rift stages, the SLT uplift was progressively inundated, reducing sediment supply to the fringing transverse depositional systems. In contrast, axial braided-river deltas became the main depositional systems, sourced by large hinterland drainage from the Yanshan fold-belt to the northwest. Volcanism in the late syn-rift and early post-rift occur as thick lava-flow and pyroclastic facies that infill rift topographic lows and locally blocked axial fluvial systems creating isolated lakes. Within hanging wall depocentres, volcanic topographic highs split and diverted axial fluvial and deltaic systems. Furthermore, volcanism supplied large volumes of volcanic sediment to the rift resulting in increased sedimentation rates, and the development of unstable subaerial and subaqueous slopes and deposits, increasing the occurrence of landslides. Based on the observations of this study we update tectono-sedimentary models for rift basins to include volcanism.

Impact of volcanism on the Lower Permian sedimentary System in the Northwest margin of Junggar Basin

[1], Wu Kong You[1*]
1. , , , , CHINA
E-mail: wukongyou@163.com

Keywords: Volcanism,Junggar Basin,The Lower Permian,Volcanic Rocks

Volcanism is a phenomenon in which lava, pyroclastics and volcanic gases are ejected through a vent to the surface of the earth. Volcanic eruptions may inject large amounts of pyroclastics and Volcanic gases into the atmosphere and into marine and terrestrial environmental systems.Volcanism has a huge impact on the sedimentary environment. In addition to provide source, affect the ecological environment and organic matter enrichment, change the local deposition (micro) environment, etc associated hydrothermal activity on the basin water salinity, pH, oxidation, and its subsequent effects need to be studied.Because the diagenesis of volcanic rocks is generally related to magmatic condensation, the burial depth reflects the performance of volcanic rock storage The sound is far smaller than the clastic rock reservoir.Volcanic rock reservoirs are often available in oil-containing basins where volcanic rocks are widely developed It has become an important target of deep oil and gas exploration and development, and often has the characteristics of thick yield, high yield and large reserves.

Junggar Basin Early Permian Jiamu River Formation-Fengcheng Formation evolved in the weakly extruded foreland basin.Carboniferous to the Early Permian, northern Xinjiang from ocean basin to continental basin conversion, that is, from Marine environment to continental environment .In the Early Permian, the complete closure of the Junggar residual ocean caused the land fissure and subsidence, accompanied by the eruption of a large number of volcanic rocks and the invasion of.The Junggar Basin Permian system is the result of the "overlap" of the lower extended basin and the upper extrusion basin, with the extended fault basin formed during the Early Permian period.The northwest edge of the basin, including Kebai and Wuxia reigion, is the western Junggar uplift belt, adjacent to Mahu depression, is Junggar plate and Kazakhstan plate collision suture, performance as the reverse cover fault zone in different directions, can be further divided into tip zone, broken step zone, leading edge belt and slope belt.

This study is to study the rock type, petrology and distribution characteristics of junggar Basin in the northwest margin of junggar Basin as an example, using the volcanic rocks of junggar Basin with earthquake, drilling and core analysis.During the deposition of the Jiamu River Formation on the northwest margin, its sedimentary boundary can extend northwestward to near the Darbute fault (the northwest boundary of the Late Carboniferous and Early Permian ancient Junggar basins, while its sedimentary center is located in front of the present-day Mount Zaire.The sedimentation phase diagram of the stroke city group indicates that the sedimentation boundary of the newer wind city group is greatly far away from the Darbute fault, with plane movement distances ranging from 10 to 20 k m.Overall, the migration distance of the sediment boundary (20~30km) is much greater than that in Hashan (about 10km).The study shows that the formation environment changes the eruption mode, the structure and structural characteristics of the eruption products, and the central plains of volcanic rocks The spatial type of raw reservoir set and its development degree and development law have great influence.

E-mail: andrea.dicapua@igag.cnr.it

Keywords: clastic-lava apron, volcaniclastic, 3D model

Clastic aprons represent sedimentary architectures controlled by the accumulation of sediments at the toe of slopes or at the mouth of narrow valleys. The main mechanisms driving their progradation are represented by mass-wasting deposits, such as rock avalanches and debris flows. When apron progradation occurs on slopes of active volcanoes, lava flows could become fundamental in their construction and evolution. Despite the abundance of topographic empties created by volcanic lateral collapses, the literature lacks examples in this sense.

Therefore, this work explores stratigraphic, petrographic, and architectural features of a mixed clastic-lava apron developed on the SE flank of El Hierro Island (Canaries Island – Spain). Fieldwork, including mapping of main volcanic and sedimentary facies, measurement of 7 logs, 5 landscape-style photographs, and a digital elevation model has been assembled into a GIS database. Ten samples of clastic and lava beds have been collected for textural and minero-chemical analyses. Six of them have been cut into standard thin sections and analyzed under a polarized microscope for the identification of textural features

The result is a 3D architectural model of a clastic-lava apron developed onto a lateral collapse of multiple surfaces, where clastic sedimentation is constantly interrupted by the accumulation of thick basaltic lava flows that also drove the sedimentary geometries. Petrographic analyses highlight the presence, at the base, of a thick basaltic lava flow, where zeolites grew onto primary glassy groundmass. This basal level can be considered a sea paleo-level marker and could be further correlated across the entire Island.

Keywords: Siberia Craton,Riphean,sedimentary succession,magmatism,extension event

The Eastern Siberia Basin is one of the oldest petroliferous basins in the world. Riphean strata, as the main source of hydrocarbons for East Siberian oil and gas fields, is widely distributed in the craton marginal basin. Thus, the dynamic settings of the cratonic marginal depression basin plays a key role in controlling the distribution of oil and gas resources in this area. The sedimentary succession corresponding to the extensional basin and mafic dyke swarms can be used as key clues for the identifying of the Riphean Extension in Siberian margins. A common feature of the Riphean stratigraphy in the Siberian craton is their gradual thickening towards the cratonic boundaries, representing passive continental margin depositional features during the Rifting process, which indicating that the Siberian Craton margin probably faced an open ocean during the Meso- and Neoproterozoic. These passive continental margin depositional sequences developed along the eastern, southern, western, and even northern margins of the craton, forming several extensional basins such as the Pre-Patom Basin. The Riphean extensional magmatism of the Siberian Craton shows different characteristics in different periods. In the Early–Middle Riphean, the mafic dykes were mainly distributed in the northern part of the craton, probably associated with intraplate extension result from the mantle plume. The mafic magmatism in Late Riphean was widely developed in the southern part of the craton, associated with the Rodinia supercontinent rifting and opening of the Paleo Asian Ocean, which migrated from the southeast to the west. The Riphean evolution process of the Siberia Craton southern marginal basin: continental rift (~1 000 Ma), the opening of the ocean (~850 Ma), and the formation of the foreland basin (~ 650 Ma) were reconstructed.

Volcanic architecture and its related processes on sedimentary evolution in salt-walled mini-basin --Example from Cretaceous post-rift marine depositional system, offshore Brazil

Xiao-Fa Yang[1*]
1. Research Institute of Petroleum Exploration & Development, PetroChina, Beijing, CHINA
E-mail: ouyangxiaofa@petrochina.com.cn

Keywords: Volcanic architecture, mini-basin, sedimentary fill history, magmatic processes

The preserved volcanic and sedimentary expression of mixed successions accumulated in salt-walled mini-basins records the complex subsidence of basin evolution, the style of sedimentary stratigraphy, and the pattern of igneous rock distribution in response to a range of magma processes throughout the evolution of such basin. This paper provides an example of the control of volcanism on the evolution of post-salt sedimentary strata in a salt-walled mini-basin, offshore Brazil.

In this paper, 3D seismic data was integrated with biostratigraphic, petrophysical, geochronological and petrographic information from several drilled boreholes of the offshore basin, southeast brasil. The interpretation of 3D seismic data adopts a multidisciplinary method to integrate the insights of structural geology, stratigraphy and volcanology into a unified model to explain the geological characteristics of the studied area.

Compared with the surrounding sedimentary strata, igneous rocks show high impedance properties on the seismic profile. Various volcano-related facies, such as laccoliths, dikes, and sills, are frequently observed in the volcanic system. Sub-volcanic zones can be associated to uplift and arching of pre-eruptive strata deformed by laccoliths, dikes, and sills. According to the temporal and spatial filling patterns and changes of sedimentary thickness, the spatial location of volcanic crater and the relationship between sedimentary rocks and intrusive rocks beneath volcanic cones, the history of sedimentary filling history and/or mini-basin subsidence and active period of magmatism can be constrained.

This paper demonstrates a range of sediment–magma interactions, which demonstrate the current understanding of sedimentary fill history response to magmatic processes in a salt-walled mini-basin evolution.

Sedimentary characteristics and the significance of volcanic ash in organic-rich shale of Shahejie Formation in Jiyang Depression, Bohai Bay Basin, China

Jiahong Gao[1], Xinping Liang[1*], Zhijun Jin[1], Quanyou Liu[1,2], Juye Shi[3], Peng Li[2]
1. Institute of Energy, Peking University, Beijing, CHINA
2. State Key Laboratory of Shale Oil and Gas Enrichment Mechanisms and Effective Development, Sinopec Petroleum Exploration and Production Research Institute, Beijing, CHINA
3. School of Energy Resources, China University of Geosciences, Beijing, CHINA
E-mail: xinping.liang@pku.edu.cn

Keywords: Volcanic ash, organic-rich shale, Shahejie Formation, Jiyang Depression

Most of the organic-rich shales of the world's source rock are deposited with volcanic ash layers. For one reason, the volcanic ash is the provenance of the sedimentary basin; for another, the substances and energy of volcanism carried before and after its subsidence process can change the physical, chemical, and biological fields of the sedimentary water column, and thereby changing the primary productivity and the preservation environment of organic matter in sedimentary basins. Therefore, this paper takes the organic-rich shale of the upper submember of Member 4 (E_{s4s}) and the lower submember of Member 3 (E_{s3x}) of the Shahejie Formation in the Jiyang Depression as the research object, by comparing and analyzing the sedimentary characteristics of organic-rich shales, which deposited with volcanic ash layers, we discussed the impact of volcanism on the formation and preservation of organic-rich shale, obtained the following understandings:

(1)The tuff of the organic-rich shale layer in the E_{s4s} and the E_{s3x} is composed of variable-sized volcanic debris. The volcanic debris in the tuff layer is coarse to fine from the bottom to the top in the organic-rich shale layers. Furthermore, there are biological debris and glass fragments in the thin piece of tuff layers. The irregularly shaped glass fragments mean less roundness and closer handling distances. XRD shows that the content of crispy minerals in the tuff layer sample is 0.0-56.1% (11.7% on average), and the content of clay minerals is 0.0-49.8% (25.7% on average). The clay mineral is dominated by the mixed layers of illite and montmorillonite. Other components in the tuff layer sample are rhodochrosite, magnesite, pyrite, galena, barite, and common pyroxene.

(2)The TOC in the upper and lower sections of the volcanic ash is richer than that in the volcanic gray section, but generally not more than 6%. Furthermore, the content of the TOC is not more than 0.5%, which is generally low in the roller gray section or gray mud section. XRF shows that the main element components of the tuff layer sample of the E_{s4s} and the E_{s3x} are SiO_2 (28.22-69.43%), CaO (0.49-41.85%), and Al_2O_3 (2.54-16.71%), followed by Fe_2O_3, MgO, K_2O. ICP-MS shows the tuff layer samples have enriched light rare earth elements (LREEs) represented by $(La/Yb)_N$ (subscript N denotes the chondrite normalized) ratios of 15.04-87.22 (29.19 on average). They mainly show slightly negative Eu anomalies in the chondrite-normalized REE patterns $2(Eu)_N/(Sm+Gd)_N$=0.22-0.27, 0.27 on average).

(3)The comprehensive sedimentary and geochemical analysis shows that the nutrients (Fe, Cu et al) carried by volcanic ash have promoted the biological bloom during the deposition of the E_{s4s} and the E_{s3x} and therefore improved the primary productivity. Furthermore, biological bloom consumed an amount of oxygen and quickly formed the hypoxic environment that was conducive to the burial and preservation of the organic matter.

E-mail: Paul.Durkin@umanitoba.ca

Keywords: sedimentology, volcaniclastic, fluvial, lacustrine, geochronology, archeology

Volcaniclastic sediment delivery to a rift-basin setting influences the spatial distribution and temporal evolution of sedimentary environments and their paleoecology. Additionally, intercalated tephra can provide high-quality ages to quantify sedimentary processes and rates of environmental change. Olduvai Gorge, Tanzania is a world-renowned archeological site; it's steep valley walls expose a Pleistocene terrestrial-to-lacustrine succession with frequent volcaniclastic input. Here, we utilize 40Ar/39Ar dating and detailed sedimentary characterization to quantify temporal and spatial variations in depositional environments and sedimentation rates from ~2 to 1.7 Ma.

Western Olduvai Gorge exposes ~45 m of rift-platform basin stratigraphy. Previous studies have characterized the stratigraphy and identified key marker tuffs, however, a detailed evaluation of sedimentological relationships at a finer scale has yet to be undertaken. We present bed-scale sedimentological characteristics compiled from seven measured sections that document bedding, grain size, and sedimentary structures, aided by thin-section analysis to characterize texture and mineralogy. A digital outcrop model was constructed to aid with physical correlations and stratigraphic architecture analysis. Samples of tuffs and an ignimbrite were separated for k-feldspar phenocrysts (i.e. sanidine) and dated by 40Ar/39Ar geochronology; additional geochemical analyses further support marker tuff identification and correlation.

Our results demonstrate spatial and temporal variations in depositional environments under changing conditions of volcanic activity. The lower portion of the succession is dominated by volcaniclastic input. The basal Naabi Ignimbrite (2.038 +/- 0.002Ma) is overlain by a thick volcaniclastic fan succession, including mass flow diamictites, weakly developed paleosols, and small-scale fluvial channel deposits. As volcanic mass flow events diminish, a lacustrine-to-fluvial system develops from east to west and is characterized by waxy clay lacustrine sediments and coarse-grained fluvial channel deposits, capped by a fluvially-reworked tuff (IA; 2.019 +/- 0.002 Ma). Lacustrine shoreline mud-flat deposits with episodic tuffaceous input persist throughout the remainder of the succession and contain thick intercalated tuffs (IB 1.867 +/- 0.006 Ma; IC 1.852 +/- 0.027 Ma). During times of high volcaniclastic input, we document sedimentation rates of ~1 m/ka; as the lacustrine-fluvial system develops, rates decrease to 0.02 m/ka. This change may be attributed to a combination of diminished volcaniclastic sediment input and decreased basin subsidence during a period of rifting quiescence. The decrease in sediment input is further supported by the development of persistent lacustrine environments in an endorheic basin. Overall, our study demonstrates rapidly changing environmental conditions driven by sediment input sources and basin subsidence. These results are applicable to analogous terrestrial-lacustrine settings globally and refine the paleoenvironmental context for past and future archeological discoveries at Olduvai Gorge.

Records of oceanic and climatic changes in sedimentary evolution of Cretaceous basins in NW Turkey (Central Pontides)

Ismail Omer Yilmaz[1*]
1. Geological Engineering, Middle East Technical University, Ankara, Cankaya, TURKEY
E-mail: ioyilmaz@metu.edu.tr

Keywords: Black Sea Basin, Pontides, Paleoclimate, Cretaceous OAE, NW Turkey

Stable isotopes values (O, C) of the bulk samples are obtained from measured stratigraphic sections in Cretaceous successions (Hauterivian-Barremian, Aptian, Cenomanian-Turonian) around Central Pontides (NW Turkey), (Hu et al., 2012a,b; Yilmaz et al, 2004, 2010 and 2012).

Lower Aptian platform carbonates of Pontides are generally composed of alternation of alternation of sandy limestone and subtidal facies. Average paleotemperature data in Pontides is 31,210C. Lower Aptian pelagic equivalents in Pontides display 24,380C in average. This change is interpreted to be related to OAE1a in the basin (Yilmaz et al, 2004, Hu et al., 2012a,b).

Hauterivian –Barremian platform carbonates of Pontides display different sedimentary evolution and present a drowning of the carbonate platform in western part. Presence of black shales over the drowned platform is related to the Faroni Event in the basin (Yilmaz et al, 2012). However, the Barremian is represented by shallow water carbonates in the north. Hauterivian platform carbonates display 16,170C and pelagic Barremian presents 26,030C. However shallow water Barremian displays 35,100C in the north.

Average paleotemperature value obtained in pelagic Late Cenomanian in Pontides is 24.50C and average paleotemperature of Early Turonian is 22.80C. Record of OAE2 within these pelagics are correlated in the whole basin (Yilmaz et al, 2010).

Temperature values fit to Global Cretaceous ocean values in Mediterranean Tethys Ocean, and it has been seen that there is good correlation of Cretaceous Global Events in Pontides (NW Turkey) successions. Paleotemperatures of platform and equivalent pelagics displayed considerable difference and can be used in global and regional correlation.

Geochemical characteristics of the Kındıralık Dere formation: New insight into Late Cretaceous evolution of the Eastern Pontides, NE Turkey

Merve Özyurt[1*], Raif Kandemir[2], Selim Yıldızoğlu[2]
1. Geological Engineering Department , Karadeniz Technical University, Trabzon, turkey, TURKEY
2. Geological Engineering Department, Recep Tayyip Erdogan University, Rize, Black Sea, TURKEY
E-mail: merveyildiz@ktu.edu.tr

Keywords: Eastern Pontide, Geochemistry, Cretaceous, Sandstone

The Eastern Pontides, as eastern contination of the Alp-orogenic belt, has a complex Mesozoic geodynamic evolution that is highly controversial. The Upper Cretaceous sedimentary successions constitute important products of Mesozoic geodynamics evolution of Tehysan basin. One of the important units is Kındıralık Dere Fm., which commonly known as yellowish sandstone lithofacies. The sandstone unit preserve important implications for paleoenvironmental conditions and tectono-sedimentary evolution of Tethys Ocean.
The sandstones are mainly sublithic-calclithic arenites in lithology showing poor textural maturities. They are mostly represented by relatively low SiO2 values and high CaO values, high CIA and CIW (98,99-99,35), wide range of SiO2/Al2O3, Cr/Th, La/Co, La/Sc , Co/Th, Zr/Sc vs Th/Sc. Their geochemical features, where sediments were subjected to intermediate weathering conditions and rapid erosions, and were finally transported to the studied area. The petrographic and geochemical characteristics imply that the sediments may have experienced relatively intermediate weathering processes and slight reworking and recycling processes with a short transport distance before deposition in the basin. The geochemical results show that the terrigenous fragments were derived from the acidic and intermediate products of an arc magmatism. The studied samples can be considered as transgressive series were deposited on slopes or the deep shelf basin at a complex CIA setting under a well oxygenated condition, which are most likely a extensional tectonic setting.

The paleogeomorphic background and tectonic evolution of the Qaidam Jurassic Basin

yilun liu[1], fusheng yu[1*]
1. , , , CHINA
E-mail: fushengyu@cup.edu.cn

Keywords: Qaidam Basin,Jurassic Basin, paleogeomorphic background, Tethys Ocean,tectonic evolution

The development of the Qaidam Jurassic Basin is inseparable from the pre-Jurassic tectonic evolution in this area. Before the Jurassic, the area experienced three major tectonic evolution and transformation stages. (1) The Cambrian-Early Silurian was the formation and development of the Qinqikun ocean basin and the closed-collision orogenic stage of the Early-Middle Silurian. The Sinian-Ordovician sedimentary caprocks are formed, and two types of sedimentary assemblages are mainly developed: the first type is distributed in the Quanji-Oulongbuk Mountains in the northern margin of the Qaidam Basin, which is platform-type stable sediments, and consists of shallow metamorphic carbonate rocks, clastic rocks, etc. It is characterized by rock assemblages (excluding volcanic rocks); the other type is distributed in the periphery of the Qaidam block, represented by the Tanjianshan Group, which is an orogenic belt-type active deposition, with fine-grained clastic rocks and thin-bedded carbonate rocks as the Features (including volcanic rock assemblages). (2) The Late Devonian-Carboniferous period was the formation of the Southern Kunlun Ocean (Paleo-Tethys) and the development of the trench arc basin system, the closure of the Permian, and the stage of the South Qilian epicontinental sea. It is the upper Devonian-Permian sedimentary caprock. After the Middle Devonian, due to the formation of the Eurasian unified plate, a new stage of sedimentary basins began to develop in the Qaidam area and its periphery in the Late Devonian. A set of clastic rocks and carbonate rocks of the marine-terrestrial interaction facies were deposited in the margin and South Qilian area. (3) The Middle Permian-Middle Triassic was the formation of the Jinshajiang Ocean and the development of the island arc basin, the end-Triassic-early Jurassic collision and closure, and the strike-slip thrust orogeny stage in the northern margin of the Qaidam and the southern Qilian. The Jurassic-Cenozoic sedimentary caprocks are formed. The Jurassic and its overlying Mesozoic and Cenozoic are the most important sedimentary caprocks in the Qaidam Basin, as well as the main hydrocarbon-bearing layers in the Qaidam Basin.

Tectonic stress influence the reliability of paleomagnetic data from the Upper Cretaceous redbeds in the Lhasa Terrane

Hongliang Lu[1], Baochun Huang[1*], Qian Zhao[1]
1. School of Earth and Space Science, Peking University, Beijing, CHINA
E-mail: bchuang@pku.edu.cn

Keywords: redbed, AIRM, CPO, India-Asia collision, Lhasa terrane

The paleomagnetic results from the Lhasa terrane are commonly used to constrain the shape and paleo-position of the southern margin of Asia before the India-Asia collision. However, the reliability of the paleomagnetic data from the Upper Cretaceous sedimentary rock in the Lhasa terrane has long been under debate. We use the anisotropy of magnetic susceptibility (AMS), the anisotropy of isothermal remanent magnetization (AIRM), and the crystal preferred orientation (CPO) to analyze the remanence-carrying ferromagnetic minerals in the redbeds of the Shexing Formation. We found that no matter what structure the AMS data show, the AIRM data of these redbeds indicate a deformational magnetic fabric, whose minimum axes are roughly corresponding with the c-axis of hematite. We suggest choosing AIRM as the substitution of AMS to estimate the reliability of the paleomagnetic data from sedimentary rock. We recommend the data from the Upper Cretaceous redbeds in the Lhasa terrane should not be used for paleogeographic reconstruction before careful correction of the remanent magnetization direction, which calls for a full understanding of the deformation process of the rock.

Major, trace elements and Sr isotope characteristics of Guadalupian bedded chert in the north margin of Yangtze religion: Implications for chert source, depositional environment and palaeooceanographic

Yu Yu[1*]

1. State Key Laboratory of Oil and Gas Reservoir Geology and Exploitation, Chengdu University of Technology, Chengdu, Sichuan, CHINA

E-mail: yuyu@cdut.edu.cn

Keywords: Permian Chert Event, Sr isotope, Conodont, geochemical, Guadalupian

Unusual chert accumulation depositions were well developed worldwide in the Permian with a time span of tens of millions years, and are known as Permian Chert Event (PCE). In the Upper Yangtze region, the Middle Permian cherts are widely distributed and occurrenced in the form of nodule and bedded. In the northern and eastern of the Sichuan Basin, bedded cherts is developed near the boundary between the Midlle Permian Maokou Formation and the Upper Permian Wujiaping Formation. Based on the identification of micro paleontological fossils of limestone interbedded with bedded cherts from the middle and upper part of Maokou Formation to the bottom of Wujiaping Formation in northern Sichuan, the results show that the bedded cherts belong to the Capitanian of the Guadalupian and are the same age as the Gufeng Formation in the middle and lower Yangtze region. Geochemical analysis indicates that the bedded cherts have high Al/(Al+Fe+Mn) values ranging from 0.6 to 0.7, which are non-hydrothermal chert, and the large number of siliceous radiolarians observed in microscopic thin sections suggests that the silica origin of the Guadalupian bedded cherts is mainly biological. The LaN/YbN value, δCe, LaN/CeN value and diagram of LaN/CeN-Al2O3/(Al2O3+ Fe2O3) indicate that the cherts formed in a pelagic basin far from land. The measured 87Sr/86Sr values of cherts (HNO3 plus HF dissolved) range from 0.706903 to 0.708298, and after correcting with the Sr and Rb values of samples, the initial 87Sr/86Sr values ranging from 0.706315 to 0.707568, which is consistent with the global 87Sr/86Sr values of the Guadalupian. The 87Sr/86Sr values of seawater decreased to the lowest in the Paleozoic during the Capitanian at the end of the Guadalupian, which is related to the eruption of basaltic rocks in Emeishan and the addition of mantle-derived strontium in seawater at that time. In addition, the agreement of 87Sr/86Sr values of bedded cherts with those of seawater during the same period further indicates that the genesis of cherts was dominated by seawater deposition, but indirectly influenced by the eruption of the Emei Mountain basalt.

Feature and origin of the Late Jurassic sandy neptunian dykes in the Tibetan Tethys Himalaya

XIANGHUI LI[1*], JINGYU WANG[1], ZHEN WEI[1], MIN ZHOU[1], XIAOLONG FAN[1]
1. School of Earth Sciences and Engineering, NANJING UNIVERSITY, NANJING, JIANGSU, CHINA
E-mail: leeschhui@126.com

Keywords: Quartzose sandstone, neptunian dyke, syndeposition, Late Jurassic, Tethys Himalaya

Neptunian dykes/sills (nepdykes) are widely recognized through the Phanerozoic sequence. In general models, nepdykes are commonly formed in older rocks, few were formed in the syndepositional (unlithified) sediments, and nepdykes have been interpreted to form under two main tectonic circumstances. In compressional tectonic settings, nepdykes typically form due to liquefaction when over-pressurized conditions lead to the injection of sands into the overlying strata. This produces nepdykes that are composed mainly of sandstone. In extensional tectonism, nepdykes are typically considered to form when rocks are fractured and are infilled with much younger pelagic sediments, nearby-sourced talus, and precipitated carbonates. These nepdykes have been largely reported in the Jurassic-Cretaceous sequences in western Tethys, but are rare in eastern Tethys. In those examples, nepdykes are composed of non-sandstone and developed within lithified platform deposits and some in the pre-Triassic granites and gneiss.

During the investigation of the uppermost Jurassic strata in the Tibetan Tethys Himalaya, we discovered a great number of a new type of sandstone nepdyke which differ from previously reported styles. We characterized the nepdykes and their host rocks through a comprehensive field study, together with petrographic observations and detrital zircon U-Pb dating.

Field investigations show that the nepdykes are meters to hectometers long and centimeters to meters thick. The nepdykes taper downward at relatively high angles and crosscut country rocks. Microscopic observations show that the sandstones within the nepdykes and the sandstone host rocks consist of predominant quartzose grains set with muddy matrix and moderate-bad sorting and roundness, and share the same detrital zircon U-Pb age clusters (600−500 Ma and 1000−800 Ma). Using available biostratigraphy data, we propose that both the nepdyke and stratal sandstones are contemporaneous in deposition and share the same provenance, implying the quartz sands were transported in a mass/gravity current to infill existing tensile fractures. There is no evidence of ptygmatic folds, liquefaction, or shale fragments observed within the nepdykes, indicating the tensile factures were yielded in an extensional tectonic setting which are consistent with the rifting tectonic circumstance within the East Gondwana.

E-mail: Guohui.Chen@live.cn

Keywords: Ordovician to Eocene, Sandstone provenance, Zircon geochronology, Antalya Complex, N Gondwana

Detrital zircon geochronology of the Antalya Complex (=Antalya Nappes) sheds light on the pre, syn- and post-rift sedimentary-tectonic development of N Gondwana, related to opening and closure of S Neotethys in the E Mediterranean region. Recent fieldwork indicates that the Antalya Complex in its easterly (Güzelsu) outcrop includes three main thrust sheets of Lower Paleozoic-Upper Cretaceous platformal sediments, underlain by structurally dismembered Middle Triassic-Upper Cretaceous deep-sea sediments, Triassic volcanics and sparse ophiolitic rocks (imbricated thrust sheets and melange). The allochthonous units are restored as a pre-rift platform, Triassic rift and later-Mesozoic passive margin that bordered S Neotethys. The Antalya allochthon was assembled during the latest Cretaceous and finally emplaced onto the adjacent Tauride carbonate platform during Paleocene-Eocene.

Detrital zircons were extracted from 7 representative sandstone samples, previously dated (paleontologically) as Ordovician to Eocene, and then analysed for U-Pb ratios by LA-ICP-MS, yielding 700 discrete ages. For the upper structural units (platformal), the Ordovician (n=1) sandstone yielded abundant 600-740 Ma ('Pan-African') and Tonian ages, together with less pronounced clusters at 2.0 Ga and 2.6 Ga. The Upper Permian sandstone (n=1) has similar Precambrian-dominated zircon populations, mainly clustering in the Ediacaran (610 Ma peak), Tonian (950 Ma peak) and Paleoproterozoic (2.0 Ga). For the lower structural unit, Middle-Upper Triassic sandstones (n=2) contain abundant Precambrian detrital zircons, with major age peaks at ca. 640 Ma, 960 Ma, 1.9 Ga and 2.5 Ga, together with Devonian-Carboniferous (3%) and Triassic (1%). One sample of uncertain age (Jurassic-Cretaceous) is dominated by Neoproterozoic detrital zircon clusters (630 Ma peak), together with rare Devonian (1%) zircons. Another sample also of uncertain age (U. Triassic or U. Cretaceous) is Cretaceous based on a similar zircon age spectrum including Carboniferous zircons (299-343 Ma; 18%) together with rare Cretaceous (91 Ma) zircons. The Upper Paleocene-Eocene sandstone of the regionally underlying, autochthonous platform is dominated by Precambrian zircons, with Ediacaran (ca. 635 Ma), Tonian (750 Ma and 930 Ma) and also minor Paleoproterozoic (1.9 Ga) and Archean (2.5 Ga) fractions. Late Carboniferous zircons (7%) peak at 310 Ma, whereas Permian is minimal (n=1). Th/U ratios suggest that all of the Ordovician-Late Cretaceous grains analysed from all 7 samples are likely to be of igneous origin.

The Ordovician zircon age spectrum is consistent with a NE-Gondwana provenance. The Triassic sandstones include Late Paleozoic zircons that probably resulted from exhumation/reworking of Upper Paleozoic Paleotethyan units farther north, together with a more local rift-related Triassic source. The Upper Cretaceous terrigenous sandstone is interpreted as belonging to a foredeep, related to initial emplacement of the Antalya Complex. The upper structural units have few Late Paleozoic zircons, whereas the lower structural units have minor to common Devonian-Carboniferous grains. The early Cenozoic detrital zircon age spectrum is consistent with field and petrographic evidence of derivation from the Antalya Complex during its final emplacement onto the Tauride carbonate platform. Overall, the dominant NE Gondwana provenance is similar to tectonically transported rift/passive margin units elsewhere in the E Mediterranean; e.g., Taurides elsewhere, Cyprus, Crete and the Peloponnese (Greece).

The significance of Tethys domain tectonic evolution to the petroleum system: a case study of Central Sumatra

Zengyuan Zhou[1,2,3], Xiaowei Fu[1,2,3*]
1. State Key Laboratory of Marine Geology, Tongji university, Shanghai, CHINA

Keywords: Central Sumatra, Tethys domain, Sediment provenance, hydrocarbon resources

The Tethyan tectonic domain is acknowledged as a worldwide petroleum enrichment area. Central Sumatra Basin is the most oil-rich basin in S-SE Asia, the study of its structure and sedimentary evolution can not only understand the law of oil and gas enrichment in this area and implement its oil and gas resource potential, however, it is also necessary to define the resource influence of the Tethyan tectonic domain 's evolutionary process. Affected by the subduction of Indian ocean crust to the continental margin of SE Asia, early-middle Eocene to early Oligocene, the environment of alluvial fans, rivers, and lakes in the basin contributes to the formation of major source rocks under the action of back-arc expansion. Early Miocene, regional thermal settlement stage, formed sandstone reservoir mainly composed of Sihapas Formation. From middle-middle Miocene to the late Miocene, the Indo-Australian plate was subducted obliquely and most tectonic units in the basin were active. A large number of traps composed of anticline and faults have been formed. Due to crustal thinning and subsidence, the maturity of source rocks in different zones of the basin also varies greatly. The average geothermal gradient value in the basin is 4.98 ℃/100m, and Pedada Oilfield reaches 13.66 ℃/100m. Structural events caused by the subduction of the ocean crust make high heat flow values an important factor for hydrocarbon enrichment in this area.

Keywords: foreland basin, Lower Cretaceous Duoni Formation, Lhasa-Qiangtang block collision, sedimentological, provenance, Tibetan Plateau

The Mesozoic sedimentary record in the central segment of the Bangong-Nujiang Suture Zone provides crucial information to constrain the timing of the Lhasa-Qiangtang block collision in the Tibetan Plateau. In this study, we perform detailed facies analysis and provenance analysis on the Lower Cretaceous Duoni Formation in the Baingoin basin, central Tibet. The nonmarine Duoni Formation widespread and unconformably overlies the Jurassic ophiolite and accretionary complex initially deposited in the lacustrine and deltaic environments adjacent to the shoreline, then evolved into a continental highland-related fluvial and alluvial environment upwards. Palaeocurrent data suggest a northward source for the lower portion and a southward source for the upper portion of the Duoni Formation. Quartzite clasts of the Conglomerates increase upward, and the composition of sandstones changes from greywacke to subarkose to quartz arenite upward. Detrital modal of sandstones supports a mixed to a recycled orogenic source transition through time. Zircon U-Pb dating of multiple interbedded andesite layers in the Duoni Formation indicates a depositional age at ca. 113 Ma. Collectively, integrated sedimentological evidence suggests that the Lower Cretaceous Duoni Formation was deposited in a collisional foreland basin system related to the Lhasa-Qiangtang block collision.

Sedimentary pattern influence of regional tectonic uplift: A case study of the Late Triassic in the southeastern Sichuan Basin of China

Tenghui Lu[1], Tingshan Zhang[1*], Xi Zhang[1], Jianli Zeng[1], Hao Huang[1], Shixin Li[1], Zhiheng Ma[1]
1. School of Geoscience and Technology, Southwest Petroleum University, Chengdu, Sichuan, CHINA
E-mail: zhangtingshan@swpu.edu.cn

Keywords: Tectonic uplift,sedimentary patterns,Sichuan Basin,Luzhou Paleo-uplift,Late Triassic

Regional tectonic uplift has a significant impact on regional sedimentary patterns. The Luzhou Paleo-uplift, which developed in the Sichuan Basin of Southern China during the Indochina period, sprouted during the sedimentary period of the early Triassic and died out in the Late Triassic, which had a significant impact on the sedimentation and ecological environment in the southeastern Sichuan Basin and was recorded in sedimentary strata. In the Luzhou Paleo-uplift core area, the Xujiahe Formation is directly covered above the Jialingjiang Formation, and the stratigraphic sequence is generally missing the Leikoupo Formation, but whether there is a sedimentary record of the firstsecond member of the Xujiahe Formation is still controversial, and the extent to which the paleo-uplift influenced the sedimentary patterns of the early Xujiahe period in the southeastern Sichuan Basin is unclear.

The study shows that the influence of the Luzhou Paleo-uplift on the sedimentary pattern in the southeast of the Sichuan Basin is limited, and the early strata of the Xujiahe Formation are still normally deposited. There are two main pieces of evidence: (1) Cyclostratigraphy: through the analysis of cyclostratigraphy, the sedimentary time of the XujiaHe period in southeast Sichuan was calculated to be about 5.9 Ma, which was basically consistent with the relatively complete stratigraphic development of the Xujiahe period in the Xuanhan Qilixia area of eastern Sichuan; (2) Sporomorph EcoGroup model analysis: sedimentary environment and biological succession were analyzed by SEG curves, and similar abundance changes were compared with the section of Tanba and Qilixia.

In addition, this study also shows that the Luzhou paleo-uplift affects the sedimentary differences between the East and West regions of the early Xujiahe period by controlling the regional sedimentary pattern, the eastern paleo-uplift region is dominated by continental sedimentation, and the western paleo-uplift is dominated by marine sedimentation. There are three main pieces of evidence: (1) Geochemistry: the ratios of Sr/Ba, MgO/Al_2O_3 and CaO/(Fe+CaO) indicated that the southeastern part of the Sichuan Basin was a freshwater sedimentary environment, It was not until the late sedimentary period of the first member of Xujiahe Formation, that the southeastern part of the Sichuan Basin began to transform into a marine sedimentary environment consistent with the whole basin; (2) Distribution of paleontology: The strata of the first member of the Xujiahe Formation in the western part of the Sichuan Basin contain abundant marine Lamellibranchia, while the eastern part is a large number of terrestrial plant fossils due to the uplift to land; (3) Stratigraphic distribution: the stratigraphic thickness of the Xujiahe Formation in western Sichuan is gradually thinning towards the eastern part of the basin. And the Xujiahe Formation of the core area of the Luzhou Paleo-uplift has been obviously thinner from firstthird member compared with other regions.

The above understanding is not only of great significance for determining the sedimentary time of the Xujiahe Formation and the comparison scheme of stratigraphic division in the basin at this period, but also has certain enlightenment for understanding the impact of regional tectonic uplift on sedimentary patterns.

Keywords: Palaeogeography, Middle Triassic, Western Tethys, Biostratigraphy, Sardinia

The Sardinian Middle Triassic successions (SMTs) have been studied from the end of the 19th century. Their importance in understanding the paleogeographic evolution of the southern margin of Paleo-Europe is long debated for its crucial significance. The SMTs, found in Germanic facies (Buntsandstein, Muschelkalk and Keuper), are reduced in thickness and they have been deeply dislocated by the alpine tectonics. Despite of this, they contain biostratigraphic key-elements allowing more precise insights about the modalities of the Western Tethys transgression. This westward transgression proceeded in a complex paleogeographic framework through a network of marine corridors, outlined by tectonically elevated blocks and subsiding areas. The present work focuses on the stratigraphical, sedimentological, and paleontological data of the Middle Triassic (Anisian and Ladinian) and aims in better understanding the paleogeographic evolution of the area.

To this end, the continental-to-transitional successions of Sardinia in Buntsandstein facies contain rich microfloristic associations that have been found mainly in key areas of the island (Iglesiente and Sarcidano-Gerrei, southwestern and central parts of Sardinia respectively). An extensive review of palynological content of these successions allows precise dating of the marine transgressive process and provides fundamental indications about the steps of the paleogeographic evolution of the island. In fact, during the late Anisian-early Ladinian period, Sardinia together with Minorca and the eastern area of Castellón (Spain), constituted an elevated area and acted as a barrier between the Paleotethys (in the northeast) and the Neotethys (in the southeast) domains.

The Ladinian shallow marine successions in Muschelkalk facies contain different and equally important paleontological elements (ammonoids, bivalves, conodonts, foraminifera etc.) and were deposited due to the regional transgressive episode recorded throughout the W Mediterranean. These biostratigraphic data, especially recorded in the Nurra region (northeast of the island), show the progressive westward settling of carbonate platforms, and consequently the development of new migration and irradiation routes for (i) the Sephardi faunas from the southeast (Paleotethys) and (ii) Alpine faunas (Neotethys) from the northwest.

The accurate study and revision of these associations allowed us to compare them with those of the adjacent domains (Balearic Islands, Levantine area) and to refine their paleoecological distribution. Moreover, the whole Anisian-Ladinian biostratigraphic record allowed us to better frame Sardinia in the paleogeographic evolution of the Western Tethys.

Keywords: Triassic Volcanic Rock , Extensional Tectonic Environment , Rift Volcanic Rock Formation , Simao Basin

Simao basin is located in the southeast of Qinghai-Tibet Plateau and belongs to the Sanjiang tectonic domain in the east of Tethys tectonic domain. A set of Triassic volcanic-sedimentary rock strata dominated by basic volcanic rocks are exposed in the Manghuai - Dachaoshan area of Yunxian County on the northwest edge of Simao basin. The strata are completely exposed and have obvious rhythmic cycle characteristics. It is an ideal material for understanding the tectonic evolution of Simao basin and the southeast edge of Qinghai-Tibet plateau.

The Triassic volcanic-sedimentary rock strata are distributed between Lancangjiang fault and Jiufang fault in nearly north-south direction. They are in unconformable contact with Pre-Triassic strata and integrated or unconformable contact with overlying Jurassic strata. From bottom to top, the Triassic strata are divided into Manghuai formation and Xiaodingxi formation, the lower Triassic strata are missing. Among them, the Manghuai formation is divided into upper and lower segments, the lower segment is a set of andesite, siltstone and mudstone mixed with pyroclastic rock, and the upper segment is a combination of high potassium rhyolite and pyroclastic rock mixed with a small amount of basalt. The volcanic rocks of the Manghuai formation are characterized by high silicon and high potassium, which are calc-alkaline volcanic rocks.

The Xiaodingxi formation is a set of alkaline-subalkaline basalt, andesitic basalt with rhyolite, pyroclastic rock and sedimentary tuff, which can be divided into five sets of rhythmic layers composed of lava-pyroclastic rock-sedimentary tuff. Volcanic effusion facies and eruption facies, strong eruption and weak eruption occur alternately.

The SiO2 content of volcanic rocks in Xiaodingxi formation is concentrated between 47.94% ~ 54.02% and 76.92% ~ 84.16%. The basic volcanic rock is rich in sodium and the acidic volcanic rock is rich in potassium. Both basic and acidic volcanic rocks are rich in large-ion lithophile elements (LILE) and relatively deficient in high field strength elements (HFSE). The REE distribution curves are right inclined with enrichment of light rare earth (LRE). The basic volcanic rocks have weak Eu negative anomalies and the acid volcanic rocks have strong Eu and Sr negative anomalies.

The Triassic volcanic rocks are the result of subduction and closure evolution of Lancangjiang Ocean in the ancient Tethys, which completely records the transformation process from collision compression environment to post collision extension environment in the area. The volcanic rock assemblage has the dual characteristics of arc volcanic rock and intraplate volcanic rock, and the volcanic activity is intermittent and multistage. From 248 Ma to early Jurassic, there were at least five active periods of volcanism, with an interval of 8 ~ 10 Ma. Coupling tectonic and volcanic activity, the western margin of Simao basin experienced the evolution stages of pre-rift uplift and rift basin. To the late Triassic Carnian period, a set of rift volcanic rock formation was formed in the western margin of the basin.

Study on hydrocarbon accumulation model of Paleogene-Cretaceous in North Sandaoqiao area of Tarim Basin

wei jie tong[1*]
1. School of Geosciences, Yangtze University, wuhan, , CHINA
E-mail: 1206101973@qq.com

Keywords: Sandaqiao, Tarim Basin, ternary controlled reservoir, structural trap, fault characteristics

In order to clarify the exploration direction of the Paleogene-Cretaceous in the northern Sandaoqiao area, the structural characteristics, formation and reservoir development are studied by using the comprehensive analysis technology of oil and gas accumulation, seismic inversion technology and core drilling data, and the conditions of oil and gas accumulation are discussed, and the controlling effect is analyzed, and the accumulation model is established. The results show that, under the influence of hercynian, Indosinian, Yanshan and Himalayan multi-stage tectonic movement and unconformity, faults and strata match to form structural traps, and oil source in Kuqa Sag is transported to Cretaceous and Paleogene traps along the migration network formed by faults and unconformity. Faults control the spatial distribution characteristics of oil and gas reservoirs. The unconformity between Paleogene and Cretaceous is an important channel for long-distance migration, and the paleogene plaster salt and mudstone cap is an important guarantee for long-distance accumulation. Based on the reservoir forming conditions and controlling effects, a reservoir forming mode of "lateral migration, vertical adjustment, three-way reservoir control and structural enrichment control" is established. It is pointed out that fault-controlled trap is the next favorable exploration direction in Sandaoqiao area.

Tectonic Evolution and Sedimentary Response of Yinggehai Basin

Li Wang[1*]
1. School of Geosciences, China University of Petroleum (East China), Qingdao City, Shandong Province, CHINA
E-mail: wangli0926454@126.com

Keywords: Yinggehai Basin,the Red River Fault Zone,Left-lateral Strike-slip and Right-lateral Strike-slip,Tectonic Evolution Stages,Sedimentary Response

Yinggehai Basin is located in the intersection of Eurasian plate, Indian-Australian plate and Pacific plate, and is one of the Cenozoic sedimentary basins in the western part of the continental shelf in the northern South China Sea. Its tectonic evolution is controlled by the plate collision caused by the intersection and recombination of the two tectonic domains of Tethyan-Himalaya and the Pacific. It is mainly the relative compression between the Indo-China block and the South China block caused by the collision between the Indian plate and Eurasian plate. The tectonic development of Yinggehai Basin has experienced three stages: rifting, left-lateral strike-slip and right-lateral strike-slip. The tectonic pattern and sedimentary response of different evolution stages are obviously different. Rifting stage (56-32Ma): The Yinggehai Basin is controlled by NW-trending boundary faults. The Yingxi slope zone, the central depression zone and the Yingdong slope zone are left-middle-right. During this period, the faults have strong vertical activity and obvious sedimentation control. The lacustrine Lingtou Formation and the swamp coastal plain Yacheng Formation are deposited, and the sedimentary center is located in the descending plate of No. 1 fault.Left-lateral strike-slip stage (32-5.5Ma): Affected by the left-lateral strike-slip of the the Red River Fault Zone (RRFZ), the vertical activity of the basin fault is weakened, and only the basin boundary fault has the characteristics of continuous activity, mainly the Yingxi fault and the Yingdong fault and the No. 1 fault, which control the sand body deposition from the Kunsong uplift in the west of the basin and the Hainan uplift in the east of the basin, respectively. The sedimentary center range is expanded to two large sedimentary centers, which are distributed in the southern part of the Lingao uplift and the descending plate of the No. 1 fault. Until the left-lateral strike-slip movement of the RRFZ is gradually stopped, the subsidence-controlling fault activity of the Yinggehai basin is reduced, the sedimentary rate of the basin is reduced, and the two sedimentary centers are merged. A new sedimentary center with smaller range is formed in the middle of Yinggehai Sag. From bottom to top, fan delta facies-shallow sea facies Lingshui Formation, shallow platform facies Sanya Formation, coastal facies Meishan Formation and shallow-semi-deep sea facies Huangliu Formation are developed. Right-lateral strike-slip stage (since 5.5Ma): Controlled by the right-lateral strike-slip of the RRFZ, the sedimentary center transited to the eastern part of the basin. Under the control of the continental shelf – slope break zone in the basin, the sedimentary center continued to migrate to the southeast of the basin. During this period, the faults were almost inactive, the sand bodies rapidly subsided, and the deposition rate reached the maximum. The shallow-semi-deep marine strata of the Yinggehai Formation of the Pliocene and the Ledong Formation of the Quaternary were deposited.Clearing the spatial and temporal differences of tectonic pattern and sedimentary response in Yinggehai Basin is of great significance for revealing the distribution of oil and gas.

Tectonic sedimentary evolution and overlapping unit division in Sichuan Basin

Ma Chen Xi[1*]
1. School of Geosciences, China University of Petroleum(East China), Qingdao, Shandong , CHINA
E-mail: 1701050219@s.upc.edu.cn

Keywords: superimposed basin, basin superposition unit, basin evolution, vertical stratigraphic framework, sichuan Basin

Sichuan basin is located in the northwest of South China plate, and is located in the intersection area of Eurasian plate, Indian-Australian plate and Pacific plate. Its tectonic evolution is controlled by the intersection and combination of the two tectonic domains of Tethyan-Himalayan and the Pacific. In the tectonic dynamic background of the subduction of the ancient and modern Pacific to East Asia, the collision of the Indian-Australian plate and the interaction between plates wedged by the Philippine plate, Sichuan basin has experienced multiple tectonic movements such as Jinning-Chengjiang movement, Tongwan movement, Caledonian movement, Dongwu movement, Indosinian movement, Yanshan movement and Himalayan movement. It can be divided into five evolution stages : basement formation (Anz), marine sedimentary (Z-S), marine sedimentary associated with volcanism (D-T_2), continental clastic sedimentary (T_3-K_1) and differential denudation of whole basin uplift (K_2-Q). It has the characteristics of intracontinental basin formation, peripheral compression, multi-stage uplift, late denudation, planar composite and vertical superposition. The tectonic sedimentary pattern of the basin varies obviously in different periods. According to the vertical superimposed relationship of prototype basins in each stage, three types of superimposed units can be divided in Sichuan Basin.Type I : It is distributed in the Leshan-Longnvsi paleo-uplift, and continuously accepts marine stratigraphic deposition from Sinian to Ordovician. During the Caledonian movement in the late Silurian, it was eroded with the uplift of Leshan-Longnvsi paleo-uplift, and lacked stratigraphic deposition of Silurian, Devonian and Carboniferous. The continental clastic rock strata developed from Triassic to Jurassic, and only the sedimentary strata of western Sichuan foreland basin in the Cretaceous. After the late Cretaceous, the superimposed unit was eroded with the uplift of the whole basin. Type II : It is distributed in the range of Luzhou paleouplift and Kaijiang paleouplift. The Paleozoic sedimentary sequence is complete. During the Indosinian movement, it was eroded with the uplift of paleouplift, and the Triassic strata were missing. The Jurassic strata were deposited on it, and continued to be eroded until the late Cretaceous. Type III : distributed in the basin area except Leshan-Longnvsi paleo-uplift and Luzhou-Kaijiang paleo-uplift. Since the Paleozoic, marine and continental strata have been continuously deposited, and the vertical framework of strata is continuous. The northern Sichuan foreland basin area in the front of Longmen Mountain and the Chishui-Yibin area in the southern basin continue to accept the Cretaceous deposition, and then the other areas of the composite unit are subjected to differential erosion together. Different types of superimposed units have experienced different subsidence histories and have different combinations of source, reservoir and cover. Therefore, the division of superimposed units has important guiding significance for oil and gas exploration practice in Sichuan Basin.

Keywords: Low temperature thermochronology, exhumation, internal drainage, low relief topography, Tibet

Much of the interior of the Tibetan Plateau is characterized by internal drainage, low relief topography and high altitude. How and when this landscape formed is controversial. In this study, we use new zircon U-Pb data and low temperature thermochronological data (apatite and zircon (U-Th/He), apatite fission track (AFT)) from the Late Cretaceous to Cenozoic Nima basin sedimentary rocks and Xiabie granite in the adjacent Muggar Thrust hanging wall (part of the regional Shiquanhe-Gaize-Amdo thrust system), to determine the palaeodrainage and timing of exhumation in the region. Individual AHe and ZHe cooling ages range from 9 to 60 Ma and 58-118 Ma, and the AFT ages range from 30-90 Ma. The thermal history derived from the Northern Nima Basin sediments and Xiabie granite require a period of exhumation between 70 and 40 Ma in the thrust fault hanging wall, and 40 to 30 Ma in the Nima Basin. Across the region this event was followed by low rates of exhumation and the deposition of locally-sourced sediment, lacustrine and evaporitic deposits that are indicative of an internal drainage system. We suggest that the exhumation event is associated with development of thrust-elevated relief that may have disrupted the drainage network favouring the development of an endorheic system. This system, sediment accumulation and/or post-30 Ma tectonic quiescence led to the generation of low relief topography.

Tectonic evolution Controlling on hydrocarbon accumulation in the central and western of the Tethys

Danny Shi[1*]

1. Overseas Exploration and Project Evalutiation Department, Petroleum Exploration and Production Research Institude ,SINOPEC, BEIJING, CHINA

E-mail: shidanni.syky@sinopec.com

Keywords: Tethys,Paleo-uplift,Hercynian

The central and western section of the Tethys is an important oil and gas resource enrichment area in the world. The evolution cycle of the Tethys Ocean controls the formation of a pattern of east-west division and north-south division. The east-west division is represented by the Paleozoic basin in the west, the superimposed Paleozoic and Mesozoic basins in the middle, and the Mesozoic and Cenozoic basin in the east. The north-south division is shown in the north The Mesozoic and Cenozoic strata near the Tethys Ocean are developed, and the Mesozoic and Cenozoic strata far from the Tethys are not developed. The pre-Cambrian NS-trending paleo-tectonic belt laid the foundation of the tectonic framework and influenced the later sedimentary-tectonic framework. The Hercynian structure controls the appearance of the Paleozoic basin, strengthens or transforms the earlier structure, develops two types of paleo-uplift evolution and development models, and controls the distribution of Silurian source rocks and Paleozoic reservoirs. The Mesozoic-Cenozoic Hercynian new-genetic Paleo-uplift in North Africa was reversed to form a basin on the edge of the Tethys Ocean, which controlled the development of Mesozoic basins, the sedimentary centers of Mesozoic basins are mostly located in the Hercynian paleo-uplift area. While the Mesozoic in the Middle East shows an early extensional and late compressional basin model, forming an oil and gas accumulation model jointly controlled by a near-north-south structure, Hercynian structure, and Tethys extension.

Winter and Summer Sedimentary Dynamic Process Observations in the sea area off Qinhuangdao in the Bohai Sea

Chongguang PANG[1*], Deqiang ZHANG[1]
1. Circulation and Waves Lab, Institute of Oceanology, CAS, Qingdao, Shandong, CHINA
E-mail: chgpang@qdio.ac.cn

Keywords: Sedimentary dynamic process, Winter and summer observations, Residual currents, Suspended sediment flux decomposition, Sea area off Qinhuangdao, The Bohai Sea

Using seabed base observation platform measurements obtained in February 2017 and August 2019, this study examines the winter and summer hydrography and suspended sediment concentration (SSC) in the sea area off Qinhuangdao in the Bohai Sea. In summer, accompanied with high temperature and low salinity, the relatively weak residual currents flowed northeastward and showed little correlation with the wind field, especially in the middle layer of the water column. In winter, the residual currents were strengthened, flowing to the northeast during strong wind periods, and predominantly to the southwest during intermittent periods. Moreover, driven by the pressure gradient force associated with the wind-induced sea surface height variations, the winter current was closely related to the wind speed, with correlation coefficients ranging from 0.4 to 0.6 and a time lag of 10 hours. The summer SSC was lower and mainly controlled by the tidal current, whereas in winter, owing to the enhanced Reynolds stress and turbulent kinetic energy, strong wind bursts triggered significant sediment resuspension and led to a higher SSC. The frequent sediment resuspension in winter further reduced the consolidation degree of the seabed sediment. For the suspended sediment flux (SSF), the advection terms contributed more than 80% in the winter and summer, while the vertical circulation terms contributed 13% in winter, and approximately half that much in summer. Generally, the suspended sediment is transported back and forth, with a little net northward and northeastward motions in winter and summer, respectively. This may explain the low SSC sustaining in coastal Qinhuangdao all year round.

Morphodynamic evolution of the macro tidal Sittaung River Estuary, Myanmar: Tidal versus seasonal controls

Kyungsik Choi[1*], Dohyeong Kim[1], Joohee Jo[1]
1. School of Earth and Environmental Sciences, Seoul National University, Seoul, KOREA, SOUTH
E-mail: tidalchoI@snu.ac.kr

Keywords: tide-dominated estuary, bedload convergence, morphodynamics, tidal bore, river flood, anthropogenic activity

The inner part of a tide-dominated estuary is often typified by a tight meander bend, where bedload transport from both upstream by river flows and downstream by flood tidal currents merges to establish a bedload convergence (BLC) with the weakest energy condition in the estuary. Despite the potential significance in evaluating relative importance between tidal and river processes, the morphodynamics of the inner estuary remains relatively unexplored in terms of their response to governing processes. This study, based on satellite imagery and field observation, demonstrates that the inner part of the Sittaung River estuary in Myanmar has evolved via active morphodynamics over various temporal scales ranging from monthly to centennial cycles. Channels, including swatchways and flood barbs, migrate rapidly in response to mutually evasive tidal currents on monthly time scales, leading to an increase in the channel sinuosity. Annually, seasonal river floods accelerate channel migration, causing a tight meander bend. A chute cutoff of the point bar at the tight meander bend occurs during the river floods every 6 to 9 years, triggering substantial down-estuary changes in the position of the main channel, bars, tidal flats, and saltmarshes. Over centennial time scales, the main channel formed a large-scale, tight meander bend with a sinuosity exceeding 5, near the downstream end of the inner estuary, which corresponds to the BLC of the estuary. A chute cutoff of the large-scale tight meander bend during the high river flows resulted in the morphologic changes throughout the fluvial-marine transition zone of the Sittaung River estuary: widening of the main channel and the estuary via accelerated channel migration to accommodate an increase in river flows and tidal prism caused by an increase in the hydraulic gradient due to the shortening of the channel length. The tight meander bend has migrated seaward at centennial time scales, suggesting that the river influence has increased over the time, and the estuary is in the progradational phase to become a sediment- exporting delta. The recurrence of the bend tightening after the chute cutoff, however, indicates that flood-tidal currents drive the morphodynamic evolution of the estuary, and the gradual transition from an estuary to a delta is unlikely. Rapid channel migration with bar growth, frequent cutoff, and subsequent infilling of the abandoned channels over various temporal scales all typify the tide-dominated estuary is charged with high sediment loads imported from both rivers and offshore. Despite the construction of dams and reservoirs that reduced sediment supply into the estuary, other anthropogenic activities such as mining activities and deforestation appear to drive an increase in sediment loads, promoting the morphodynamics of the inner part of the Sittaung River estuary.

Estimation on Centennial relative sea level change along the Quaternary sedimentary coast using InSAR and satellite altimeter, Wenzhou Bay, China

Zhaoquan Huang[1*], Fengling Yu[1]
1. Department of Geological Oceanography, Xiamen University, Xiamen, Fujian, CHINA
E-mail: hzq@xmu.edu.cn

Keywords: relative sea level,Quaternary sedimentary coast,InSAR,satellite altimeter

Land subsidence prevailed on Quaternary sedimentary coasts due to sedimentary compaction, which exacerbated the threat of relative sea level rise. In the past research on relative sea level change trend, point observation data is usually used instead of regional data, and it is assumed that the trend of coastal land deformation is very stable, which is inconsistent with the situation in areas frequently affected by human activities. This study aims to estimate the relative sea level change in Wenzhou Bay area, a typical Quaternary sedimentary coast, with high resolution land deformation correction, and evaluate the potential risks of sea level changes to the coast. We firstly use satellite SAR data to extract the surface deformation of the coastal area of Wenzhou Bay. Accordingly, we adapt the method of spatiotemporal replacement to estimate the trend of surface deformation for the modern terrain correction. Based on this corrected modern terrain, the relative sea level in Year 2100 and scenarios of extreme sea level change are analyzed by applying the machine learning methods on InSAR and satellite altimeter data. Finally, the impacts of relative sea level change over scales on the coastline are analyzed. Three main findings are concluded: 1) The results show that sedimentary compaction is the main reason for the vertical displacement of the estuary and coastal areas, and the sedimentary compaction has been strongly impacted by the enhanced coastal construction activities ;2) The relative sea level in this area is unevenly distributed along the coastline due to the different land deformation rate along the coast; 3) Coastal areas with different land use types are under different levels of risks to sea level change, especially to extreme sea level changes. The results of this study are helpful to improve the spatial and temporal resolution of coastal hazard risk analysis in Quaternary sedimentary coasts.

River, tide and morphology interaction in a macro-tidal estuary with active morphological evolutions

Dongfeng Xie[1*]

1. Key Laboratory of Estuary and Coast of Zhejiang Province, Zhejiang Institute of Estuary and Hydraulics, Hangzhou, Zhejiang Province, CHINA

E-mail: dongfeng.xie@hotmail.com

Keywords: Tidal dynamics, River discharge, Tidal amplification, Morphological evolution, Qiantang Estuary

Understanding tidal dynamics in estuaries is essential for tidal predictions and assessments of sediment transport and associated morphological changes. This study analyzes the multiple-timescale tidal dynamics in the Qiantang Estuary, a macro-tidal estuary with an extremely active morphological evolution. A large dataset including water levels at representative stations, river discharges and bathymetries has been collected. The results of the analysis show that within a spring-neap cycle, the tidal amplification in the upper estuary is stronger during spring tide than during neap tide. On the seasonal and interannual timescales, the low water levels in the upper estuary depend on the local bathymetrical conditions. Tidal ranges in the upper estuary are larger in the high flow season and years, than in the low flow season and years, due to the erosion at high flow, in contrast to estuaries with less active morphological changes. During low flow season and years, the bed is gradually recovered, the low waters are elevated, and the tidal ranges decrease accordingly. A good relationship exists between the tidal ranges and the depth of the upper estuary. In the lower estuary, the flood dominance increases continuously due to embankment. In the upper estuary, the flood dominance is increased during the high flow periods, explaining the fast sediment input and bed recovery in the post high flow periods.

Response of beach landform to different coastal engineering practices

Xiaojing Zhong[1*], Peng Yu[2], Shenliang Chen[3]
1. College of Harbour and Coastal Engineering, Jimei University, Xiamen, Fujian, CHINA
2. Big Data Institute of Digital Natural Disaster Monitoring in Fujian, Xiamen University of Technology, Xiamen, Fujian, CHINA
3. State Key Laboratory of Estuarine and Coastal Research, East China Normal University, Shanghai, CHINA
E-mail: xjzhong@jmu.edu.cn

Keywords: artificial island, revetment, underwater barriers, beach nourishment, beach landform

From 2010 to 2018, 12 offshore artificial islands were constructed along the coast of Hainan, China. In this research, beach profile surveys over 8 years at sandy beaches in the vicinity of offshore artificial islands are analyzed to study How has the land coast evolved under the influence of artificial islands in the past decade, and What measures have been taken to protect the land coast.

The artificial island of Nanhai resort is in the south of Gaolong Bay, and the nearest offshore distance is about 108 meters. Profile 31 is in the south of the artificial island of Nanhai resort, where the beach was constantly eroded. The beach slope became steeper and the coastline retreated by more than 30 m. After the construction of the artificial island, block stone revetment was built on the beach surface on both sides of the road and bridge into the island, which destroys the continuity of the beach profile. When the wave propagates to the land, the stone dike will block the diffusion and infiltration of the upwelling wave flow along the slope, but increase the strength of the backflow and its scouring and erosion to the beach. If things go on like this, the collapse of the stone dike may also occur.

During the survey, sand replenishment works were carried out on the beach where profile 38 on the north side of the artificial island of Tamen fishing port. From July to December 2015, the beach elevation increased significantly due to human activities. The backshore of profile 56 is located on the coastal unsurfaced road used for the construction of Riyue Bay artificial island. From December 2013 to December 2014, the road was gradually piled up and reinforced, and block stone revetment was built on the upper part of the beach. The artificial sand replenishment of the beach temporarily increased the elevation and width of the beach, due to the lack of supporting wave dissipation works, the beach surface continues to retreat after sand replenishment. Today, the beach width is less than that before sand replenishment, but the beach shape is not stable and erosion continues. The block stone revetment on the beach also caused the erosion retreat of the lower part of the beach in profile 56.

Factors in the site selection, design, and construction of artificial islands, such as the short distance between artificial islands and land coasts, the inbound embankment intercepting the alongshore current, and the inadequate or improper protection measures for beach erosion have aggravated the impact and destruction of artificial islands on adjacent natural beaches and landscapes. In 2017, we suggested that "soft engineering", e.g., artificial underwater barriers and artificial reefs, as well as a combination of various ecological management scheme, could be considered to restore the damaged natural coast. Since 2020, we are pleased to see that such a combined project has effectively protected the land coast. Of course, their long-term role needs our continuous attention.

Keywords: delta, morphodynamic change, estuarine engineering, regime shift, tide

Numerous river deltas have been extremely altered by anthropic activities, where a regime shift from net accretion into net erosion may have occurred. For a mega-river delta, morphodynamic changes are quite obvious over different spatial and temporal scales. We examine these variations in the Changjiang Delta using time series bathymetric and remote-sensing data, together with numerical modeling by FVCOM.

The results show that a regime shift from net accretion into net erosion in the subtidal channel over the entire estuary should have occurred in 2009. However, nine sub-morphological units varied significantly in their responses to external and internal stresses. A mean annual erosion rate of -5.59 cm/yr was calculated in the subtidal channel during the period 2007-2019, and peak erosion occurred both in the South Branch and the delta front with mean annual erosion rates of -12.64 cm/yr and -8.11 cm/yr, respectively. The erosion lessened toward the middle estuary where sandy shoals prevail, and a net accretion rate of 3.13 cm/yr was solely measured at the Chongming shoal. Intertidal flats are accretional until now due to flood tidal dominance in the Changjiang Estuary. Coarse sediment by the channel erosion from the lower reach favors the river mouth accretion. We predict the accretion on the shallow mouth bars and intertidal flats will continue into the near future because of sediment supply from the river channel erosion and the tidal pumping effect to transport sediment landward from the offshore erosion.

Different from other distributary units, the North Branch is a typically abandoned distributary having evolved into a tide-dominated estuary where flood tides take a predominant role over ebb tides in sediment transport. Channel siltation has been accelerated recently due to land reclamation regardless of sediment deficit after the implementation of TGD and other mega-dams in the upper reach. This could be explained by strengthened tidal amplification due to the artificially reduced channel volume in the middle and upper segments of the North Branch after the implementation of several large-scale land-reclamation projects in the first stage (1997-2007) according to the numerical simulation of FVCOM. While tidal amplification was relaxed by the channel narrowing project at the lower segment through the large-scale land reclamation and the waterway improvement project through channel dredging works at the middle and upper segments during the second stage (2007-2017). Spatiotemporal variation in channel accretion and erosion patterns in response to estuarine engineering projects was vividly mirrored by the change of simulated bed shear stress in that the areas with increased (decreased) bed shear stress underwent severe erosion (accretion). These findings highlight again the dynamic feature of tide-dominated estuaries and the importance of simulation tools to the estuarine management.

Human-induced changes in sediment transport and sedimentary environment in a macro-tidal estuary

Zhixin Cheng[1*]
1. School of Environmental Science and Engineering, Dalian Maritime University, Dalian , Liaoning, CHINA
E-mail: chengzhixin@dlmu.edu.cn

Keywords: Yalu River Estuary, FVCOM, sediment transport, suspended sediment concentration, land reclamation

During the past decades, extensive coastal areas have been reclaimed along the coastline of China, and a massive land reclamation activity was completed in the early 1970s in the Yalu River Estuary (YRE), China. To investigate the impacts of such human intervention, a three-dimensional (3D) coastal model is established using the Finite Volume Coastal Ocean Model (FVCOM) to explore the changes in the hydrodynamics and sediment transport in the YRE. Model results show that the tidal system was flood dominant both before and after the land reclamation, but the degree of flood dominance decreased slightly after the reclamation. Tidal-choking effect was enhanced in the main branch after reclamation, with a decreased tidal range and resulted in stronger tidal currents. Both vertical and horizontal mixing processes were strengthened due to the enhanced tidal-choking. As a consequence, sediments in the estuary became more well-mixed and homogeneous. Suspended-sediment concentration (SSC) in the estuary increased after the reclamation, and the horizontal gradient of SSC between the estuary and neighbouring shallow waters also became larger. The landward sediment flux caused by tidal pumping decreased significantly after the reclamation while the seaward sediment flux increased. Furthermore, according to results from a newly improved Lagrangian 3D particle-tracking model, sediments in the main branch were likely from different sources before reclamation but were more homogeneous with a common composition of sediment sources afterwards: fluvial sediments and local resuspended sediments contributed more to sediments in the estuary and material from the Western Korean Bay were more restricted out of the estuary after reclamation. This study shows that anthropogenic influence can dramatically change the sedimentary environment in a medium-scale estuary over a short period and the estuary may turn into a sediment source instead of a sink if more land is reclaimed in the future. The conclusions of this study could be useful for marine management and show the utility of using a coastal model to resolve marine-geology problems.

Shoreline protection with geotextile sandbags: the application of a stability equation

Yongqing Li[1], Zai jin YOU[2*], Ye MA[2], Bing REN[1]

Keywords: Stability equation, geotextile sandbag, coastal protection

Storm-induced coastal erosion is one of main natural hazards in China, taking place over one-third of the Chinese coastline. Because of the effectiveness and cost reduction, geosystems could be an alternative approach to mitigate the erosion of the coast, comparing with conventional coastal structures. The design equation was established to evaluate the hydraulic stability of geotextile sandbags under wave loads in many studies in the laboratory environment, but the application of the design equation has not been extended at the field scale. Based on the in-situ experiments of various design schemes with different sandbag structure, the field study was carried out from October 2018 till present. The field site is located on eroded coast of Chudao Island, China. We found that the existing sandbag stability equation has its limitations, which overestimates the design size of sandbag. Therefore, it is required to re-analyze the field condition, when waves hit the sandbag revetment to establish a stability equation that could be widely applied. According to the field observation, the general stability equation of geotextile sandbag structure is derived to satisfy coastal protection schemes, and the reference values of parameters are given by physical model test data, which are from the literature. The proposed sandbag stability equation can improve the design method of shoreline protection with the utilization of sandbags structures. Furthermore, the response of characteristic curves for the sandbag structure and the dynamic beach profile were obtained, with the consideration of several different field geotextile sandbag structure protections experiments.

Keywords: beach stability,beach nourishment,cross-shore sediment transport

Much of the world's population live within the coastal zone and are vulnerable to coastal disasters as the impacts of sea level rise and extreme storm. This result in extreme erosion problem of sandy beach and serious shoreline retreat. Beach nourishment has been increasing believed as a common coastal management strategy to handle the coastal erosion resulting from storms and longshore transport imbalances. However, most present equilibrium theory is always used for underwater topography, there still has some problem in subaerial beaches equilibrium prediction. As rugged environment, there remains a lack of suitably measurements for foreshore stability research. As an alternative to obtaining natural or prototype data, smaller-scale physical models often behave in qualitatively similar ways to prototype beaches and shorefaces, forming the same characteristic features at a wide range of scales. Novel series of experiments are presented on different initial slope beaches to study the physical processes of sandy beach stability in a laboratory wave flume of 30 m long, 1m wide and 0.8 m high. Five initially uniform plane beach slopes of tan =1/5, tan =1/7, tan =1/10, tan =1/12.5 and tan =1/15 were used to discuss the mechanism of beach stability. Novel techniques were applied to simultaneously collect lab data on surface elevation and beach elevation profile. This lab experiment has the following new features that distinguish from traditional ones.

Firstly, non-intrusive instrumentations, video cameras, were applied during the whole experiment to monitor the continuous beach profile evolution in a spatial resolution of 2 mm and a temporal resolution of 0.1s, respectively. Image distortion was compensated by the calibration of grids of known dimensions. Time series of beach profile evolution and synchronous surface elevation can be obtained precisely with this image technique to measure the beach response on different initial slope beach.

Secondly, the influence of beach initial slope on beach profile stability is detail analyzed. During beach nourishment or artificial beach building, the purpose of construction scheme is hoping to make beach efficiently approach to equilibrium profile. The rate of beach approaching to equilibrium on different initial slope is compared. As beach profile approaching to equilibrium profile, the beach slope of different initial slope beach tends to same slope by cross-shore sediment exchange, and foreshore slope is evidently steeper than that of underwater part.

All data collected in this study are being analyzed. As beach approaching to equilibrium profile, better beach stability is believed to have smaller morphology change and shorter time. It is found that the influence of initial beach slope on sediment transport and beach stability is more obvious. Compared to beach initial slope S>1:10, beach initial slope S≤1:10 present better beach stability. As wave run, beach morphology in constant adjust by cross-shore sediment transport, when the overall beach slope is around 0.1 (S=1:10) and the foreshore slope is among 0.2~0.4 (S=1:5~1:2.5), sandy beach has the best stability, the beach profile is more close to the equilibrium profile, and the process of beach evolution to equilibrium is more efficient.

Experimental study of supercritical CO2-H2O-coal interactions and the geochemical effect on pore structure of high-rank coal

Yi Du[1*], Shuxun Sang[2], Changqing Fu[3]
1. DEPARTMENT OF GEOLOGY, NORTHWEST UNIVERSITY, Xi'an, Shaanxi, CHINA
2. School of Mineral Resource and Geoscience, China University of Mining and Technology, Xi 'an, Shanxi, CHINA
3. College of Geology and Environment, Xi'an University of Science & Technology, Xi 'an, Shanxi, CHINA
E-mail: duyicumt@163.com

Keywords: scCO2-H2O-coal, pore structure, permeability, high-rank coal, geochemical effect

Transformation of pore and fracture structure of coal with supercritical CO_2 ($scCO_2$) -H_2O is a key to CO_2 injection and CH_4 production efficiencies during the CO_2 enhanced coalbed methane process. To investigate the effects of $scCO_2$ - H_2O on the pore structure in high-rank coal, coal samples from Qinshui Basin, China was exposed to $scCO_2$ and deionized water for 240 h under 45 °C, 10 MPa and 80 °C, 20 MPa. Field emission scanning electron microscope, nuclear magnetic resonance, high pressure mercury intrusion, X-ray CT scanning and permeability experiments were performed. The results show that the reaction on carbonate in coal is the strongest, forming corrosion pit, corrosion crystal cone, dissolution ditch and so on. The congruent dissolution mode leads the element Ca and Mg shows the highest mobility. The second is aluminum silicate which crystallinity and morphology of the reaction are changed. The incongruent dissolution mode of aluminosilicate minerals leads to the migration of more cations in the interlayer than in the octahedral lattice; and the mixed elements of the isomorphism are more likely to migrate than the intrinsic elements in the crystal lattice. The interaction of $scCO_2$-H_2O can increase or enlarge pores and fractures, leading to an increase in the porosity, pore volume, specific surface area, and permeability, which will augment along with the increase of experimental burial depth, under the interactions of mineral dissolution-precipitation, clay hydration and expansion, coal expansion, and pyrite oxidation-precipitation. The change of pore volume was mainly due to the erosion cones and dissolution trenches on the surface of remaining carbonate particles and dissolution pores of other minerals, as well as the intragranular pores of the expansion and exfoliation of clay minerals. However, the change in the specific surface area is mainly caused by the change in pore volume. Due to the effect of coal expansion, micro-fractures were added and enlarged, which could enhance the connectivity between seepage pores and fractures, so that the growth of permeability could be as high as 114.10 times.

Dynamic fluid interactions during CO2-enhanced coalbed methane and CO2 sequestration in coal seams

Sijian Zheng[1*]
1. Carbon Neutrality Institute, China University of Mining and Technology, Xuzhou, Jiangsu, CHINA
E-mail: sijian.zheng@cumt.edu.cn

Keywords: Coalbed methane (CBM), Nuclear magnetic resonance (NMR), Wettability, CO2 injection, CO2 sequestration

The injection of CO2 into coalbed methane (CBM) reservoirs to enhance methane recovery has a second desirable benefit in simultaneously sequestering CO2. However, the real-time dynamic evolution of native adsorbed and rejected non-adsorbed methane/water during the process of CO2-enhanced coalbed methane (CO2-ECBM) production remains poorly constrained as a result of the nonlinear and hysteretic response of both CO2−CH4 interactions and CO2−H2O wettability of the coal under recreated reservoir conditions. By introducing the nuclear magnetic resonance (NMR), a non-invasive method, we explore the mechanisms of 1) methane desorption and CO2 replacement during multiple cycles of CO2-ECBM flooding, 2) influencing factors (pressure, temperature, water-state) on CO2-H2O wettability during CO2-ECBM. Results show that the cumulative methane sweep efficiency increases monotonically with successive cycles of CO2 injection, albeit at a reducing incremental efficiency, identifying the utility of cyclic CO2-ECBM as an effective method in both CO2 sequestration and enhanced gas recovery. CO2 wettability also increases with a decrease in temperature suggesting that shallower reservoirs may be marginally improved in this trend. Additionally, the presence of non-adsorbed water in coals significantly reduces both the sensitivity of CO2 wettability to pressure and the absolute magnitude of wettability relative to the case where free-water is absent. Thus, draining free-water from the reservoir will serve the dual purposes of both increasing gas transport and the potential for desorption from the perspective of CO2-H2O wettability. The far-reaching results in this study are significant for evaluating CO2-ECBM improvement both in enhancing methane recovery and CO2 utilization in coals.

Molecular Modeling of Interfacial Properties of Complex Multiphase Systems for CO2 Flooding and Sequestration

Yafan Yang[1*]

1. State Key Laboratory for Geomechanics and Deep Underground Engineering, China University of Mining and Technology, Xuzhou, Jiangsu, CHINA

E-mail: yafan.yang@cumt.edu.cn

Keywords: CO2 Flooding and Sequestration, Multiphase Systems, Interfacial Properties, Molecular Simulation, Density Gradient Theory

In the process of carbon dioxide miscible/immiscible flooding and geological storage, interfacial properties of complex multiphase systems determine the capillary force that stores carbon dioxide and releases oil/gas. Understanding the interfacial behaviors of multiphase systems is crucial for evaluating the carbon dioxide storage capability and stability, and the oil/gas recovery efficiency. The interfacial properties (e.g. interfacial tension, wettability, etc) of multiple multiphase systems containing gas, oil, water, and solid have been studied by molecular dynamics (MD) simulation and equation of state-based density gradient theory (DGT). Studies on several multiphase systems including gas/brine two-phase, gas+oil/water two-phase, gas+oil/water/solid three-phase, gas/oil/water three-phase systems will be presented. In general, MD and DGT can accurately predict the interfacial properties by comparing them to the available experimental data. Our results also showed that the interfacial properties are greatly affected by environmental factors including temperature, pressure, gas impurity, oil type, solid type, etc. Importantly, the behavior of the interfacial properties was analyzed based on the density distributions in the nano-scale interfacial region. The enrichment of components in the interface significantly affects the interfacial properties. Finally, we will present a novel molecular simulation protocol for evaluating the interfacial properties of gas/oil/water three-phase systems. These results could help optimize carbon dioxide flooding and geological storage techniques.

Gas desorption and diffusion characteristics in coal under different pressure-drop conditions

Zheng Dang[1], Xianbo Su[2*], Xiaoming Wang[1]
1. Key Laboratory of Tectonics and Petroleum Resources, China University of Geosciences (Wuhan), Wuhan, Hubei, CHINA
2. Institute of Resources & Environment, Henan Polytech University, Jiaozuo, Henan, CHINA
E-mail: suxianbo@hpu.edu.cn

Keywords: Gas desorption, Gas diffusion, Pressure-drop condition, Water block effect, Pore structure

To compare gas desorption and diffusion characteristics under different pressure-drop conditions, coal samples with different ranks were collected for conducting desorption and diffusion experiments under the direct pressure-drop condition (DPDC) and progressive pressure-drop condition (PPDC). Moreover, the mercury injection capillary pressure analysis (MICP) was performed to determine pore structure characteristics. When the pressure-drop condition is changed from DPDC to PPDC, the initial desorption rate decreases, the desorption volume increases, and the diffusion coefficient increases. The maximum change of these three parameters occurs in the medium-volatile bituminous coal, which increases from 0.255 to 0.063 $cm^3/(g \cdot min)$, from 2.96 to 18.82 cm^3/g and from 0.4732×10-10 to 3.8239×10-10 cm^2/s, respectively. Micropore and transition pore are predominate in all coal samples. With increasing coal rank, the pore volumes show generally decrease trend, while the fractal dimensions show generally increase trend. The difference in diffusion coefficient between DPDC and PPDC is attributed to the various diffusion regimes at different pressure ranges. Specifically, DPDC causes the atmospheric pressure condition throughout the experiment, under which Knudsen diffusion and transitional diffusion play dominant roles in micropores and transition pores during the diffusion process, resulting in the lower diffusion coefficient. The difference in the desorption volume between DPDC and PPDC arises from the water block effect. In DPDC, a large bubble easily forms with a rapid desorption rate in the micro-/transition-pore throat and shows large deformation when passing through the pore throat, which increases capillary resistance and intensifies the water block effect. In contrast, in PPDC, the size of the gas bubble in the same pore throat is smaller than that in DPDC, which can weaken the water block effect and enhance desorption capacity. The results of this study can provide strategies for optimizing the pressure-drop rate during CBM production periods.

Keywords: CO2 geological storage, Modified assessment method, Anthracite, Adsorption mechanism, Reservoir environment, Geological storage model

Global climate deterioration forces mankind to make breakthroughs in greenhouse gas control and carbon emission reduction. As an important part of CCUS (carbon capture, utilization and storage), CO_2 geological storage in deep coal is one of the effective pathways to reduce atmospheric CO_2 concentration and achieve carbon neutrality in the immediate future. This study, taking No. 3 coal in the Zhengzhuang Block as an example, was based on the CO_2 isothermal adsorption experiments at various temperatures. The modified assessment method of CO_2 geologic storage capacity was established, the curves of CO_2 storage capacity in coals at depth profile in the Zhengzhuang Block were analyzed, CO_2 adsorption mechanism at different depths was presented, and theoretical CO_2 storage capacity of No.3 coal in Zhengzhuang Block, Qinshui Basin was estimated. The results show that: (1) The supercritical DR model for CO_2 adsorption data of CZ and SH coals has a high fitting accuracy. Their adsorption capacities at different temperatures ranged from 1.58 to 2.47mmol/g and from 1.51 to 2.38mmol/g, respectively. (2) The curves of the modified calculated CO_2 storage capacity per 1 g coal (CO_2-SCC) combined adsorbed and free CO_2 of CZ and SH coal presented maximum values (2.71mmol/g and 2.80 mmol/g) near 250m in the Zhengzhuang Block. At the depth of 2000m, the CO_2-SCCs of CZ and SH coals still maintained 76% and 67% of their respective maximum values. (3) At depth profile, the CO_2 adsorption behaviors were composed of three states: a. surface coverage adsorption at low density, b. micropore filling adsorption at high density and c. surface coverage adsorption at high density. The modified assessment method of CO_2 geological storage capacity can more truly demonstrate the spatial variation of CO_2 adsorption at different depths and therefore has a higher accuracy. (4) The theoretical CO_2 storage capacity of No.3 coal seam in Zhengzhuang block is 536.3 Mt, and the storage capacity in gas and gas-like zone, and liquid-like zone are 385.51 Mt and 150.79 Mt respectively. Although there is no significant difference in CO_2 storage capacity under different depths, CO_2 injection projects should be preferentially implemented in areas with high gas content and high permeability.

Effect of Pore Structure on Water Vapor Adsorption Behavior of Coal with Different Coal Ranks

Wenwen Chen[1], Xiaoming Wang[1*]
1. Key Laboratory of Tectonics and Petroleum Resources, China University of Geosciences (Wuhan), Wuhan, Hubei, CHINA
E-mail: sunwxm@cug.edu.cn

Keywords: coal rank, pore structure, water adsorption, molecular simulation

The existence of water in the coal seam will not only reduce the adsorption capacity of CH_4, but also restrict the gas migration with the evolution of coal pore structure. It is of great significance to study the effect of pore structure of different rank coals on its water adsorption behavior, which can be used to analyze the production process of coalbed methane. Therefore, we selected 9 coal samples with different coal ranks, firstly conducted water vapor adsorption isothermal experiments under 10 relative humidity. Revealed the microscopic adsorption mechanism of water adsorption behavior through molecular simulation methods and discussed the differences in water adsorption behavior of different coal rank coals. Finally, analyzed the influence of different rank coal pore structures on water adsorption behavior by low-pressure N_2 and CO_2 gas adsorption experiments. The research results show that the dominant adsorption sites of water molecules in coal pores decrease with the increase of coal rank, and the water adsorption capacity also decrease in single-layer adsorption stage, multi-layer adsorption stage, water cluster connection stage, and pore filling stage. The inflection point of water vapor adsorption isotherm disappear with the increase of coal rank, which completes the adsorption isotherm transition from type II to type III. The water absorption increase with the increase of macropore volume in the four stages, The macropore volume play the dominant role in the water molecule single-layer adsorption stage. The mesopore volume has a promoting effect on water adsorption. The micropore volume has a certain positive correlation with the water absorption in the single-layer adsorption and multi-layer adsorption stagesthe correlation with the water cluster connection stage is not obvious, but it has a significant negative correlation with the pore filling stage. Micropore volume perhaps limited the water adsorption behavior in the pore filling stage. The fractal dimensions D_1 and D_2 are negatively correlated with the water absorption in the four stages, and the roughness of the pore surface and the irregularity of the pore structure will limit the water adsorption behavior in coal. The research results have theoretical significance for understanding the influence of different rank coal pore structure on its water adsorption behavior.

Study on carbon dioxide geological storage potential and favorable structural units in the Pearl River Mouth Basin

yutong fu[1*], xudong guo[1], dongyu lu[1]

1. Sanya Institute of South China Sea Geology, Guangzhou Marine Geological Survey, sanya, hainan, CHINA

E-mail: fytxuzhidan@163.com

Keywords: zhujiang mouth basin, ccs, Zhuyi depression

The annual carbon dioxide emission of Guangdong Province is about 470 million tons, which puts great pressure on carbon dioxide emission reduction. Carbon dioxide geological storage technology is the key link of CCUS technology. It is also a carbon neutralization technology most in line with China's resource endowment and national conditions. According to the estimates of the Chinese Academy of Sciences and the IEA, the contribution rate of carbon neutralization of CCS technology will be about 5% ~ 15% by 2060. Carbon dioxide emission sources in Guangdong Province are mainly large point sources such as iron and steel plants, chemical plants and power plants in coastal areas. There is a lack of large sedimentary basins in the land area. Therefore, it is necessary to evaluate the carbon sequestration potential of the Pearl River Mouth Basin in the adjacent sea area of Guangdong Province, delineate the favorable area suitable for carbon sequestration.

The project has carried out research in four aspects: Firstly, based on the systematic investigation of the latest research results of carbon sequestration in sea areas at home and abroad, and combined with the regional geological survey data, the carbon sequestration data set of China's sea areas is established; Secondly, the basic geological conditions of carbon sequestration in the Pearl River Mouth Basin are analyzed from the aspects of stratum, structure, reservoir cap rock characteristics, temperature and pressure system. Thirdly, using the deep learning model, complete the evaluation of regional carbon sequestration potential and select the favorable target areas suitable for carbon sequestration; Then the three-dimensional geological model of the favorable target area is established, and the migration law and storage effect of carbon dioxide under formation conditions are simulated. Finally, the geological feasibility and development route of the pilot project of marine carbon sequestration in the Pearl River Mouth basin are discussed.

The results show that the carbon sequestration potential of Zhuyi depression is 128 billion tons that is the largest in the Pearl River Mouth Basin, and the carbon dioxide storage life can reach more than 1000 years, which is the most suitable for carbon dioxide storage. The pilot project of marine carbon sequestration is recommended to be carried out in the distribution area of depleted oil and gas reservoirs in Zhuyi depression.

Effects of Supercritical CO2 on Adsorption capacity of Coals with different ranks

Shiqi Liu[1*], He Wang[1]
1. Carbon Neutrality Institute, China University of Mining and Technology, Xuzhou, Jiangsu, CHINA
E-mail: liushiqi@cumt.edu.cn

Keywords: Pore volume, Specific surface area, Mesopores, Micropore, Adsorption capacity, Coal rank

CO2 geological storage-enhanced coalbed methane recovery (CO2-ECBM) can be used to enhance coalbed methane (CBM) development and reduce CO2 emissions by effectively displacing CH4 using CO2, and this approach is considered as an important technology of CCUS (Carbon capture, utilization, and storage). The effects of supercritical CO2 (ScCO2) on pores in coal play a critical role in determining the CO2 capacity of coalbeds. To investigate the effects of ScCO2 on adsorption capacity of coals with different ranks under coalbed temperature and pressure conditions, CO2 sequestration processes are replicated using a ScCO2 geochemical reactor. Six coal samples with different ranks are exposed to ScCO2 and water for 240 h at 62.5 °C and 15 MPa, and gravimetric isothermal adsorption test, CO2 adsorption tests, mercury intrusion porosimetry, and nitrogen adsorption tests are performed to determine the adsorption capacity and volume and pore size distribution of the coal samples before and after the ScCO2-H2O treatment. Results show that the changes of pore volumes and pore specific surface areas determine the coal adsorption capacity after scCO2-H2O treatment. Among them, macropores have a weak effect on coal adsorption capacity, which is related to the small volumes and specific surface areas of macropores in coals with different ranks. The changes of coal adsorption capacity mainly depend on the changes of pore volumes and specific surface areas of mesopores and micropores after scCO2-H2O treatment. Under scCO2-H2O treatment, the variation trend of pore volumes and specific surface areas of mesopores and micropores in coals with different ranks is not uniform. With the increase of coal ranks, the adsorption capacity of coal samples decreases first and then increases after scCO2-H2O treatment. That is, the adsorption capacity of sub-bituminous coal slightly increases after scCO2-H2O treatment, due to the increases of pore volumes and specific surface areas of micropores. While that of high- and medium- volatile bituminous coal slightly decreases, because of the decrease of pore volumes and specific surface areas of mesopores after scCO2-H2O treatment. Then, the adsorption capacity of low-volatile bituminous coal, semianthracite, and anthracite greatly increases, thanks to the great increase of pore volumes and specific surface areas of micropores, although pore volumes and specific surface areas of mesopores decrease.

Pore morphology changes of coals associated with CO2 geological storage

Changjiang LIU[1*]
1. School of Geosciences, China University of Petroleum (East China), Qingdao, Shandong, CHINA
E-mail: liuchangjiang@upc.edu.cn

Keywords: CO2 geological storage, pore morphology, coal rank, ECBM

The understanding of CO_2 effects on coal pore morphology is important during CO_2 geological storage (CGS). The CGS was simulated with four different samples from 32-80 ℃ and 9-20 MPa respectively. Mercury intrusion porosimetry (MIP) and low-pressure nitrogen adsorption (LP-N_2GA) were employed to study pore size distributions, pore shapes, roughness and compressibility. The results show that the pore size distributions of high-rank coals are mainly influenced in the micropore range while low-rank in the macropore range. The pores in ScCO_2 treated samples become more complicated due to two peaks showing at 7.2 nm and 13.7 nm in the MIP curves, while only one occurs in the untreated samples. The CGS process is able to open, reshape or enlarge existing pores, which improve pore connectivity and porosity. The fractal dimension shows that the surface and structure morphology becomes more complex after the treatment with the increasing temperatures and pressures, leading to the increments of specific surface areas and total pore volumes. These parameters of SH samples treated under 62.5 ℃ and 15 MPa increase from 1.3579 m^2/g to 3.048 m^2/g and 0.001076 cm^3/g to 0.001338 cm^3/g. The compressibility changes indicate that coal samples are easier compressed after the treatment, which might negatively affect CGS. Even though no clear tendencies exist among different coal ranks, the compressibility does change with the increasing temperatures and pressures. The results show that the CGS increase the gas adsorption volume, specific surface areas and pore connectivity, which improve the storage capacities and benefit the enhanced coalbed methane recovery.

Evolution of pore structure and gas adsorption properties in coal and shale by supercritical CO2

shaoqiu Wang[1*], sandong Zhou[1], dameng Liu[2], zhejun Pan[3]
1. , , , , CHINA
2. , , , CHINA
3. , , , , CHINA
E-mail: Wangshaoqiu@cug.edu.cn

Keywords: coal, shale, supercritical CO2, pore structure, adsorption properties

CO_2 injection into coal and shale strata can not only enhance the recovery of coalbed methane or shale gas, but also achieve the goal of CO_2 geological sequestration, reducing greenhouse gas emissions(Chen et al,.2022). CO_2 is likely to be stored in the form of supercritical state, when the burial depth of rock strata exceeds 800 m. Understanding the pore structure and adsorption properties effects of supercritical CO_2 ($ScCO_2$) on coal and shale plays an essential role in carbon capture utilization and storage (CCUS)(Klewiah et al,.2020).The experimental results of different types of coal (low, medium and high-rank coals) and shale (terrestrial or marine shale) are selected to discuss the interaction mechanism between $ScCO_2$ and matrix in coal and shale, as well as the pore structure and gas adsorption under different treatment conditions. The CH_4 and CO_2 adsorption, X-ray diffraction, scanning electron microscope and low-pressure N_2 adsorption measurements were carried out on the shale samples before and after exposure. The major conclusions are summarized as follows:

1. The changes in pore structure caused by $ScCO_2$ may be related to the following two mechanisms: (i) The $ScCO_2$ fluid has a certain ability to dissolve some organic matter and minerals. Carbonic acid is generated by the reversible chemical reaction between CO_2 and free water in shale, which dissolves some clay minerals and carbonate minerals in shale, thus broadening the pore structure of shale. (ii) The strong adsorption capacity of shale for CO_2 induces irreversible adsorption expansion of the matrix, resulting in the shrinkage of the pore throat size of shale(Lan et al,.2019). The initial pore structure of the rock and its own properties (TOC, Ro, mineral composition) are significant factors in determining which mechanism dominates the energy.

2. By researching the correlation between the integrated heat of adsorption and the adsorption capacity of different coal samples, it is found that compared with untreated coals, the adsorption amount and integral adsorption heat for the coal treated with supercritical CO_2 are reduced, and the decrements are largely dependent on the coal rank(Kang et al.,2020). The integral adsorption heat relates linearly with the adsorption amount, and the ratio coefficients for medium rank coals decrease after supercritical CO_2 extraction, whereas an increasing trend is found for low-rank and high-rank coals. In addition, it is revealed that the volume of micropores is reduced by supercritical CO_2 treatment for low-rank and medium-rank coals, while no significant change is found for high-rank coals(Liu et al.,2019).

3. The pore structure of clay-rich continental shales was more affected by $ScCO_2$ treatment compared to quartz-rich marine shales(Lu et al.,2020). These findings suggested that the adsorption capacity of clay-rich shales could be reduced after the CO_2 treatment, while the uniformed pore size distribution profile displayed by quartz-rich shales could cause an increase in the adsorption capacity(Fatah et al.,2022).

Study of Carbon Sequestration Effect of Different Sediment Types in the Taiwan Strait

Jian Chen[1*]

1. Geology, Third Institute of Oceanography, Ministry of Natrual Resources, Xiamen, Fujian, CHINA

E-mail: chenjian@tio.org.cn

Keywords: Carbon Sequestration, Sediment, Mollusk shell, Benthos

As most of the organisms with calcium carbonate shells in the benthic animals are concentrated in mollusks, the calcium carbonate shells formed by mollusks play an important role in absorbing CO2 from the atmosphere and seawater. Through analysis of the data of 450 stations of carbonate content of surface sediment and 165 stations of benthos, there are 6 types of seabed sediment in the Taiwan Strait , which are gravel, sand, silty sand and sandy silt, mudy silt and mud, mollusks biomass in sandy silt type in the highest, accounted for 38.4%, followed by mud, accounted for 26%, the third for silty sand, accounted for 18.0%, the fourth is mudy silt, accounting for 12.2%. Which means that the three kinds of sediments with high content of silt (sandy silt, silty sand and argillaceous silt) account for about 68% of the total biomass of benthic organisms, and play an important role in the carbon sequestration of benthic organisms. At the same time, the standard deviation of mollusk biomass distribution in silt related sediments are also large, indicates that the distribution of mollusk in these types of sediments is not uniform. Analysis of carbonate content in surface sediments with different grain sizes shows that the carbonate content in sediment of grain size range (-1 ~ 7) has no significant difference, ranging from 4.58% to 17.30%, and presents an exponential distribution, which decreases with the decrease of grain size. In addition, the grain size increased slightly in the range of 2.5~3 and 3~3.5 . Statistics of the data indicate that :(1) The distribution characteristics of mollusk biomass in benthic organisms and carbonate content in surface sediments has a lot of difference, which may be related to the accumulation of shells in coarse-grained sediments under hydrodynamic condition; (2) Finding out the main distribution area of mollusk and its controlling factors, will be of great significance to play the role of fishery carbon sink by developing shellfish farms appropriately. (3) Conventional sediment carbonate analysis mainly studies the content of carbonate components in terrigenous clasts, and shells are usually taken out before sample processing, these data should be carefully used when studying the role of sediment carbon sequestration.

Emerging and outlook of Carbon Neutrality Sedimentology

Shuxun SANG[1*]
1. Carbon Neutrality Institute, China University of Mining and Technology, Xuzhou, Jiangsu, CHINA
E-mail: shxsang@cumt.edu.cn

Keywords: Carbon Neutrality Sedimentology, definition, rationale, research areas and application directions, challenges and outlooks

Sedimentology is closely related to carbon neutrality, and Carbon Neutrality Sedimentology came into being. Hereby the authors try to explore the new research field and new branch, so as to give full play to the role of sedimentology in the realization of carbon neutrality goal. This paper advances and explains the scientific concept, constructs the rationale, defines the major research areas and application directions, concisely puts forward the key challenges, and looks forward to the development prospect of Carbon Neutrality Sedimentology. It is regarded as follows: Carbon Neutrality Sedimentology is a new branch of sedimentology that studies the sedimentary records and generalized sedimentation related to carbon emission or carbon sink alteration caused by human factors and their carbon neutrality effect. The core of its rationale is the carbon sequestration mechanism of generalized sedimentation and the geological carbon sink potential of sediments and sedimentary rocks. Carbon sequestration by rock weathering, biological sedimentation, chemical sedimentation, epigenetic diagenesis, water-rock interaction and mineralization constitute the major connotation of the study on the carbon sequestration mechanism of sedimentation. The research on the carbon sequestration potential of sediment and sedimentary rock includes coastal sediment carbon sequestration, soil carbon sequestration, typical sedimentary environment sediment carbon sequestration likely in lakes and wetlands, CO2 geological utilization and geological sequestration, solid waste imitated mineralization carbon sequestration, biological carbon sequestration, etc.. Modeling and numerical simulation of sedimentary carbon sequestration is also an important research area of Carbon Neutrality Sedimentology. It can provide an important fundament applied to carbon neutrality geological technologies related to the above sedimentary carbon sequestration. The carbon sequestration mechanism, mode and model of sedimentation, the evaluation method of carbon sequestration potential of sediment and sedimentary rock, and commercial engineering application of the related carbon neutrality geological technologies are the key challenges faced by carbon neutrality sedimentology. In the future, it will cross integrate with relevant disciplines like geology, geography, ecology, atmospheric science etc. to form an interdisciplinary knowledge system, and rapidly develop and be widely used.

An analysis on influence factors of permeability of coal seam with CO2 injection

Qinghe Niu[1], Shuxun Sang[2*], Wei Wang[1], Jiangfang Chang[1]
1. School of Civil Engineering, Shijiazhuang Tiedao University, Shijiazhuang, Hebei , CHINA
2. Carbon Neutrality Institute, China University of Mining and Technology, Xuzhou, Jiangsu, CHINA
E-mail: shxsang@cumt.edu.cn

Keywords: CO2-ECBM, CO2 adsorption swelling, effective stress, anisotropic permeability, CO2 injectivity, deep coal seam

Injecting CO_2 into deep coal seams cannot only improve the recovery of coalbed methane but also achieve CO_2 geological sequestration, which possesses dual benefits of energy and environment and meet major needs of carbon neutralization and low-carbon energy exploitation. However, the attenuation of CO_2 injectivity is the key technology bottleneck restricting the application and development of CO_2-ECBM. To reveal the attenuation mechanism of CO_2 injectivity, the anisotropic permeability test and CO_2 injection simulation experiment were conducted, and the characterization model of permeability evolution with CO_2 injection was established. Results show that effective stress and CO_2 adsorption swelling are the two main factors to control the dynamic evolution of permeability during the CO_2 injection process. Increasing the CO_2 injecting pressure can decrease the effective stress and promote the permeability of coal, while the concomitant adsorption swelling strain can compress the fracture space and reduce the permeability of coal. The permeability during the CO_2 injection process exhibits obvious anisotropic characteristics, the permeability in parallel face cleat and bedding plane direction is the maximum, followed by the permeability in parallel butt cleat and bedding plane direction, the permeability in vertical bedding plane direction is the minimum. The face cleat and butt cleat are narrow and short, which are easily affected by the CO_2 adsorption swelling deformation and contribute to the decrease of permeability during the CO_2 injection process. Based on the three-dimensional distribution structure of the face cleat, butt cleat and bedding plane, the anisotropic permeability model considered the adsorption swelling, effective stress and swelling deformation directivity is built and verified by the experimental data. The CO_2 injection process under the in-situ stress condition is simulated, and the changes in CO_2 injectivity are forecasted by the anisotropic permeability model. This study can rich the theory of efficient CO_2 injection into deep coal seams and promote the process optimization of CO_2-ECBM.

Geological records in sandstone after CO2 emplacement and its implications for CCS: a case study from Pliocene reservoirs in Yinggehai Basin, South China Sea

Lei Yu[1,2], Sanzhong Li[1,2*], Li Liu[3]

3. College of Earth Sciences, Jilin University, Changchun, Jilin, CHINA

E-mail: sanzhong@ouc.edu.cn

Keywords: carbon capture and storage, diagenesis, CO2 emplacement, authigenic carbonates, kaolinite enrichment

Anthropogenic greenhouse gas, such as CO_2, which is generated from industry activities into atmosphere has been a key issue for global warming. Thus, reducing the impact of CO_2 concentration increasing in atmosphere is one of current major tasks. At present, more and more scientists propose that injecting CO_2 into subsurface formations, such as unminable coal seams, brine formations or sandstone aquifers, and depleted oil/gas reservoirs, etc., could be potential options for carbon storage and capture (CCS). Sandstone aquifers with impermeable cap-rock system could be ideal CO_2 storage sites due to their not only adequate permeability but also wide distribution in sedimentary basins across the world. In Yinggehai (YGH) basin, South China Sea (SCS), a lot of CO_2- and hydrocarbon gas-rich reservoirs have been discovered during natural gas explorations in recent decades. It has been established that there are several natural gases injection and replacement periods occurred in the reservoirs. Among these reservoirs, CO_2 injection time is later than hydrocarbon gases. In addition, CO_2 emplacement also displaced hydrocarbon gases in some of reservoirs. These current CO_2 enriched reservoirs give us an excellent opportunity to study the petrographic and geochemical impacts in sandstone aquifers or reservoirs due to CO_2 emplacement. This can also provide a natural analog for CCS managements.

Here, we did a series of analyses such as petrographic observations, carbon and oxygen isotopes, and numerical modelling to constrain geological records after massive CO_2 emplacement. According to the petrographic observations, we could conclude the sandstone types are mainly Quartz arenite and Sublitharenite in the Pliocene reservoirs in YGH basin. The detrital minerals are dominated by quartz, albite, mud matrix, lithic debris and biological debris. Wherever authigenic minerals formed in sandstone pores are secondary quartz, pyrite, siderite, dolomite, dawsonite, ankerite and kaolinite. The secondary minerals precipitated after CO_2 injection are microcrystalline quartz, kaolinite, dawsonite, siderite and ankerite, respectively. The $\delta^{13}C$ and $\delta^{18}O$ results for ankerite and dawsonite confirmed that these two authigenic minerals are tightly related to CO_2 emplacement. In addition, compared to the hydrocarbon reservoirs which are not impacted by CO_2 injection, most of CO_2 enriched reservoirs are especially enriched kaolinite if dawsonite was absent in YGH basin. This phenomenon is supported by our numerical modelling results, which shows that kaolinite, quartz, ankerite, and siderite are the dominated minerals during the fluid-rock reactions after massive CO_2 injection. Thus, we conclude that in the reservoirs of YGH basin, siderite, ankerite, and dawsonite could be carbonate minerals to effectively storage CO_2. Kaolinite enrichment in sandstone, wherever, could be a potential indicator for CO_2 accumulation in subsurface reservoirs if dawsonite was absent.

Depositional Architecture and Reservoir Properties of Lower Cretaceous Bedload-Dominated Fluvial Deposts in a World-Class CO2 Storage Complex, Kemper County Energy Facility, Gulf of Mexico Basin, Mississippi, USA

Jack Pashin[1*], Conn Wethington[1], Stone Urban[1], Dave Riestenberg[2], Richard Esposito[3]
1. Boone Pickens School of Geology, Oklahoma State University, Stillwater, Oklahoma, UNITED STATES
2. Advanced Resources International, Advanced Resource International, Arlington, Virginia, UNITED STATES

E-mail: jack.pashin@okstate.edu

Keywords: Lower Cretaceous, Gulf of Mexico, Mississippi, CO2 storage, fluvial deposits

The Mesozoic-Cenozoic section at the Kemper County energy facility contains a 1.7-km thick succession of saline reservoir and sealing strata composing a CO_2 storage complex with exceptional reservoir properties and complex depositional architecture. As part of the U.S. Department of Energy National Energy Technology Laboratory CarbonSAFE program, six exploratory wells have been drilled to characterize strata at the 137 km^2 energy facility. The wells were logged and cored, and CT scans were made of the cores and oriented using interpreted FMI logs. The cores were analyzed using a variety of stratigraphic, sedimentologic, paleocurrent, petrologic, and routine core and pressure decay permeability analyses.

Prospective reservoirs are mainly medium-grained, subarkosic, cross-bedded sandstone in the Cretaceous-age Paluxy Formation and Washita-Fredericksburg interval. The lower parts of the sandstone bodies are dominated by planar and tangential cross-beds, and the upper parts fine upward and contain adhesive meniscate burrows and localized current ripple cross-strata. Paluxy cross strata dip northwest, parallel to depositional strike. Porosity of Paluxy and Washita-Fredericksburg sandstone averages 28.5%, and permeability has a geometric mean of 3.6 Darcies. Red mudstone units are abundant in the Lower Cretaceous section and have permeability ranging from 1 nD to 1 µD, with values of 10-30 nD being typical. The sandstone was apparently deposited in transverse and longitudinal bars constituting multi-storey sandy braided stream deposits. Mudstone units contain desiccation structures, ferriginous nodules, roots, and meniscate burrows. The mudstone has high water saturation and plasticity, and depositional features indicate an origin as spodic paleosols deposited in longitudinal bars and interfluves. The mudstone is smectitic and has variable thickness and lateral extent, constituting a system of baffles, barriers, and seals.

Paluxy and Washit-Fredericksburg were deposited during Albian time (100-112 Ma) as 3 major 3rd-order sequence sets. Geochronologic analysis indicates that the individual sequences composing the sets have a frequency of about 100 ky, suggesting climatic control of sedimentation in the Milankovitch short eccentricity band. Accordingly, the bases of individual sandstone storeys are interpreted as widespread erosional surfaces representing minor {~10 m) base level drops, and the most widespread mudstone units apparently accumulated as the culmination of the 100 ky aggradational episodes.

The total storage resource at the energy facility is estimated to be about 1.4 Gt, or 10.5 Mt/km^2, and reservoir properties favor high injectivity. Characterizing the depositional architecture of the Cretaceous section is essential for developing storage and monitoring strategies, such as injecting sequentially upward in section with the aid of multi-zone monitoring to characterize reservoir performance and verify hydraulic confinement. Sealing intervals within the Lower Cretaceous section and the major topseal atop the storage complex contribute to a high level of storage security.

The Cretaceous varves in NE China and their paleoclimatic implications

Xing Tian[1], Yuan Gao[2], Chengshan Wang[2], He Huang[2], Yongjun Jiang[1*]
1. Chongqing Key Laboratory of Karst Environment &School of Geographical Sciences, Southwest University, Chongqing, CHINA
2. State Key Laboratory of Biogeology and Environmental Geology & School of Earth Sciences and Resources, China University of Geosciences (Beijing), Beijing, CHINA
E-mail: jiangjyj@swu.edu.cn

Keywords: Cretaceous, paleoclimate, varve, interannual, NE China

In effort to project future warm climate scenarios, it is invaluable to investigate times in the geologic past. The Cretaceous period is an archetypal example of a greenhouse climate, and the high-resolution geologic records (e.g. lacustrine varve) in this time interval offer important insights into how the Earth system responds to warm climates. The 'varve' includes all annually deposited laminae in terrestrial and marine settings, and it's a high-resolution climatic archive with at least annual and sometimes even seasonal resolution. Despite a lot of varved sediments are found across the globe, deep-time (i.e. before the Quaternary) varves are less studied compared to the Quaternary. Luckily, the Cretaceous varves are sporadically reported, especially in Western and Northern Liaoning, Northeastern China (NE China), researchers have found various lacustrine varves in the Early Cretaceous Yixian Formation of the "Jehol Biota". For the Late Cretaceous, previous work also showed varved lake sediments of the Nenjiang Formation in the Songliao Basin, NE China. With increasing amount of varve research, a systematic summary is needed. In this paper, the Cretaceous varves in NE China was compiled, and their implications for paleoclimate are reviewed. The specific objectives of this paper are as follows: 1) to briefly introduce the processes of varve formation in different areas of the NE China; 2) to dig for information about the Cretaceous climate variability on interannual to centennial timescales; and 3) to discuss the mechanisms affecting the deposition and preservation of those lacustrine varves in NE China. The varved records obtained in this study will be compared with other regions of the world and used to provide an important reference for the Cretaceous high-resolution paleoclimate studies at a regional scale.

Lunar nodal tide cycle influences on the input of coarse detrital sediments during the last glaciation in the deep southern South China Sea

Hongchao Zhao[1], Zhifei Liu[1*], Yulong Zhao[1], Jiawang Wu[1], Christophe Colin[2]
1. School of Ocean and Earth Science, Tongji Universtiy, Shanghai, CHINA
2. Geosciences Paris-Saclay, Université Paris-Saclay, Orsay, Essonne, FRANCE

Keywords: lunar nodal tide cycle, laminae, X-ray fluorescence core-scanned elements, last glaciation, across-slope transport, southern South China Sea

Across-slope transport of coarse detrital sediments is thought to be dominated by hyperpycnal flow or gravity flow processes triggered by events. However, whether long-term non-event hydrological processes can affect longitudinal transport is still unclear. Here, high-resolution (1 mm) X-ray fluorescence core-scanned elements combined with coarse-fraction observations in typical samples have been conducted on laminae of Core MD05-2892 in the deep southern South China Sea. The laminated section developed during the last glacial 14.5–20.7 cal ka BP based upon AMS ^{14}C dating and oxygen isotope stratigraphy. The laminae show interbedded millimeter-scale dark and light layers. Dark layers are characterized by coarse-grained deposits rich in Ca, Zr, and Si, while light layers are characterized by fine-grained deposits rich in K, Ti, and Fe. Zr/K and Si/K ratios are then used to indicate laminar occurrence, and the ratios are well correlated to grayness value. Spectral analyses of the ratios and the grayness value both present a persistent 18.6-yr period, which is interpreted as the lunar nodal tide cycle. This signal in laminae could be related to remobilization of coarse sediments by mean-high-water-line variations driven by the lunar nodal tide at the low sea-level stage. The coarse fractions were then likely transported from the shelf break by suspended-load-dominated hyperpycnal flow to the lower slope to form dark layers, while fine fractions were dispersed during other time of the last glaciation through hemipelagic transport to form light layers. Our study firstly highlights the lunar nodal tide can periodically trigger longitudinal transport of coarse sediments.

Search for crypto tephra in varve sediments using synchrotron micro-XRF

Andrey Viktorovich Darin[1*], Fedor Darin[1], Yakov Rakshun[1]
1. Geology, Institute of Geology and Mineralogy SB RAS , Novosibitsk, NSO, RUSSIA
E-mail: darin@ngs.ru

Keywords: varve sediments, crypto tephra, synchrotron micro-XRF

Scanning micro-XRF with synchrotron radiation (SR) was used to search for traces of the Changbaishan volcano eruption (~ 960 AD) in the bottom sediment core of Lake Bele (Khakassia). A core with a length of 1240 mm was obtained by a gravity tube in 2014. After opening, solid samples for scanning synchrotron XRF and optical thin sections were prepared from a half of the core. The age model for the Bele-2014 core was made by the varve chronology method using optical thin sections. Solid samples were scanned by synchrotron XRF with a step of 1 mm. At a depth of 860 mm (varve age 945 AD ± 30), a layer 2 mm thick with a high content of zirconium was found. Detailed scanning with a 20 μm focused SR beam was carried out. A large number of microparticles with a high content of Zr, Y and Nb were found. The possibility of finding traces of the eruption of the Changbaishan volcano is discussed. The study was supported by the Russian Foundation for Basic Research, grant No. 19-05-50046 Mikromir.

Strawberry pyrite as a mineral indicator for sedimentary environment

Mingshuai Xu[1*]
1. College of resources, China University of Geosciences Wuhan, Wuhan, Hubei , CHINA
E-mail: 986541054@qq.com

Keywords: strawberry pyrite,paleo-redox environment, particle size, Microcrystalline morphology

Strawberry pyrite, as an important mineral, is sensitive to geochemical conditions. It has a special formation mechanism and widely exists in sedimentary rocks. Because of its special formation mechanism, the formation of strawberry pyrite is controlled by the paleo-redox environment, so it plays an important role in the reflection and reconstruction of the sedimentary paleo-environment and can be used as an environmental indicator. This paper reviewed the reaction of particle size, morphology and existing form of strawberry pyrite to sedimentary environment, discusses the indicative significance of strawberry pyrite for the paleo-redox environment and proposes that the formation of strawberry pyrite may be affected by the combination of Fe saturation, S content, redox conditions and deposition water the strawberry pyrite formed in the oxidation environment has a large particle size, (maximum particle size greater than 20 μm), wide distribution, and round crystallite shape, whereas the strawberry pyrite formed in the reducing environment has smaller particle size (maximum particle size less than 20 μm) and narrow distribution, whose microcrystalline morphology tends to be square. The number of crystal sides of strawberry pyrite increases with increasing the S Fe ratio (Tetrahedron octahedron sub sphere). Transition from strawberry pyrite to euhedral crystalline pyrite shows that the paleosedimentary physicochemical conditions are changing, the water saturation may be changing slowly, which needs to be further confirmed.

E-mail: pfrancus@ete.inrs.ca

Keywords: Detritic varves, NAO, Thin-sections, MicroXRF, hydrological regime

Grand Lake, Labrador, is a 250-m deep fjord lake that contains thick and very well-preserved detritic varves that can be correlated over tens of kilometres within this sedimentary basin. The chronology of this varved sequence is based on counts made from high-resolution images of thin sections at the scanning electron microscope, and from 100 µm-resolution microXRF profiles. The varve chronology established from these counts was validated by ^{210}Pb, ^{137}Cs and ^{14}C dating. Their thickness and grain-size can be directly linked to the discharge of its two main tributaries. The statistically significant correlation between varve thickness and the main tributary discharge during the instrumental period allows to develop a robust hydroclimatic reconstruction of the region. The river discharge was higher during the Medieval Climate Anomaly (1050–1225 CE) and lower during the Little Ice Age (15th–19th centuries). Moreover, the 1500-year-long record reveals strong similarities with large-scale atmospheric and oceanic variability modes, such as the North Atlantic Oscillation (NAO) and the Atlantic Meridional Overturning Circulation (AMOC). Finally, we found four different hydrological regimes during last fifteen centuries, against two only during the instrumental period.

Keywords: Asian dust storms, Varve sediments, Atlantic Multi-decadal Oscillation, Northeastern China

Abstract: Dust storm events have significant impacts on climate changes and human activities, and the patterns and forcing mechanism of long-term variations of dust storm are essential for predicting their future changes and impacts. However, high-resolution dust storm records are scarce, though large amounts of the records have been reconstructed. In the present study, the clastic materials in varve sediments from Lake Xiaolongwan, a maar lake in northeastern China, were demonstrated to be mainly eolian deposits using Sr-Nd isotopes and element ratios. Then, a 5000-yr dust storm record, with the average time resolution of ~5-yr, was reconstructed using proxies including lightness and element concentrations. The results show an increasing trend of dust storm events during the past 5000 years, with higher values during 3200-2500 a BP, 2100-1400 a BP, and after 1000 a BP. The record shows obvious ~116 yr, ~78 yr, ~49 yr, 30-39 yrs, and 22-26 yrs cycles, some of which are consistent with those in solar irradiance. The co-variances of the dust storm record with the total solar irradiance and the AMO (Atlantic Multi-decadal Oscillation) further suggest that changes in dust storms in East Asia might be modulated by the sun through internal factors in the earth system.

Anthropogenic and climatic driven vegetation succession during the past 300 years in Sihailongwan Maar Lake, NE China

luo yong[1], Zhou Xin[1*], Liu Xiaoyan[1], Jiang Shiwei[1], Cui Shukun[1], Liu Xuanqiao[1], Ding Min[1]

E-mail: xinzhou@ustc.edu.cn

Keywords: pollen,vegetation succession, human activities,climate change

Anthropogenic activities and climate change are the two critical drivers of vegetation succession, but the magnitude of their roles in vegetation succession has been highly debated. Here, we obtained a high-resolution 300-year pollen record from the Sihailongwan Maar Lake (SHML) in northeastern (NE) China. A precise chronology was established by the combination of varve counting, ^{210}Pb, ^{137}Cs, and AMS^{14}C dating of plant remains. The pollen assemblages indicate that the vegetation in the study area has been characterized by a shift from temperate coniferous forests to temperate deciduous broadleaved forests over the past 300 years. Before 1900 AD, the vegetation in the study area was mainly temperate coniferous forest dominated by *Pinus* showing relatively low intensity of human activities and natural succession of vegetation, which is consistent with historical documents. After 1900 AD, the proportion of temperate deciduous broadleaved forests dominated by *Betula* secondary forests increased at the expense of natural forests of *Pinus*, which was related to the intensification of human activities (e.g. Qing government's closure policy, selective felling of pine trees by wars, and the population explosion in northeastern China). Besides, *Artemisia* dominated the herbaceous vegetation and was sensitive to precipitation, identifying two relatively large droughts in the periods 1875-1910 and 1940-1960 AD. In addition, according to the results of principal component analysis (PCA), human activities and precipitation jointly drive vegetation changes in the study area over the past 300 years, with the former playing a more prominent role. We suggest that it is essential to formulate reasonable policies to enhance vegetation conservation in the context of the increasing intensity of human activities and global warming.

Tsunami Hazard in the Tiran Straits (Red Sea)

Sam Purkis[1*], Steven Ward[2], Hannah Shernisky[1], Giovanni Chimienti[3], Arash Sharifi [1]

E-mail: spurkis@rsmas.miami.edu

Keywords: Submarine landslide, Tsunami, Geohazard, Tiran Straits, Gulf of Aqaba

The Red Sea is a maritime rift. Tsunamigenic submarine landslides are common in these deep, steep-sided and seismically active basins. Because the Red Sea is narrow, tsunami formed on one margin dissipate little before impacting the opposite side. Red Sea slope failures are therefore especially hazardous. We examine the tsunamigenic potential of a recently discovered incipient landslide in the Tiran Straits that started, but then stopped after a short distance. Radiometric and biotic analyses fix the age of this landslide to within the last 500 years. Tsunami modelling of the incipient slide predicts ~10 m wave runup-heights on the Egyptian coastline. This event eluded the historical record as the afflicted coastline was virtually uninhabited at this time. Of present concern is that the slope will eventually slide to completion with even more hazardous results. Tsunami simulated for this future event are twice as large as that generated by the incipient slide, so the threat posed by a future slide is consequential. Sharm El Sheikh, an Egyptian resort town now lies in its path, as does Neom – a Saudi gigaproject. While exact prediction is impossible, this study warns of credible tsunami risk in the rapidly urbanizing Tiran Straits.

The “two-step” yielding process of the natural mud under steady and oscillating shear stress

Shaohua Wang[1], Zhiguo He[1], Yuezhang Xia[1*]
1. Ocean college, Zhejiang Zniversity, Zhoushan, Zhejiang, CHINA
E-mail: yzxia@zju.edu.cn

Keywords: natural mud, rheological properties, exterior loads, yield stress, two-step yielding

The yielding process of the natural soft mud have a significant effect on the morphology evolution, wave attenuation, nautical depth estimation, etc. In this study, both steady and oscillating rheological tests were performed through a rheometer with four natural mud samples collected from Luxi Island and Zhoushan Island, China. And the shear stress sweep, the oscillating amplitude sweep tests were carried out to obtain corresponding yielding process and yield stress of the natural mud. Both steady and oscillating experimental results show the existence of the “two-step” yielding feature of the natural mud samples, meaning that the “two-step” yielding process is the instinctive feature of the natural soft mud, despite the imposed manner of the exterior loads. Two yield stress, namely static yield stress and fluidic yield stress correspondingly to the state transition from solid to solid-fluidic state and from solid-fluidic to fluidic state respectively, were compared with its counterpart for steady and oscillating tests. The results show that the static yield stress of natural mud in steady shear tests is higher than oscillating shear tests, and the fluidic yield stress of natural mud in oscillating shear tests is higher than steady shear tests, this difference can be explained by the theorical analyzes. Furthermore, the higher frequency means the higher yield stress when natural mud is subjected to oscillating loads. The “two-step” yield process closely correlates to the internal structure of the mud sample, which is influenced by the density and the particle size of the natural mud, the results show that both density and particle size have a significant influence on the yield stress of the natural mud.

4. College of Resource & Environment, Henan Polytechnic University, Jiaozuo, Henan, CHINA
E-mail: 957576033@qq.com

Keywords: liquefaction, M5.1 earquake, sandy dyke, Hami

A M5.1 shallow moderate earthquake, just only being 4km in depth, occurred in December 14, 2009, in the city Hami, Xinjiang, western China, struck about a 10000 km2 area and formed very large quantities of exquisite, polygonal network, wedge-shaped, inclined and well-sorted sandy dykes. Typically, they occur mainly in sandy gravelly sediments, not being susceptible to liquefaction, with no fined grain cap and but salted crust cap or salt-rich cap. They are generally slightly inclined, on average, 75.10°. Largely because of the widely distributed salted crust and the shallow rigid basement the maximum epicentral distance of liquefied sites may extend to more than 100 km. Through the detailed research, we conclude as follows:

(1) The M5.1 moderate earthquake, the December 14, 2009, Hami, Xinjiang, convincingly form widely distributed small-medium-scale polygonal, wedge-shape, inclined, well-sorted sandy dykes. The 3D geometric morphology of these upward injected sandy dykes has been documented herein clearly. This kind of sandy dykes may be a reliable criterion used to distinguish them from similar but non-seismically generated sandy dykes.

(2) The sandy gravel layer may be genetically undoubtedly liquefied and form numerous sandy dykes without fine grain cap. This process has two important requirements--the widely-distributed salted crust and shallow basement apart from other general liquefaction factors.

(3) Conceivably, although unlikely according to the classic theory, the maximum epicentral distance of liquefied sites of more than 100 km, formed by the moderate earthquake (M5.1) in Hami, is characteristic of the composite-effect of the wide salted crust and shallow rigid basement.

(4) Well-sorted feature of the sandy dykes is certainly attributed to the well liquefaction and fluidization of sandy gravel layer.

The well-exposed seismically-induced sandy dykes in Hami provides an important avenue for future research on primary seismically-induced sand dykes. It is a very rare case in the world.

E-mail: mshirai@tmu.ac.jp

Keywords: lahar deposit, Fuji Sagamigawa Mud Flow, Fuji Volcano, Sagami River, central Japan

Lahar is a general term for a rapidly flowing mixture of rock debris and water from a volcano (Smith and Fritz, 1989). The Fuji Sagami-River Lahar (Fuji Sagamigawa Mud Flow) originated from the Fuji Volcano (Older Fuji) around 22 ka (Machida, 2009) flowed eastward along the Sagami River valley through the southwest Kanto District, central Japan. The lahar deposit is covered by younger lava flows at the foot of the Fuji Volcano, and it is exposed intermittently along the Sagami River from ca.20 km to ca. 90 km apart from the present Fuji Volcano summit. Although the lahar deposit was investigated intensively by Geographical and Geological Research Group in Sagamihara City (1990), detailed description of the upper reaches of Sagami River has not been performed yet.

Our minute investigation of the lahar deposit in the upper reaches of the Sagami River revealed that (1) the lahar deposit filled the Sagami River valley floor entirely with ca. 20 m thick at least the studied area, (2) the deposit is divided the lower unit composed by boulder–cobble sized basalt and the upper unit composed by pebble sized basalt and scoria, (3) the upper unit is divided 6 or more subunits intercalating scoria or fluvial deposits and (4) the lower unit is more than 10 m thick at ca. 30 km apart from the present summit. Although the lower unit is almost hidden below the valley floor, it would be distributed up to 40 km or more distal from the present summit.

Acknowledgment: This study is performed as a part of investigations of the Research Center for Volcanic Hazards and Their Mitigation, Tokyo Metropolitan University. We thank to Tsuru University permitting us to use the boring data for constructing buildings. Drs. M. Kobayashi and T. Takahashi are thanked for their assistance for field survey.

Infuence of biopolymers on the rheological properties of natural silt

Hengye Gu[1], Yuezhang Xia[1*]
1. Ocean College, Zhejiang University, Zhoushan, Zhejiang, CHINA
E-mail: yzxia@zju.edu.cn

Keywords: biopolymers,rheological properties,solid-liquid state transformation,yield stress,EPS network

In order to explore the effect of adding biopolymers (EPS) on the rheological properties of silt, we used rotary rheometer to study the shear dynamic response of kaolinite-quartz suspension and silt from tidal flat of Zhairuoshan Island, Zhoushan. Rheological properties of kaolinite-quartz suspension with different proportions and natural silt with different bulk densities were compared with or without the addition of biopolymers (xanthan gum was used instead). The results show that the tidal flat silt of Zhairuoshan Island has the characteristics of dual-Bingham under shear load, and the relationship between shear stress and shear rate can be quantitatively described based on dual-Bingham rheological model. With the increase of shear loading rate, the silt shows complex solid-liquid state transformation, and its dynamic response process can be divided into three typical stages: quasi-solid state, solid-liquid state and liquid state. In addition, biopolymers (EPS) can affect rheological properties in natural systems. Our experiments demonstrated that the fow behavior of sediment suspensions or natural silt mixed with an analogue material of EPS (xanthan gum) can be described by a Herschel–Bulkley model. The addition of EPS can also enhance the yield stress of silt, by means of formation of an EPS network that binds silt particles.

Repeated deposition of earthquake-induced turbidites along the landward slope of the northern Japan Trench: how large ground shaking is necessary for generation of surface-sediment remobilization along the slope?

Ken Ikehara[1*], Kazuko Usami[2,3], Toshiya Kanamatsu[4]

4. Research Institute of Marine Geodynamics, Japan Agency for Marine-Earth Science and Technology, Yokosuka, Kanagawa, JAPAN

E-mail: k-ikehara@aist.go.jp

Keywords: turbidity current, surface-sediment remobilization, slope sediment response, earthquake ground shaking, Japan Trench

Deep-sea turbidites have been utilized to understand the history of past large earthquakes. From a paleoseismological point of view, it is important to understand the trigger conditions of earthquake-induced turbidity currents. Surface-sediment remobilization is considered to be a mechanism for the initiation of earthquake-induced turbidity currents, based on the studies of the event deposits formed by the recent great earthquakes, such as the 2011 Tohoku-oki earthquake, although submarine slope failure has been considered to be a major contributor. Small age differences (less than a few 100 years) in radiocarbon ages between turbidite and hemipelagic muds in a piston core collected from the mid-slope terrace (MST) along the northern Japan Trench at 40.13˚N suggest that initiation of turbidity currents caused by the earthquake-induced surface-sediment remobilization has occurred repeatedly during the last 2300 years. A profile of excess 210Pb activities of an undisturbed surface sediment core from the same location suggests that the uppermost three event beds are correlative to three historical earthquakes along the northern Japan Trench. Estimations of peak ground acceleration (PGA) for the historical earthquakes indicate that >0.6 G of PGA is necessary for deposition of each event bed at the slope near the coring site. This limit is slightly larger than that (~0.4–0.5 G) at slope of 39.25˚N, suggesting the spatial difference of response of slope sediments to the earthquake ground shaking. However, the frequency of the event beds at 40.13˚N is higher than those at 39.27˚N and 39.12˚N. Great earthquakes near junction of Japan/Kuril trenches are possible candidates to form additional event beds at the northern Japan Trench slope.

4. Graduate School of Life and Environmental Sciences, University of Tsukuba, Tsukuba, Ibaraki, JAPAN
E-mail: shige-fujino@geol.tsukuba.ac.jp

Keywords: tsunami deposit, Miocence, Tanabe Group, Japan, mega-tsunami

Tsunamis generated by fault displacements, volcanic eruptions, and landslides on the seafloor often occur, with time intervals of tens to hundreds of years in active plate margins. Several such tsunamis have occurred in recent years, and some have been recorded in written documents since the dawn of history. Since mega-tsunamis, which are much larger than recent tsunamis and are generated by bolide impacts, violent volcanic activities, and oceanic island flank collapse, for example, are less frequent, they may not have been experienced by humans, and even if they were, they may not have been documented. However, sedimentary rocks with significantly longer time scales may record tsunamis of a magnitude never experienced or documented by humans.

This presentation will report on a shallow marine tsunami deposit found in the Miocene Tanabe Group, Wakayama Prefecture, Japan. The deposit is intercalated in tide-dominated shallow marine deposits. The deposit consisting of medium- to coarse-grained sandstones, rip-up clasts, and subangular-subrounded pebbles, is estimated to have eroded the underlying strata up to 1.5-6 m or more. The maximum thickness of this deposit is 8.8 m. The bed can be traced approximately 1 km in some coastal outcrops, and is characterized by the following sedimentological features; (i) multiple sub-layers separated by internal erosional boundaries, (ii) HCS, (iii) flame structure at sub-layer boundaries, (iv) fluid escape structures, and (v) organic debris at some sub-layer boundaries and the top. Trace fossils and bioturbate textures are not observed throughout the succession.

The existence of multiple sub-layers is a feature that has been reported from submarine and onshore tsunami deposits, and each sub-layer is considered to have been formed through the tsunami uprush or backwash. HCS indicates that this deposit was formed under the influence of waves with longer periods. Fluid escape structures may reflect that a large amount of sediment was supplied and deposited instantaneously. The abundant organic debris suggests that the onshore areas were also eroded during this event. This deposit shares characteristics with previously reported tsunami deposits, but its thickness and degree of substrate erosion far exceed those of present-day shallow marine tsunami deposits. This implies that the tsunami deposits found in the Miocene Tanabe Group were exceptionally large even in the geological time scale

Soft-sediment deformation structures in a lacustrine depositional context: An example from the Eocene Dongying Depression in the Bohai Bay Basin, East China

Jiayi Meng[1], Zaixing Jiang[1*]
1. School of Energy Resources, China University of Geosciences, Beijing, Beijing, CHINA
E-mail: Jiangzx@cugb.edu.cn

Keywords: Soft-sediment deformation structures, Deformation mechanisms, Seismites, the Dongying Depression

The study documents soft-sediment deformation structures (SSDSs) in the lacustrine Dongying Depression, a Paleogene synrift basin located in the southeastern corner of the Bohai Bay Basin, East China. The focus of this study is the lower part of the upper 4th member of the Eocene Shahejie Formation ($Es4^{U}$), characterized by littoral to sublittoral deposits in the southwestern Dongying Depression. Nine lithofacies are grouped into the upper shoreface facies associations (FA1-1), lower shoreface facies associations (FA1-2), and sublittoral facies associations (FA2). Fine-grained calcareous sandstone was mainly deposited in FA1-1, with thinly alternating calcareous mudstone and siltstone or sandstone in FA1-2, while deposition in FA2 was dominated by mudstone, containing sediment gravity flow deposits. The SSDSs widely encountered in the lower $Es4^{U}$ can be classified into seven categories: (1) load structures, (2) water-escape structures, (3) folds and convolute lamination, (4) sediment-injection structures, (5) microfaults, (6) autoclastic breccias, and (7) slumps. Detailed observations of SSDSs from cores indicate liquefaction and fluidization as the main deformation mechanisms in the sands and muds. Moreover, rupturing of cohesive deposits also contributes to the soft-sediment deformation. The types and morphologies of the SSDSs are closely related to the rheologies of the sediments (e.g., the sand content), influenced by the facies that determine the lithologies and stratigraphic stacking patterns. Except for some deformation structures related to subaqueous sediment gravity flows (e.g., muddy debrite flows and slumps), most SSDSs are ascribed to rift-related seismicity due to the activity of the adjacent synsedimentary faults when the Dongying Depression underwent quick subsidence during the Eocene.

Sediment dynamics on a tidal flat in macro-tidal Hangzhou Bay during Typhoon Mitag

Yuezhang Xia[1*]
1. Ocean College, zhejiang University, Zhoushan, Zhejiang, CHINA
E-mail: yzxia@zju.edu.cn

Keywords: Sediment dynamics, Tidal flat, Typhoon, Hangzhou Bay

Field records of waves, currents, and suspended sediment concentration (SSC) in the southern tidal flat (Andong) of the macro-tidal turbid Hangzhou Bay, China, were collected during Typhoon Mitag. The record showed little variance in the magnitude of the tidal currents during the typhoon. The directions were disordered with the peak ebbing currents changing from the southeast to the east, presumably due to the winds and northerly currents from the tidal creeks during the precipitation period. The significant wave heights (Hs) and turbulence kinetic energy (TKE) significantly increased during Typhoon Mitag. The SSC obtained by the optical backscatter sensor (OBS) near the bottom level rose rapidly to 6–7 kg/m^3 during the initial stage of tidal cycles during calm conditions but decreased to 4–6 kg/m^3 during Typhoon Mitag, probably due of the enhanced upward sediment transport by turbulent mixing. During normal weather conditions, the bed shear stresses induced by currents (τ_c) were mostly larger than those induced by waves (τ_w), while the τ_w exceeded the τ_c during the storm. The instantaneous bed shear stresses induced by currents and waves were mostly lower than the critical shear stress. Extracting turbulence from waves effectively diminishes the overestimation of turbulence. In calm conditions, the small-scale features (>0.5 Hz) of the scalograms exhibited some degree of disorder owing to the random nature of turbulence. Small-scale characteristics were embedded in relatively large-scale motions during extreme conditions, and a small quantity of plume-like streaks appeared between the frequency bands of 1/16 and 1 Hz. The temporal distributions of the high wavelet power regions of $U'W'$ and $c'W'$ coincided with each other, indicating the critical role of intermittent turbulence in sediment dynamics. The results of this study shed light on the study of coastal morphology and marine disasters.

Sedimentary Record of Coastal Hazards in Zhangjiang Estuary since the Late Holocene

Fengling Yu[1*], Zixian Zhuang[1], Nannan Li[1], Zhaoquan Huang[1], Shengtao Liu[1]
1. Department of Geological Oceanography,State Key Laboratory of Marine Environmental Science, College of Ocean and Earth Sciences, Xiamen University, Xiamen, Fujian, CHINA
E-mail: fengling.yu@xmu.edu.cn

Keywords: Typhoon hazard, Storm deposit, Zhangjiang Estuary, Bulk organic carbon isotope, Late Holocene

Rising sea levels as a result of global warming pose a great threat of coastal hazards to coastal areas, with flooding and storm surges being one of the most prominent. Such fact highlights the necessity of improving the resilience of coastal areas to risks, which strongly relies on accurate future risk assessment, for which, an improved understanding on the reoccurrence interval of major typhoon-induced coastal hazards is crucial. Due to the limited accuracy or timeframe for historical and instrumental records, sedimentary records have found to be useful for archiving strong coastal overwash events, especially for capturing catastrophic events usually with a returning period longer than 100 yrs. in order to understand the sedimentary features of coastal hazard deposits and to explore the temporal and spatial characteristics and driving mechanism of coastal hazards, this study focuses on the Zhangjiang Estuary in Fujian Province, southern China, where a sediment core was collected in 2018. By employing a range of biogeochemical indicators, this study reconstructs the history of coastal paleo-hazard since about 4200 years ago in this region and comes into three main findings: 1) Under fair weather conditions, the sediments in the Zhangjiang Estuary area are mainly composed of silt, while during strong hydrodynamic conditions, sediments are usually poorly sorted and of complex sedimentary provenances as indicated by biogeochemical indicators. 2) The intensity of the typhoon hazard in the Zhangjiang Esturay area has been increasing since the Late Holocene. Specifically, there were three periods of frequent coastal hazards during 1400-700 cal a BP (3 times / 700a), the frequency of which was about twice that during the period of 3900-2500 cal a BP (3 times / 1400a). 3) The spectrum analysis has identified ca. 700-year and ca. 400600-year cycle in late-Holocene climate change history in Zhangjiang Estuary. The 600-year cycle may be the cycle of frequent strong typhoon period, which may be related to Holocene solar activity at different time scales.

Keywords: Seismite, Marine/Lacustrine Paleoseismology, In situ soft-sediment deformation, Computational fluid dynamics modeling, Kelvin-Helmholtz Instability

The Dead Sea Basin is the deepest and largest continental tectonic structure in the world. *In situ* folded layers and intraclast breccia layer in the ICDP Core 5017-1 that recovered from the Dead Sea depocenter are identified as earthquake indicators, based on their resemblance to the lake outcrop observations of seismites that are known to be earthquake-induced.

Analysis of the physics of formation and temporal distribution of 413 seismites in the 457-m-long Dead Sea ICDP Core 5017-1 yields a continuous earthquake record spanning 220 kyrs in and near the Dead Sea Basin. Based on the Kelvin-Helmholtz instability, we model the ground acceleration (seismic shaking intensity) needed to produce each seismite by using the physical properties of the Dead Sea deposits. We invert acceleration for earthquake magnitude by considering regional earthquake ground motion attenuation, fault geometry, and other constraints. Based on the magnitude constraints, we develop a 220 kyr-long record of M_w ≥7 earthquakes.

The unique location of the drill site makes the 220 kyr-long earthquake record the most complete on the central Dead Sea Fault. Our analysis shows that the recurrence time of large (M_w ≥7.0) earthquakes follows a power-law distribution, with a mean of ≤ 1400±160 years. This mean recurrence is significantly shorter than the previous estimate of 11,000 years for the past 40 kyrs. Our unique record confirms a clustered earthquake recurrence pattern and a group-fault temporal clustering model, and reveals an unexpectedly high seismicity rate on a slow-slipping plate boundary.

Our study highlights the potential of in situ deformed sediment layers in a subaqueous environment as a strong-motion paleo-seismometer to record long seismic sequences covering multiple recurrence intervals of large earthquakes. Long records are vital for accurate hazard assessment. Our quantitative method of seismic record reconstruction, with paleo-earthquake intensity (ground acceleration) and magnitude estimation, is also applicable to other subaqueous environments along faults.

Seismic and non-seismic triggers of soft-sediment deformation structures in a landslide-dammed lake at Diexi, eastern Tibetan Plateau

Jingjuan Li[1*], Xuanmei Fan[1], Paul A Carling[2], John D Jansen[3]
1. State Key Laboratory of Geohazard Prevention and Geoenvironment Protection, Chengdu University of Technology, Chengdu, Sichuan, CHINA
2. Geography & Environmental Science, University of Southampton, Southampton, UNITED KINGDOM
3. GFÚ Institute of Geophysics, Czech Academy of Sciences, Prague, CZECH REPUBLIC
E-mail: fightingkhc@qq.com

Keywords: Soft-sediment deformation structure, Late Pleistocene, Triggering mechanism, Seismic shaking

A variety of triggers can form soft-sediment deformation (SSD) structures, such as gravity-induced loading and slumping, floods, mass movement and debris flows. Much existing research is focused on understanding seismically-induced SSD structures known as seismites. Palaeo-earthquake information obtained from SSD structures has been applied to a wide range of earthquake attributes, but most studies on palaeo-earthquake were identified from field sections, the relationship between SSD structures in cores and seismic events remains unclear, and distinguishing seismic from non-seismic triggers remains a major challenge.

Diexi Lake formed when seismically-induced landslides blocked the main valley, creating the largest landslide-dammed lake in the upper Minjiang River, eastern Tibetan Plateau. An excellent record of SSD structures is preserved in a ~166 m-long drill-core (DX-2A) retrieved from Diexi Lake in 2019. Here, we identify and describe 454 SSD structures in the core and consider their mechanism of formation. Based on their morphological characteristics, we classify the SSD structures into three main types: (1) liquefied flow structures, (2) load structures, and (3) thixotropic flow structures. In addition, we propose at least five mechanisms for the formation of SSDs that are not necessarily linked to seismicity: (i) overpressure caused by gravity; (ii) fluidization of sediments affected by river runoff velocity; (iii) floods, landslides, debris flows and other slope failures triggered by extreme precipitation events; (iv) lake surface waves generated by wind; and (v) sediment instability at the lake floor margins. According to previous studies on the relationship between SSD structures and earthquake, if the SSD structures in DX-2A are triggered by earthquakes, the magnitude (Ms) of palaeo-earthquakes may be 2-7.5, mostly are Ms≥5-5.5. These findings provide a useful basis for a quantitative analysis of palaeoseismicity on the eastern margin of the Tibetan Plateau.

Sediments prone to liquefaction – implications from field studies: review

Szymon Piotr Świątek[1*], Małgorzata Pisarska-Jamroży[1], Szymon Belzyt[2]
1. Institute of Geology, Adam Mickiewicz University, Poznań, Wielkopolskie, POLAND
2. Department of Geology and Hydrogeology, Nicolaus Copernicus University, Toruń, Kujawsko-pomorskie, POLAND
E-mail: szymon.swiatek@amu.edu.pl

Keywords: liquefaction, soft-sediment deformation structures, statistical analyse, grain-size analysis

Liquefaction-induced soft-sediment deformation structures (SSDS) can be triggered by wide spectrum of mechanisms, e.g. seismic activity, volcanic eruption, ice and sediment loading, storm waves and tsunamis. To better understand their origin Owen (2003) suggested dividing liquefaction-induced SSDS into two groups: synforms (e.g. load casts, pseudonodules) and antiforms (injection structures).

The aim of this study was detailed grain-size analysis of the sediments (170 samples) within synforms and antiforms recognised in eight study sites in the southern part of the Baltic Sea basin (Latvia, Lithuania, Germany). Mastersizer 2000 by Malvern particle size distribution of each sample were analyzed using laser diffraction. Then, using the GRADISTAT software, the sediments were determined according to the Friedman and Sanders (1978) classification. Furthermore, basic statistical parameters were calculated: mean diameter, skewness, standard deviation and kurtosis (Blott and Pye, 2001).

Preliminary results of the research have shown that antiform structures are mainly composed of silty sediments (coarse-grained silt, very coarse-grained silt, very fine-grained sand), while the synform structures - sandy sediments (fine-grained and medium-grained sand). The sediments within antiforms are characterized by very poor and poor sorting, and leptokurtic (up to extremely leptokurtic) distribution. Sediments within synforms are moderately good and good sorting, and their distribution is platykurtic or very platykurtic (only a few % of the samples charactrised mesokurtic distribution).

The obtained results are in contradiction with previous studies suggested that the antiforms are composed of well-sorted sediments (e.g., Obermeier, 1996; Owen, 2003; Maltman and Bolton, 2003; Owen and Moretti, 2011).

The study has been financially supported by a grant for the GREBAL project (No. 2015/19/B/ST10/00661) from the National Science Centre Poland.

A PIONEER STUDY OF HURRICANE IDA'S STRATIGRAPHIC SIGNATURE AND SIGNIFICANT DAMAGE TO THE MISSISSIPPI DELTA SHORELINE

Qiang Yao[1*], Marcelo Cohen[2], Kam-biu Liu[1], Erika Rodrigues[2]
1. Oceanography and Coastal Sciences, Louisiana State University, Baton Rouge, Louisiana, UNITED STATES

E-mail: qyao4@lsu.edu

Keywords: Hurricane Ida, Mississippi River Delta, Paleotempestology, Multi-proxy analysis, Remote sensing, mangrove

Hurricane Ida devastated the Mississippi River Delta at the end of August 2021. The multi-proxy dataset from Port Fourchon, Louisiana, the eye of Ida at landfall indicates that backbarrier lake is a more sensitive repository in receiving and preserving storm surge deposits, and backbarrier mangrove swamp shows promising effects on attenuating storm surge impacts. The remote sensing analysis shows that the sand volume of the ~2 km studied beachfront was reduced by 240,858 m3 after consecutive landfalls of Hurricane Zeta and Ida in 2020 and 2021, losing almost 40% of its volume in 2019, while the average dune crest height was reduced by over 1 m and the shoreline retreated ~60 m after the two hurricane strikes. Our spatial-temporal analytical dataset suggests that the human-engineered beach nourishment effort is not adequate to protect the shorelines at the Mississippi River Delta from intense hurricane landfalls.

Simulated reconstruction of the Super Typhoon events along the coast of Hangzhou Bay during the decline of Liangzhu Culture

Shuo Wang[1*]
1. College of Urban and Environmental Science, Northwest University, Xi'an, Shanxi, CHINA
E-mail: shwang@nwu.edu.cn

Keywords: Storm deposit,Dynamic process simulation,Liangzhu Culture

Liangzhu Culture symbolizes the peak of neolithic culture development in the Yangtze River Delta. Its archaeological ruins spread the coast of Hangzhou Bay and reflects an early regional civilized country. But the Liangzhu Culture suddenly declined around 4300 yr BP, which may be related to the rapid sea level rise and the frequent occurrence of extreme storm events in a warm climate. However, previous studies mostly focused on the identification of the single storm based on sedimentary storm records, but failed to reconstruct the intensity, path and impact on cultural succession of extreme events. Therefore, this study intends to analyse the time and space distribution of the sedimentary storm records at Liangzhu sites, to obtain the inundated area of extreme storm events at the end of Liangzhu Culture; based on the paleotopography at the end of Liangzhu culture, a hydrodynamic model is established to simulate the tides, waves and inundation by paleo-storms with different intensities and paths and a sediment model is established to simulate the erosion and depositional processes along the coast of Hangzhou Bay. By comparing the sedimentary records and numerical simulated results, we reconstruct the intensity and path of the Super Typhoon events at the end of Liangzhu Culture, reveal the formation mechanism of coarse-grained sediments above the cultural layer, and discuss the relationship between extreme storm events and the decline of Liangzhu Culture. Thus, this study can extend the typhoon record in eastern China and provide analogical cases for extreme weather disasters prevention in the future.

The Index of Grain Size, Sporopollen and Magnetic Susceptibility Reveal the Environmental Change and the Shijiahe Civilization in Jianghan Plain of The Middle Reaches of Yangtze River

Mingming Jia[1*]

1. School of Geography and Information Engineering, , China University of Geosciences, Wuhan, Hubei, CHINA
E-mail: 767483215@qq.com

Keywords: Tanjialing site, Sporopollen, grain size, Magnetic Susceptibility, Holocene environmental change

Shijiahe culture is the most widely distributed and developed culture type in the middle reaches of the Yangtze River at the end of the Neolithic age. The dating results obtained from the Tanjialing section and the ZJ-3 borehole are in good agreement with the stratigraphic sequence, especially the dating results of the Shijiahe culture layer, which are 4942-4097 cal. a BP after the correction of IntCal20 curve, without inversion and consistent with the relative age of The Shijiahe culture. Therefore, it can be considered that the absolute age of The Shijiahe culture in Tanjialing area is 4900-4100 cal.a BP. According to the analysis of palynology, grain size and magnetic susceptibility, the region had a warm and wet Holocene megalwarm-period before 5600 a BP, the climate tended to become dry from 5600 a BP to 4900 A BP, the climate was a relatively turbulent period from 4900 to 4800 cal.a BP, and the climate gradually became cool and dry in the following 600 years. The ancient people experienced the most prosperous period under the background of the great climate, and then gradually due to the drought of the climate, rice farming declined, which led to the decline of culture.

Seabed erosion and deposition related to the typhoon activity of the past millennium on the southeast coast of China

Haixian Xiong[1*]
1. School of Marine Sciences, Sun Yat-sen University, Zhuhai, Guangdong, CHINA
E-mail: xionghx5@mail.sysu.edu.cn

Keywords: sedimentary hiatus, erosion, typhoon, tsunami, the northern South China Sea

Catastrophic events often interrupt long-term Earth' s surface processes. In coastal areas, although millennial-scale trends of climatic and sea-level changes determine the trajectory of sedimentary landform evolution, storm and/or tsunami activity can cause abrupt changes in depositional conditions that may alter the long-term sedimentary processes. Here, we report a sedimentary hiatus that is widely observed from the late Holocene sedimentary sequence at the seabed along the southeast China coast. This hiatus was discovered by close temporal sedimentary and radiocarbon dating analyses of a seabed sedimentary sequence in the mouth area of the Pearl River estuary. The results suggest that a couple of meters in the middle to late Holocene sediment at the seabed were eroded by a catastrophic event happening c. 1000-800 cal. years BP. In theory, a mega-tsunami generated from the Manila Trench could have caused such erosion at the seabed, but there is a lack of direct geological and historical evidences to support such a hypothesis. Much more likely, a super typhoon struck the coast and caused the erosion. This hypothesis is strongly supported by the region’s historical and geological records which suggest a period characteristic of intense typhoons ranging from the Medieval Warm Period to the climate transition phase (c. 1000-600 cal. years BP). During the subsequent Little Ice Age, deposition of sandy sediment continued, suggesting frequent but weaker typhoon activity. Over the past two centuries, the deposition of sandy sediment and gravels began, implying the beginning of a phase of intensifying typhoon conditions, possibly a result of the recent warming climate.

Mid-Holocene drought and hurricane events in Central America recorded by Puerto Rico stalagmites

huiru tang[1], liangcheng tan[1*], yongli gao[2]
1. , , , , CHINA
2. , , , UNITED STATES
E-mail: tanlch@ieecas.cn

Keywords: Speleothems, Hurricanes, Mid-Holocene, Central America

In recent years, the coastal areas near the Gulf of Mexico and the Caribbean have been repeatedly hit by hurricanes, which have brought serious harm to the local social and economic development. Therefore, predicting future hurricane activity is essential, and the reconstruction of past hurricane changes provides a possibility for future hurricane prediction. Speleothems are a kind of high-quality terrestrial paleoclimate archives that are widely developed. Speleothems have accurate dating and high resolution and were commonly used in paleoclimate research. Much research has also confirmed that stalagmite has the potential to reconstruct the history of hurricanes(Vieten et al., 2018 , Lases-Hernández et al., 2020, Frappier et al., 2007 , Nott et al., 2007).

With the Atlantic Ocean to the north and the Caribbean Sea to the south, Puerto Rico is highly vulnerable to hurricanes and is an excellent location for studying the history of hurricane activity. In this study, we reconstructed the Mid-Holocene hurricane and hydrological history of Puerto Rico based on multiple geochemical indicators of stalagmite IM-94. The results suggest that the frequency of hurricane activity varied on centennial to decadal scales during the study period, which may be regulated by atmospheric dynamics related to el Nino/Southern Oscillation. At the same time, rainfall in this area is mainly affected by solar radiation on a centennial scale. When solar radiation decreases, the North Atlantic becomes cooler, the subtropical high in the North Atlantic weakens, the tropical convergence zone moves southward, and regional rainfall decreases.

Millennial Sedimentary Archives of Tropical Cyclones in South Pacific

YA-NAN LI[1*], Shu Gao[1], Jeffrey P Donnelly[2]

1. State Key Laboratory of Estuarine and Coastal Research, East China Normal University, Shanghai, CHINA
2. Geology & Geophysics, Woods Hole Oceanographic Institution, Woods Hole, Massachusetts, UNITED STATES

E-mail: yananli.nju@gmail.com

Keywords: South Pacific, tropical cyclone, sedimentary archive, reconstruction

Tropical cyclones (TCs, i.e., storms) have been causing significant damages and loss of human lives and resources in heavily populated coastal regions, and have gained extensive attention. As a result, it is critical to reveal the millennial variability of TCs for coastal risk management, while our centennial instrumental records in hand cannot meet this requirement. Fortunately, the high-energy dynamic conditions associated with TC landfalls could leave event layers in sedimentary archives from low-energy coastal environments, such as lagoons and blue holes, which allows us to recover millennial TC variability characteristics. Numerous paleo-storm reconstructions have been carried out based on sedimentary records from coastal areas prone to storm in the past several decades. For now, such reconstructing studies are relatively mature in the North Atlantic and the Northwest Pacific in terms of quality, quantity, spatial coverage and time scale, while there is a paucity of such work in the South Pacific, which is as well vulnerable to TC attacks. This status quo has restrained us to depict a full picture of TC activity characteristics from a global perspective.

In this study, three sets of sediment cores were recovered from tropical islands of Melanesia in the South Pacific (namely the Salt Lake, Fiji, a blue hole in the Bay of Islands, Fiji, and Marou Lagoon in Emao Island, Vanuatu). On basis of these sediment cores, three decadal resolution and millennial-scale time series of paleo-TCs were established by integrating sedimentological methods, statistical methods and age-depth model, and corresponding paleo-TC frequencies were calculated. The three TC time series present similar centennial variability shift; then they were combined with several previous studies in the South Pacific, and were compared with the ENSO proxy variability of the past 3000 years. It is suggested that TCs in Melanesia Archipelago and the northwest coast of Australia are active during El Niño events, and are more quiescent during La Niña events; however, in Polynesia, the TC activity patterns are in phase with the El Niño index before 1000 CE but they present reverse phase after that.

Along-slope versus downslope sedimentation patterns on the high-latitude eastern Canadian continental margin during the last glacial period

Harunur Rashid[1,2*], Min Zeng[1], Jiaxin Chen[1], Jianing He[1], A. Owen Brown[3]
1. College of Marine Sciences, Shanghai Ocean University, Shanghai, CHINA
2. Earth and Environmental Sciences, Memorial University of Newfoundland, St John's, Newfoundland and Labrador, CANADA
3. Geological Survey of Canada (Atlantic), 1 Challenger Drive, Dartmouth, Nova Scotia, CANADA
E-mail: rashid@shou.edu.cn

Keywords: Sediment dynamics, last glaciation,Holocene, nepheloid-flow deposits, mud-turbidites, Labrador Sea

Late Pleistocene Labrador Sea depositional systems developed in front of ice streams and glacier outlets from the Laurentide Ice Sheet (LIS) are documented by Huntec and 3.5 kHz seismic profiles and piston cores. Due to efficient grinding by the LIS, massive amounts of fine-grained sediments and meltwater in addition to the icebergs tied to the Heinrich events (H-events) of the last glaciation were delivered to the neighboring Labrador Sea. The position of the Hudson Strait ice stream during the periodic expansion and contraction on the Labrador margin allowed fine-grained sediments and meltwater direct delivery on the lower shelf and upper slope. These discharges were then transported southward by the Labrador Current and western boundary current. In contrast to the lower shelf and upper slope, sediment delivered on the mid to lower Labrador slope were transported by the Northwest Atlantic Mid-Ocean Channel to distal sites. Nepheloid-flow layer at or near the sea bottom or at mid-water depths develop from meltwater loaded with an excessive charge of fine-grained sediments. Contrastingly, non-discriminatory ice rafting process delivered detritus of all sizes, but its total contribution to the sediment column is only minor, notwithstanding its paleoclimatic significance during H-events.

Heinrich H1, H2, and H4 layers were identified by their characteristic nepheloid-flow layer deposits, i.e., alternating coarse silt and clay-sized laminae with thin ice-rafted debris interspersed by coarse to fine-grained dropstone. Further, the progressive thinning and eventual disappearance of the fine-laminae (i.e., coarse and fine silt/clay) in H-layers at the distal sites suggests the exhaustion and raining out of fines due to long-distance transport. However, the H3 layer was identified by a combination of nepheloid-flow layer deposits (upper slope) and finely-laminated mud turbidites (lower slope and deep basin) at proximal sites. In the lower Labrador Slope and Basin, the H3 stratigraphic equivalent layer was identified by exorbitantly thick finely-laminated carbonate-rich mud turbidites. The divergent sedimentation style (i.e., reflected by the sediment facies) and the thickness of the H3 layer compared to other H-events suggests that the Hudson Strait ice-stream position was different compared to other H-events. Therefore, our data imply that the divergence in the H3 layer between the eastern and western North Atlantic might lie with the position of the Hudson Strait ice stream on the Labrador continental margin.

Northwestern Pacific tropical cyclone activity enhanced by increased Asian dust emissions during the Little Ice Age

Yang Yang[1*]

1. School of Marine Science and Engineering, Nanjing Normal University, Nanjing, Jiangsu, CHINA

E-mail: yyang@njnu.edu.cn

Keywords: Tropical cyclone activity, Grain size, Sea surface temperature, Asian dust emissions, Little Ice Age

Instrumental records reveal that intense tropical cyclone (TC) activity varies with tropical sea surface temperature (SST) on annual-decadal scales. Drivers of intense TC activity at the centennial-millennial scale are less clear, due to the sparseness of pre-observational reconstructions. Here, we present a new 2 kyr continuous activity record of intense TCs from offshore eastern China. Our reconstruction indicates that this site witnessed enhanced TC activity during relatively warm periods, with a widespread increase in TC activity during the later part of the Little Ice Age. This latter observation reveals that enhanced TC activity was synchronized with increased Asian dust emissions during the Little Ice Age. TC activity was also lower in the late Roman Warm Period, when SST was higher but Asian dust emissions were lower than in the early phase. Such patterns suggest a centennial-millennial link between TC climatology and a combination of SST changes and Asian dust levels.

Event beds of the Changjiang River over the past 2000 years: Floods VS storms

Liang Zhou[1*]
1. School of Geography, Geomatics, and Plannin, Jiangsu Normal University, Xuzhou, Jiangsu, CHINA
E-mail: geozhouliang@126.com

Keywords: flood deposits, storm deposits, multi-proxy method, Changjiang river delta

Storms and floods have exerted significant influences on the sedimentation of the river delta. However, how to distinguish the storm deposits from flood deposits in the large river deltas has not been well understood. In this study, a multiproxy analysis method (e.g. sedimentological, geochemical analysis) was established to distinguish the storm deposits from flood deposits, by using a 4.8-m-long sediment core retrieved from the subaqueous delta of the Changjiang River. This multi-proxy analysis indicates that the sedimentological signatures of palaeoflood deposits are characterized by a high EM5 content and high Zr/Fe ratios in the subaqueous delta sedimentary sequence, while storm deposits are characterized by a high EM5 content, with anomalies in Ca and Sr peaks.

Base on this multi-proxy method, we establish a flood history for the Changjiang River during the late Holocene, and14 continuous paleoflood regimes were identified during 19–66 BCE, 25–80, 255–350, 415–475, 550–710, 740–835, 970–990, 1080–1130, 1170–1235, 1275–1390, 1440–1500, 1560–1730, 1810–1830, and 1950–2011 CE respectively. These flood units match well with the observed large floods, documentary records of floods, and sedimentary flood deposits, confirming that the coarse units in the sequence are flood-derived and are regionally representative.

Keywords: Paleoclimate, Paleoceanography, Coastal, Reconstruction, Atlantic, Storms

The year 2020 Common Era (CE) observed the most "named" tropical cyclones since the instrumental record began in 1850 CE. Most downscaled models indicate that Anthropogenic climate change will increase the frequency and destructive potential Atlantic tropical cyclones. Problematically, it is difficult to ascertain if recent high-activity is unprecedented over longer-time scales due to the short instrumental record. Coastal and marine sedimentary archives may preserve a longer record of past tropical cyclones in the form of coarse-grained beds deposited by storm waves and surge, and therefore can be used to develop high-resolution reconstructions of local-scale variability tropical cyclones. We present an updated summary of six near-annually resolved tropical cyclone activity reconstructions developed from offshore sinkholes across The Bahamas. Each reconstruction documents decadal-to-centennial-scale periods of significantly enhanced local storm frequency, however substantial inter-island heterogeneity signals that single-site reconstructions may not reflect broader regional trends. A 1500-year statistical compilation of these individual records documents significantly higher storm activity in the subtropical North Atlantic during the Little Ice Age (LIA; 1300-1850 CE), which is coincident with an intensified West African Monsoon that could have promoted cyclogenesis in the Atlantic Main Development Region. This suggests that ocean/climate conditions in the subtropical North Atlantic remained favorable for storm development despite a globally cooler climate during the LIA. Problematically, many spatiotemporal gaps remain in record coverage, particularly in the high-mid latitude Canadian Maritime Provinces. To address this, we also present preliminary findings from new high-resolution sedimentary reconstructions being developed from coastal sites in north and south Newfoundland, Canada. By reconstructing the last ~7,000 years of high-mid latitude storminess, we aim to assess how regional ocean-climate conditions (e.g., vertical wind shear, Labrador Current intensity/sea surface temperature) modulate storm activity in the high-mid latitudes beyond broader changes in overall tropical cyclone frequency reflected by the lower latitude (i.e., Bahamian) reconstructions.

4. MARUM, University of Bremen, Bremen , Bremen, GERMANY
E-mail: greena1@ukzn.ac.za

Keywords: Tempestites, continental shelf, tropical cyclones, SW Indian Ocean

Various geological proxies have been used to document pre-instrumental storminess and associated climate variability. Here we present the first such evidence for the SW Indian Ocean derived from shoreface tempestites and interpret it in the context of past and present coupled ocean-atmosphere climatic change driven by the Indian Ocean Dipole (IOD). Using a combined ultra-high resolution seismic, multibeam bathymetric, downcore-geochemical and modelling approach, we examine a series of high-energy sedimentary deposits preserved in the shoreface off Durban, South Africa. High-energy events are recorded as hummocky seismic units, the sediments of which have clear marine geochemical signatures and comprise discrete fining upward cycles characteristic of periodic high-energy storm-wave deposits (tempestites). The shoreface tempestites occur in an age range between 6480 cal yr BP to 4595 cal yr BP, a period when sea level was between 0 and + 3 m above present. Modelled wave-induced orbital velocities and bed shear stress required to entrain gravel-sized material on the shoreface for the largest historical event and the 100-year return-period storm, reveal that contemporary storms can potentially mobilise the lower shoreface seabed. The tempestite deposits in the cores were not reworked by such storm-waves and thus indicate deposition by paleo-storm waves much larger than those in the modern 100–year storm range. The time period during which the shoreface tempestites formed coincides with periods of strongly positive IOD anomalies, linked to warmer sea surface temperatures and points to much increased storm magnitudes associated with a poleward track and more intense tropical cyclones in the SW Indian Ocean. As global warming continues, stronger positive anomalies in the IOD are projected and, despite uncertainties, further intensification and poleward migration of tropical cyclones is expected. We suggest that intense tropical cyclones, likely responsible for the mid-Holocene tempestites, will impact the SE African coastline, requiring a major revaluation of coastal development and planning, especially in large coastal metropolis such as Maputo and Durban.

Viruses, Membrane Vesicles, and Gene Transfer Agents: The Transductome of a 2.5km-Deep Subseafloor Community

Donald Pan[1*], Shunichi Ishii[2], Fumio Inagaki[2], Hiroyuki Imachi[2]
1. School of Oceanography, Shanghai Jiao Tong University, Shanghai, CHINA
2. JAMSTEC, Japan Agency for Marine-Earth Science & Technology, Yokosuka, Kanagawa, JAPAN
E-mail: donald.pan@sjtu.edu.cn

Keywords: horizontal gene transfer, virus, evolution, subsurface, transduction, microbiology

Horizontal gene transfer is an important driver of adaptation and evolution in microorganisms. Transducing biological nanoparticles such as viral particles are believed to be key facilitators of horizontal gene transfer.
In deep subseafloor sediments, energy and nutrients are highly limiting, supporting only extremely slow metabolisms with doubling times estimated to be as long as decades to centuries. In such low-energy, isolated environments where communities may subsist for millions of years, the mechanisms of subsurface microbial adaptation and evolution remain a mystery. Viruses have been found everywhere that life has been found, including deep subsurface environments. Recent findings show that viruses are even more abundant in subseafloor sediment than previously expected. While there is a good understanding that microorganisms are abundant and active in the Earth's subsurface, the role of viruses in shaping and influencing these slow-growing communities is only recently starting to be explored. Here, we analyzed sediments collected from a coalbed layer 2km below the seafloor offshore Shimokita, Japan in which a resident microbial community had been buried for 20 million years (IODP Expedition 337). We harvested biological nanoparticles (<0.2um) and cells (>0.2um) from a bioreactor enrichment seeded by the 20 million year old coalbed sediment. We sequenced DNA from the cells and nanoparticles and subsequently analyzed the metagenomes. Within the nanoparticle metagenome, numerous complete novel virus genomes were reconstructed. Comparison of the virus genomes to the prokaryotic MAGs (metagenome assembled genomes) revealed that many of the virus genomes were integrated prophage within bacterial genomes, suggesting the potential for virus-host interactions to occur in the subseafloor. Additionally, lysogeny may be an important survival mechanism for viruses in deeply buried, low-energy environments. Host genes were found to be packaged by viral particles, demonstrating the potential for specialized and general transduction by viruses. Not only viral particles, but there was also evidence that membrane vesicles and gene transfer agents may participate in transduction in this deep subsurface community. Horizontal gene transfer mediated by biological nanoparticles may be an important mechanism of adaptation for deep subsurface microbial communities and may provide insight into possible evolutionary processes shaping microbial communities in the deep subsurface. These results may also shed some light onto the nature of viral infection in the subsurface, potentially revealing insights about the long-term persistence of life under the extreme conditions of nutrient and energy limitation and how viruses may survive over geological timescales.

Microbial interactions in hydrothermal systems

Yinzhao Wang[1*]
1. School of Biology and Biotechnology, Shanghai Jiao Tong University, Shanghai, Shanghai , CHINA
E-mail: wangyinzhao@yahoo.com

Keywords: biogeochemical cycle, hydrothermal ecosystem, deep sea microbes

Hydrothermal vent is a unique habitat in the deep sea. It is reported that there are more than 721 known hydrothermal regions in the world, which are widely distributed in mid ocean ridges, back arc basins and volcanic arcs. Deep sea hydrothermal vents are usually in a high-temperature and anoxic environment and rich in reducing compounds. The hydrothermal fluid is mixed with low-temperature oxygenated seawater, resulting in the imbalance of chemical reaction between reducing hydrothermal fluid and oxidized seawater. Hydrothermal autotrophic microorganisms can use the energy generated by reduced substances such as sulfur, hydrogen, methane, sulfide and iron to fix carbon, thus supporting the whole hydrothermal ecosystem. The different forms and degrees of mixing of hydrothermal and seawater shape the highly heterogeneous hydrothermal habitat. For example, symbionts formed by microorganisms and fauna, chimneys, mats, plumes, sediments and other unique microbial communities. Although some studies have made important contributions to revealing some characteristics of hydrothermal vent microbial community, these studies pay more attention to local areas, and the understanding of global hydrothermal microbial diversity, geochemical element cycle drivers and interactions is not clear. This study selected hydrothermal data from the global deep-sea microbiome to explore how the metabolic network formed by hydrothermal microbial interaction mediates the biogeochemical cycle. The purpose is to gradually sort out and form the domain knowledge base of deep-sea habitat through the research strategy from local to overall, and explore and try to reveal the mechanism of carbon, nitrogen and sulfur cycle driven by deep-sea microbial community.

Methane flux shapes the methanotrophic microbiome at cold seeps of South China Sea

Mingyang Niu[1*]
1. life science school, Shanghai Jiao Tong University, Shanghai, CHINA
E-mail: myniu@sjtu.edu.cn

Keywords: Cold seeps, Methane flux, Marine sediments, Community ecology, Methanotrophic microbiome, Deterministic processes

Marine cold seeps are chemosynthetic habitats fueled by deeply sourced hydrocarbon-rich fluids that are discharged at the seafloor. Despite the central role of the cold seep microbiome in mediating methane oxidization and other biochemical reactions, the assembly processes of seep communities remain poorly understood. Here we analyzed microbial communities and their assembling processes at two spatially distant cold seeps that cover a range of methane fluxes, habitat types, and sediment depths. We show that methane flux had a much stronger impact on the seep microbiome than geographical location, biological coverage and sediment depth. Phylogenetic-groups-based null model analyses further reveal the greater role of homogeneous selection than dispersal and drift on shaping community assembly under high methane flux. Within the community of anaerobic methanotrophic archaea (ANME), the ANME-1 clade accounted for >60% while ANME-2 and -3 accounted for >90% relative sequence abundance in sediments with high- and low-methane fluxes, respectively. Similarly, sulfate-reducing bacteria (SRB) SEEP-SRB1 and -SRB2 were abundant in the high-flux sediments, while an unclassified Desulfobulbaceae lineage enriched in the low-flux sediments. High methane fluxes also affected microbial co-occurrence patterns by supporting highly connected networks of ANME and SRB. Taken together, our results demonstrate that methane flux is a strong selective pressure that shapes the microbial community assemblages in cold seep sediments more profoundly than the seep-associated fauna and other tested habitat properties.

A map carbon and energy flow through deep sea sediments

Brett J Baker[1*]
1. Integrative Biology, University of Texas Austin, Austin, TX, UNITED STATES
E-mail: acidophile@gmail.com

Keywords: archaea, metagenomics, carbon, bacteria, deep-sea

Marine sediments contain one of the largest pools of organic carbon on the planet but our understanding of how this organic carbon is processed by seafloor microbial communities is largely unexplored. We analyzed ~5 TB of assembled metagenomic sequence data from several locations, and depths, in Guaymas Basin (~2,000 m water depth in the Gulf of California) hydrothermally-impacted sediments. We recovered 6,756 uncultivated virus genomes (UViGs) and 510 archaeal and 2,487 bacterial metagenome assembled genomes, comprising 129 phyla, 21 of which are previously undescribed. We characterized their functional capacities to create a comprehensive genome-resolved map of organic matter degradation and remineralization in the deep sea. This analysis revealed that the diversity and abundance of low molecular weight organics (alcohols, acids, methylated amines, and methylated sulfur) are key drivers of microbial diversity. This high-resolution framework of carbon and energy will enhance our ability to model biogeochemistry in seafloor environments.

Supermountains controlled the biological evolution on Earth

Ziyi Zhu[1*]
1. Research School of Earth Sciences, Australian National University, Canberra, ACT, AUSTRALIA
E-mail: ziyi.zhu@anu.edu.au

Keywords: supermountains, detrital zircons, biological evolution

Erosion of the continental crust provides the critical nutrients (P, Fe, etc.) that are essential for life in the oceans and the fastest erosion occurs on the steepest mountain slopes. We use the distribution of low-Lu zircons, derived from the roots of mountains, to identify periods of extensive high mountain (supermountain) formation, produced by continent-continent collisions. By applying this technique to 6,911 detrital zircons, from fifty-two of the world's major rivers, we show that there were two periods of supermountain formation. The first at 1.95-1.85 Ga, formed during the assembly of Nuna, likely Earth's first supercontinent. It coincided with the emergence of the first macroscopic fossils at ca. 1.9 Ga. The second, at 650-500 Ma, is associated with the amalgamation of Gondwana. It correlates with the emergence of the first large complex multicellular organisms of the Ediacara Biota at 575 Ma and the radiation of animals in the Cambrian Explosion. We argue that the rapid erosion of the Nuna and Gondwana supermountains may have caused a massive increase in the supply of bio-limiting nutrients to the oceans, increasing primary productivity and the energy flow through marine ecosystems. This increase in primary production, together with rapid burial of the resulting organic carbon, is also expected to have produced increases in atmospheric oxygen. The increases in the supply of bio-limiting nutrients and O_2 in surface oceans, both associated with supermountain erosion, might have driven organisms towards larger size and complexity.

Authigenic carbonates in the deglacial Arctic Ocean revealing Fe/Mn-AOM and ice sheet retreat

Taoliang Zhang[1], Liang Dong[1], Fengping Wang[1*]
1. School of Oceanography, Shanghai Jiao Tong University, Shanghai, CHINA
E-mail: fengpingw@sjtu.edu.cn

Keywords: western Arctic Ocean, biomineralogy, carbon cycle; anaerobic oxidation of methane; organic geochemistry, paleoceanography

Anaerobic oxidation of methane (AOM) is an important biogeochemical process which reducing the release of methane and consuming up to ~90% methane generated in anoxic marine sediments. In sulfate-depleted fresh water or melting water environments, Fe(III) and Mn(IV) is the possible electron acceptor and coupled to anaerobic oxidation of methane.

In the western Arctic Ocean sediments, **authigenic carbonates are first found in last deglaciation (18-11 ka) and MIS 4/3 deglaciation (~60 ka), and regarded as a new carbon sink in the global warming periods.** Mineralogical and geochemical evidences represented the depletion of δ13C both in authigenic carbonates and bulk sediments, which corresponded with deglacial methane emission in East Siberian Shelf. Furthermore, spatial distribution of authigenic carbonates indicated they only formed within the coverage of East Siberian Ice Sheet(ESIS), **we speculate that the authigenic carbonates were formed during the deglaciation when ice sheet melt and methane emission occurred synchronously.**

Thus, the preliminary conclusion of this study is: (1)The authigenic carbonates in MIS 4/3 boundary were formed because of Fe/Mn-AOM, as a sink of methane. (2)Existence of authigenic carbonates are likely to indicate the boundary and melting of ice sheets.

E-mail: dongh@cugb.edu.cn

Keywords: Deep Subsurface, Microbial Community, 16S rRNA, Nitrososphaeria, Acinetobacter

The terrestrial deep subsurface has been known to harbor extremophilic microbial life. Owing to the difficulties in accessing samples, there is still a knowledge gap in our understanding of the microbial community composition and functions in the deep subsurface biosphere. We extracted DNA from two rock cores (located at 1000 m, 47.5°C and 1200 m, 52.5°C) which were obtained from west Sichuan Province following standard protocol for contamination control.

The lithologies of 1000m and 1200m cores are tourmaline-bearing granite pegmatite and tourmaline-bearing two-mica pegmatite, respectively. Both rocks possess a white color and have a pegmatitic texture and massive structure. The main mineral composition in the 1000m sample is 50%-60% feldspar (albite predominantly, greyish-white anhedral columnar or plate-like), 30%-40% quartz (smoky grey or colorless transparent, euhedral crystal), 2%-5% micas, with a small amount of (1%-2%) euhedral and anhedral black tourmaline. The 1200m sample is composed mainly of 50%-60% feldspar (greyish-white euhedral columnar or plate-like), 30%-40% quartz (smoky grey or colorless transparent, anhedral crystal), 2%-5% micas, produced in flaky aggregates, with a small amount of (1%-2%) teardrop tourmaline. The major elements of these two samples mainly consist of SiO_2 (73.26%-78.47%), K_2O (6.83%-3.21%) and Na_2O (3.57%-4.03%). They both have trace elements of high Rb (477-186 ppm), Li (188-94.3 ppm), B (37.0-70.3 ppm), Mn (64.7-22.3 ppm) and Pb (69.1-43.2 ppm).

After conducting 16S rRNA V4 PCR and Illumina Novaseq DNA sequencing, we used QIIME2 feature-classifier classify-sklearn for the taxonomic annotation of the OTUs against the SILVA 138 database. The results consist of 233,278 OTUs belonging to bacteria and 8,226 OTUs belonging to archaea, including 174,429 OTUs belong to bacteria and 7,054 to archaea in the 1000m depth sample, and 58,849 OTUs belong to bacteria and 1,772 to archaea in the 1200m depth sample. The fraction of un-classified OTUs is almost negligible. The number of sequences assigned to archaea across both of the samples covered 3 classes from 2 phyla. Based on average abundance at class level, three archaeal phyla Nitrososphaeria, Methanobacteria and Bathyarchaeia account for 93.75%, 5.47% and 0.78%, respectively. Nitrososphaeria predominates both samples, including many genera of ammonia-oxidizing archaea (AOA), which is a significant contributor to ammonia oxidation in the marine nitrogen cycle and has less been studied in continental subsurface. In addition to Archaea, we also found some genera or families of bacteria associated with deep subsurface or extreme environment such as deep-sea sediments, hydrothermal vent, and permafrost. Based on average abundance at phylum level, Firmicutes (2.86%-7.12%), Bacteroidota (7.79%-5.71%), Acidobacteriota (10.71%-1.86%), Planctomycetota (13.89%-2.64%), Proteobacteria (18.56%-58.06%) and Actinobacteriota (21.2%-13.46%) constitute 75%-89% of the communities in the 1000-m and 1200-m sample, respectively. Additionally, based on genus-level, the genus *Acinetobacter* (27.17%) has the highest abundance in the 1200 m sample, while it was not found in the top 10 most abundant genera in the 1000 m depth sample. These

findings suggest that there are previously undiscovered microorganisms (such as AOA) in continental subsurface.

New insights into the roles of Asgard archaea in the origin of eukaryotes and ecological functions

Ruize Xie[1*]
1. School of Oceanography, Shanghai Jiao Tong university, Shanghai, CHINA
E-mail: xieruize@sjtu.edu.cn

Keywords: Asgard archaea, eukaryotic origin, metagenome

The hypothesis that eukaryotes originated from within the domain Archaea has been strongly supported by recent phylogenomic analyses placing Heimdallarchaeota-Wukongarchaeota branch from the Asgard superphylum as the closest knownarchaeal sister-group to eukaryotes. However, our understanding is still limited in terms of the relationship between eukaryotes and archaea, as well as the evolution and ecological functions of the Asgard archaea. Here, we describe three previously unknown phylum-level Asgard archaeal lineages, tentatively named Sigyn-, Freyr- and Njordarchaeota. Comprehensive phylogenomic analyses further supported the origin of eukaryotes within Asgard archaea and a new lineage Njordarchaeota was supposed as the known closest branch with the eukaryotic nuclear host lineage. Metabolic reconstruction suggests that Njordarchaeota may have a heterotrophic lifestyle with the capability of peptides and amino acids utilization, while Sigynarchaeota and Freyrarchaeota also have the potentials to fix inorganic carbon via the Wood-Ljungdahl pathway and degrade organic matters. Additionally, the Ack/Pta pathway for homoacetogenesis was found in Freyrarchaeota. Some previously unidentified eukaryotic signature proteins for intracellular membrane trafficking system, and the homologue of mu/sigma subunit of adaptor protein complex, were identified in Freyrarchaeota. This study expands the Asgard superphylum, sheds new light on the evolution of eukaryotes and improves our understanding of ecological functions of the Asgard archaea.

Genome-informed understandings of nitrogen loss in marine sediments

Rui Zhao[1*], Jennifer Biddle[2], Steffen Leth Jørgensen[3], Andrew Babbin[1]
1. Department of Earth, Atmospheric and Planetary Sciences, Massachusetts Institute of Technology, Cambridge, Massachusetts, UNITED STATES
2. School of Marine Science and Policy, University of Delaware, Lewes, Delaware, UNITED STATES
3. Centre for Deep Sea Research, Department of Earth Sciences, University of Bergen, Bergen, Vestland, NORWAY
E-mail: zhaorui087@gmail.com

Keywords: Genome, nitrogen cycle, marine sediment, nitrite, anammox

About two-thirds of nitrogen loss in the marine realm occurs in the sediments. Microbes with the capacity to denitrify or perform anaerobic ammonium oxidation (anammox) are considered responsible for this process. In the nitrogen cycle, nitrite is a critical inorganic nitrogen compound required by both denitrifiers and anammox bacteria and whose availability exerts profound control on the magnitude of nitrogen loss. Nitrite rarely accumulates in sediment porewater and has been largely overlooked, yet many details about nitrogen loss in marine sediments remain unknown. Because most microbes in deep sea sediments (including denitrifiers and anammox bacteria) are yet uncultured in laboratory, de novo genome reconstruction via metagenome sequencing is a powerful approach to disentangle nitrite transformation processes in these regions. Here we present a new understanding of nitrogen loss in marine sediments obtained by genome reconstruction combining with high-resolution geochemical measurements and microbial community characterization. We will 1) introduce an overlooked but ancient family of anammox bacteria prevailing in marine sediment, 2) showcase how the niche partitioning of two anammox bacteria families (accomplished in a duration of up to 55 000 years) resulted in a partial collapse of the anammox population and concomitant nitrite accumulation, and 3) elucidate new lineages of nitrite-oxidizing bacteria thriving in anoxic sediments, which enable a cryptic nitrogen loss together with other nitrogen-cycling groups. Implications of these new organisms on marine nitrogen biogeochemistry will also be discussed.

The microbial nitrogen cycle in the deepest part of the ocean

Yuhan Huang[1], Xinxu Zhang[1], Meng Li[1*]
1. Institute for Advanced Study, Shenzhen University, Shenzhen, Guangdong, CHINA
E-mail: limeng848@szu.edu.cn

Keywords: hadal trench, deep biosphere, metagenomics, nitrogen cycle

The Mariana Trench is known as the deepest region of oceans on Earth. Previous studies have described the microbiome of hadal seawater and surface sediments in Mariana Trench, but the microbial life in hadal deep biosphere is poorly explored. Here, we applied comparative metagenomics to study three hadal habitats in Mariana Trench slope, including hadal seawater (9600-10500 mbsl), surface sediment (0-46 cmbsf at water depths between 7143 and 8638 mbsl), and deep biosphere (200-306 cmbsf at water depth of 8300 mbsl). Through analyzing the relative abundance and species diversity of the metagenome-assembled genomes (MAGs) in nitrogen metabolisms, our study showed that each of the three hadal habitats was characterized by unique nitrogen cycling processes. In deep biosphere, N_2 might be produced by anaerobic ammonium oxidation (anammox) bacteria. The relative abundances of ammonia-oxidizing archaea (AOA) and nitrite-oxidizing bacteria (NOB) in the surface sediments were significantly higher than those of the deep biosphere, suggesting that chemoautotrophy is an important process in this environment. In the hadal seawater, an abundant MAG designated to *Ketobacter* (relative abundance of 4.0%) had the ability to couple n-alkane degradation and N_2 fixation. In total, this study expands our knowledge of the microbial nitrogen cycle in hadal deep biosphere.

3. School of Oceanography, Shanghai Jiao Tong University, Shanghai, CHINA

E-mail: fengpingw@sjtu.edu.cn

Keywords: Marine sediment, Iron oxides, Methanogenesis

Intermittent increases of dissolved ferrous iron concentrations observed in deep marine methanic sediments challenge the traditional diagenetic electron acceptor cascade, where iron reduction precedes methanogenesis. Here we aimed to gain insight into the mechanism of iron reduction and the associated microbial processes in deep sea methanic sediment by setting up long-term high-pressure incubation experiments supplemented with ferrihydrite and methane. Continuous iron reduction was observed during the entire incubation period. The enriched samples were then amended with 13C-labeled methane and different iron (oxyhydr)oxides in batch slurries. Intensive iron reduction was observed, the highest rates with ferrihydrite, followed by hematite and then magnetite, however, no anaerobic oxidation of methane (AOM) was observed in any treatment. Further tests on the enriched slurry showed that the addition of molybdate decreased iron reduction significantly, suggesting a link between iron reduction with sulfur cycling in the slurry. Intriguingly, ferrihydrite addition shifted the archaeal community from the dominance of hydrogenotrophic methanogens (Methanogenium) to methylotrophic methanogens (Methanococcoides). This was accompanied by the enrichment of microbes capable of dissimilatory sulfate reduction and thiosulfate oxidation, which supports the presence of a cryptic sulfur cycle in the incubation system stimulated by the addition of iron (oxyhydr)oxides. Our work suggests that under low sulfate conditions, the presence of iron (oxyhydr)oxides would trigger a cascade of microbial reactions, and iron reduction would link with the microbial sulfur cycle, changing the kinetics of the methanogenesis process in methanic sediment.

Membrane lipid composition of Thermococcs eurythermalis A501 and its response to environmental stresses

Liang Dong[1*], Miao Chen[1], Fengping Wang[1], Xiang Xiao[2]
1. School of Oceanography, Shanghai Jiao Tong University, Shanghai, CHINA
2. School of Sciences and Biotechnology, Shanghai Jiao Tong University, Shanghai, CHINA
E-mail: dongliang@sjtu.edu.cn

Keywords: Hyperthermophilic archaea, Lipids, Environmental stresses

Thermococcales is a representative group of hyperthermophilic archaea that widely exists in marine hydrothermal systems and belongs to the dominant group in hydrothermal chimney walls, plumes, and hydrothermal sediments. The broad growth span of Thermococcales poses challenges to the structure and function of its cell membrane. Here, the composition characteristics of the core membrane lipids and intact polar membrane lipids of the type strain Thermococcs eurythermalis A501 were simultaneously analyzed, and the response characteristics of A501 to different growth stages, pH, salinity, pressure, and temperature were comprehensively explored for the first time. The results showed that A501 composed three core membrane lipids, glycerol dialkyl glycerol tetraether (GDGT-0), archaeol (AR), and 2OH-GDGT-0, and seven kinds of IPLs with different polar headgroups. 2OH-GDGT-0 was identified for the first time in hyperthermophilic archaea. It was found to be tripled at low temperature, suggesting that hydroxylation modifications expand the local cell membrane area to increase penetration and broaden low-temperature boundary of A501. The monolayer membrane formed by tetraether has low fluidity and permeability, which was found that its proportion is sensitive to temperature and pressure but insensitive to salinity and pH. The ratio AR/GDGT-0 was significantly positively correlated with pressure and had the potential as a biomarker of pressure in environments with less temperature change. The content and proportion of total IPL increased under most environmental pressures, suggesting its importance under different ecological pressures. However, further research on the changes of varying IPLs under various environmental pressures found that no specific IPLs could reflect specific environmental stresses. This study completely expounds on the characteristics of the lipidome of Thermococcales under different environmental pressures and provides biological mechanisms of potential membrane lipid-based proxies in biogeochemical or ecological studies.

Response of microbial communities to different geochemical and thermal gradients in hydrothermal sediments of the Guaymas Basin

Lei Su[1,2], Andreas Teske[3], Jiangtao Li[1,2*]
1. State Key Laboratory of Marine Geology, Tongji University, Shanghai, CHINA
2. School of Marine and Earth Sciences, Tongji University, Shanghai, CHINA
3. Department of Marine Sciences, University of North Carolina at Chapel Hill, Chapel Hill, NC, UNITED STATES
E-mail: jtli@tongji.edu.cn

Keywords: Guaymas Basin, hydrothermal surface sediments, geochemical and thermal gradients, Bathyarchaeia, microbial coexistence

The Guaymas Basin in the Gulf of California is characterized by active hydrothermal activity and massive organic-rich sediments. Newly formed, and hot basalt sills convert organic matters of sediments into diverse chemical compounds including CO_2, H_2, low-molecular-weight organic acids, ammonia, and a series of hydrocarbons. These compounds migrate to the sediment surface with rising vent fluids, where they fuel various microbial communities. Although there are many studies that examined microbial communities of the Guaymas Basin sediments, most of them have focused mainly on hot hydrothermal sediments and microbial mats where temperatures reach or exceed 80°C, warm sediments with temperatures near or below 30°C are seldomly determined. To deepen our understanding of microbial communities and relevant environmental controls in different types of hydrothermally influenced sediments, we examined different Guaymas Basin sediments with various degrees of hydrothermal activity supported by week-long temperature logging, from temperate sediments with constant conditions at the Aceto Balsamico site, to moderately hot or extremely hot sediments characterized by increasingly dynamic hydrothermal fluctuations at the Cathedral Hill site. Their geochemical characteristics showed obvious differences of diverse sites profiles. To identify patterns and potential controls on bacterial and archaeal community composition, we analyzed the Non-metric Multidimensional Scaling Analysis (NMDS) of bacterial and archaeal sequence dataset, which were both separated by sampling sites and temperature, indicating that bacterial and archaeal communities followed similar structuring patterns independently. Bacterial and archaeal 16S rRNA gene sequences showed distinct differences in microbial community composition between warm and hot sediments of different depths. In the temperate Aceto Balsamico core, the most frequently detected archaea are Methanosarcinia, Bathyarchaeia and Thermoplamata in all samples, whereas the bacterial spectrum shifted from a diversified community of Planctomycetes, Gammaproteobacteria, Bacteroidetes, Deltaproteobacteria (Desulfobulbia and Desulfobacteria), Chloroflexi (Anaerolineae) and Atribacteria (JS1) in the surficial samples to a JS1-dominated spectrum of bacterial sequences in the deeper samples. In hydrothermal core of Cathedral Hill, the bacterial community changed to thermophilic heterotrophic lineages (Thermotogae, Armatimonadetes, Calditrichia) and thermophilic sulfate reducers (Desulfofervidales, Thermodesulfobacteria) are added. Within the archaeal sequence dataset, the thermophilic archaea Thermoprotei, Thermococci and ANME-1 became more frequency. While these microbial communities changed continuously in composition along the thermal spectrum of Guaymas Basin sediment cores, they consistently maintained these functions, and the functional redundancy across different lineages could tolerant more environmental fluctuations, which was well verified by co-occurrence network analysis. Through the further study of Bathyarcaheia and JS1 with the most frequency archaea and bacteria, it was found that diverse Bathyarchaeia subgroups could well illustrate the environmental and temperature preference, while JS1 could not withstand the high temperature and the subgroups had no obviously environmental implications. In conclusion, we found that in addition to temperature influencing microbial community distribution, the integrated impact of the geochemical regime within the entire sediment core a composite of electron acceptors and donors, nutrients, and carbon sources shaped the community composition at the sediment surface.

Effects of sulfurization on the microbial breakdown of organic matter in lake sediments

Longhui Deng[1*], Silvano Murk[1], Mark Lever[1]
1. Department of Environmental Systems Science, Swiss Federal Institute of Technology (ETH Zurich), Zurich, SWITZERLAND
E-mail: denglh08@gmail.com

Keywords: Lake sediment, organic matter, sulfurization, carbon burial, microbial community

Lake sediments are globally important organic carbon sinks. Yet the factors controlling the cycling and storage of organic carbon in these sediments remain poorly understood. During a process called 'sulfurization', organic matter (OM) often become recalcitrant by reacting abiotically with dissolved (poly)sulfide. Although past research has revealed the potential significance of sulfurization in controlling organic carbon cycling in lake sediments, the extent to which sulfurization affects the degradation rates of different organic compounds and the microorganisms that are involved in these processes are not understood. In this study, we test the effect of sulfurization on sedimentary carbon cycling, by adding OM with divergent reactivity (lignin, chitin, cellulose, starch) in their sulfurized and nonsulfurized forms to sediments from different depths (10, 30, 70, 500, 1300 cm) of a eutrophic lake (Rotsee, Switzerland). Preliminary results show that the effect of sulfurization on OM reactivity is inversely correlated to its original reactivity. Thereby sulfurization has nearly no impact on the degradation of the more recalcitrant lignin, while it significantly lowers the reactivity of the more labile starch to a level that is similar to lignin. The negative effect of sulfurization on OM degradation appears to increase with sediment depth, indicating an increasing contribution of sulfurized OM to long-term organic carbon preservation in deeper sediments. On-going analyses on the compositions of organic molecules and microbial communities will further reveal the largely unstudied role of microorganisms in utilizing labile and refractory pools of organosulfur in lake sediments.

Depositional dynamics determine the microbial community succession in marine subsurface sediments

Jiwen Liu[1], Xiao-Hua Zhang[1*]
1. College of Marine Life Sciences, Ocean University of China, Qingdao, Shandong, CHINA
E-mail: xhzhang@ouc.edu.cn

Keywords: Microbial community, succession, subsurface, deep biosphere, deposition

High-resolution vertical changes of marine benthic microbial diversity and association with local depositional processes are poorly described. Here, we perform microbial and geochemical analyses on sediment cores collected from different marine sediments of contrasting depositional environments including the Changjiang Estuary (CE), South China Sea (SCS) and Challenger Deep (CD). Community variation shaped by redox zonation is common in the different locations. Palaeoenvironmental factors represented by terrestrial input of dormant cells and spores are the other determinants in the SCS composed of mainly river-borne sediments. Selection induced loss of rare species leads to high species replacement effect between deeper and surface sediment layers. The subsurface communities in the CD vary to a lesser extent from the surface layer compared to SCS, which is likely contributed by massive burial of organic matter due to the high and noncontinuous sedimentary deposition. Meanwhile, microbial abundance and activities fluctuate along the vertical profile, likely as a reflection of in situ growth, a pattern different from previously characterized subsurface biosphere dominated by survival and persistence. CE represents another classical depositional system featured by intensified mobile mud. Mud mobility alters redox condition of the local sedimentary environment by increase of oxygen penetration depth. We observe an increased relative abundance of aerobes in sediments affected by mobile mud, which contributes to a higher rate of organic matter degradation. Sulfur-oxidizing bacteria is enriched and active at the oxic-anoxic interface in the deep sediment layers, likely providing a source for sulfate-reducing bacteria. Overall, our results demonstrate that the subsurface microbial community is significantly controlled by depositional and hydrodynamic processes.

Methane conversion into organic carbon regulated by pressure in cold seep ecosystems

Yu Zhang[1,2*]
1. School of Oceanography, Shanghai Jiao Tong University, Shanghai, CHINA
2. International Center for Deep Life Investigation, Shanghai Jiao Tong University, Shanghai, CHINA
E-mail: zhang.yusjtu@sjtu.edu.cn

Keywords: carbon cycling, cold seep, high pressure

In the ocean, almost all of the emission and consumption of deeply burried methane occurs in cold seeps; therefore, understanding the methane cycling in cold seeps is crucial to estimating the oceanic methane budget. Cold seeps are often found in deep ocean where the methane is saturated under high pressure. Moreover, the cold seeps are not always stable, while their eruptions lead to the dramatic destruction of microbial ecosystems that drive methane cycling. However, because of technical challenges, the direct monitoring of the methane conversion as well as the microbial communities'shifts in such unsteady high pressure ecosystem has never been achieved. In this study, we took an alternative approachby simulating cold seep using specially designed DOES (deep ocean experimental simulator) system. DOES is to construct an environment in laboratory that is similar to the deep ocean, in terms of gas pressure, hydrostatic pressure, temperature, flow rate, pH, nutrient availability, et. al. DOES also allows us to monitor the microbial activity by sampling without depressurization. Here we used an enrichment originated from Captain Aryutinov Mud Volcano (35° 39.700' N, 07° 20.012'W, water depth ~1200m) with high AOM (anaerobic oxidation of methane) activity. We performed a series incubations under different methane pressures (8, 12 MPa) and hydrostatic pressures (8, 15, 30 MPa) for 12 months, supplied with methane and sulfate as the only energy source, simulating the cold seep undergoing periodical eruptions. Every 2 days we took samples for activity analysis and every 2 months we took biomass samples for metagenomic analysis. We found that the methane conversion pathways were highly dependent on pressure. Spontaneously happened with the classical AOM process (methane is converted into carbon dioxide), approximal up to 25% of the total consumed methane was anaerobically converted into organic carbon under elevated methane pressures, e.g. acetate under 8 MPa and methyl- compounds under 12 MPa. Both genomic and enzymatic evidence supported that ANME (anaerobic methanotrophic archaea) was capable to oxidize methane into acetate via acetyl-CoA. According to the genomic analysis, Methylobacter played an important role in incomplete methane oxidation into methyl-compounds that was catalyzed by pmoABC under anaerobic condition. Therefore, we propose a modified model of carbon cycling in cold seeps: during AOM process, methane can be converted into organic carbon, which further fuels the heterotrophic community in the ecosystem. These results suggest that a more sophisticated calculation of the methane budget in cold seeps that considers the in situ pressures is needed.

Potential metabolic and genetic interaction among viruses, methanogen and methanotrophic archaea, and their syntrophic partners

Long Wang[1], Yinzhao Wang[2], Xingyu Huang[1], Ruijie Ma[1], Jiangtao Li[3], Fengping Wang[2], Nianzhi Jiao[1], Rui Zhang[1*]

Keywords: Methanogens and Methane-oxidizing Archaea, Virus, Environmental Adaptation

The metabolism of methane in anoxic ecosystems is mainly mediated by methanogens and methane-oxidizing archaea (MMA), key players in global carbon cycling. Viruses are vital in regulating their host fate and ecological function. However, our knowledge about the distribution and diversity of MMA viruses and their interactions with hosts is rather limited. Here, by searching metagenomes containing *mcrA* (the gene coding for the α-subunit of methyl-coenzyme M reductase) from a wide variety of environments, 141 viral operational taxonomic units (vOTUs) that potentially infect methanogens or methane-oxidizing archaea were retrieved. Four MMA vOTUs (three infecting the order Methanobacteriales and one infecting the order Methanococcales) were predicted to cross-domain infect sulfate-reducing bacteria. By facilitating assimilatory sulfur reduction, MMA viruses may increase the fitness of their hosts in sulfate-depleted anoxic ecosystems and benefit from synthesis of the sulfur-containing amino acid cysteine. Moreover, cell-cell aggregation promoted by MMA viruses may be beneficial for both the viruses and their hosts by improving infectivity and environmental stress resistance, respectively. Our results suggest a potential role of viruses in the ecological and environmental adaptation of methanogens and methane-oxidizing archaea.

Phylogenetically novel and catabolically diverse diazotrophs reside in deep-sea cold seep sediments

Xiyang Dong[1*]

1. Key Laboratory of Marine Genetic Resources, Third Institute of Oceanography, Ministry of Natural Resources, Xiamen, Fujian, CHINA

E-mail: dongxiyang@tio.org.cn

Keywords: cold seep, nitrogen fixation, diazotrophs

Microbially mediated nitrogen cycling in carbon-dominated cold seep environments remains poorly understood. So far anaerobic methanotrophic archaea (ANME-2) and their sulfate-reducing bacterial partners (SEEP-SRB1 clade) have been identified as diazotrophs in deep sea cold seep sediments. However, it is unclear whether other microbial groups can perform nitrogen fixation in such ecosystems. To fill this gap, we analyzed 61 metagenomes, 1428 metagenome-assembled genomes, and four metatranscriptomes derived from 13 globally distributed cold seeps. Nitrogen isotope ratio ($\delta^{15}N$) data compiled from different locations suggest microbial nitrogen fixation occurs at various types of cold seeps. These sediments contain phylogenetically diverse nitrogenase genes, spanning conventional and novel groups, corresponding to an expanded diversity of diazotrophic lineages. Diverse catabolic pathways were predicted to provide ATP for nitrogen fixation, suggesting diazotrophy in cold seeps is not necessarily associated with sulfate-dependent anaerobic oxidation of methane. Nitrogen fixation genes among various diazotrophic groups in cold seeps were inferred to be genetically mobile and subject to purifying selection. Our findings extend the capacity for diazotrophy to five candidate phyla (Altarchaeia, Omnitrophota, FCPU426, Caldatribacteriota and UBA6262), and suggest that cold seep diazotrophs might contribute substantially to the global nitrogen balance.

Geo-electrochemistry in water/rock interacted environment

Yamei LI[1*]
1. Earth-Life Science Institute, Tokyo Institute of Technology, Tokyo, JAPAN
E-mail: yamei.li@elsi.jp

Keywords: Geo-electrochemistry, Mineral catalysis, Astrobiology, Origins of life, Carbon fixation, Ammonia generation

Geo-electrochemical processes have been proposed to occur in various water-rock interacted environments, including submarine hydrothermal vents and early Mars. These environments harbor steep gradients of pH, redox, and temperature. The electrically conductive minerals (e.g., sulfides, oxides) form the electron conduit while ionic species in the fluid serve the ionic transfer function. The chemical gradients can thermodynamically drive abiotic carbon fixation or ammonia formation through mineral-catalyzed electrochemical processes. These abiotic organic syntheses could have contributed significantly to the mineral-supported origins of life scenario.

In addition, the availability of transition metals is intimately associated with the evolution of prebiotic catalytic systems. Since sulfur ligands participate actively in various types of redox-active metalloenzymes, transition metal sulfides have been proposed as protoenzymes for catalyzing carbon and nitrogen-related redox conversions (bio-inspired, enzyme-mimetic catalysis). In this presentation, I will introduce the progress in this field and some of the results obtained in the related projects.

E-mail: fengpingw@sjtu.edu.cn

Keywords: pore waters, fluorescent dissolved organic matter, PARAFAC, coastal, deep sea

Sedimentary dissolved organic matter (DOM) is an important pool of intermediates produced and consumed during microbial early diagenesis of organic matter in anoxic sediments. The accumulation of humic-like DOM has long been observed in coastal sediments and the recalcitrant pore water DOM is regarded to play an important role in the global oceanic DOM cycle and sedimentary DOM preservation. However, the bioavailability of humic-like DOM in pore waters is still under debate. Here, the geochemistry of pore waters, including concentrations of ferrous iron, sulfate and fluorescent dissolved organic matter (FDOM) components, were determined in 5 sediment cores from Pearl River Estuary to the South China Sea. The net reaction rates of sulfate and FDOM were further constrained by geochemical reaction modeling. Contrasting behavior of humic-like FDOM was found in the five cores. In marginal sediments, humic-like components are increasingly accumulated during sulfate reduction, which might be the byproducts of microorganisms degrading labile organic substrates. While in deep-sea sediments, humic-like components are consumed during sulfate reduction, especially in the deep, which indicates that recalcitrant DOM may serve as substrates for microbial early diagenetic processes in the energy-limiting sub-seafloor sediments. The microorganisms responsible for the degradation of humic-like components remain to be further studied.

Characterization of a novel extracellular contractile injection system in the deep-sea bactrium Shewanella psychrophila WP2

Xiaoli Tan[1], Xiang Xiao[2], Huahua Jian[2*]
1. School of oceanography, Shanghai Jiao Tong University, Shanghai, CHINA
2. School of Life Sciences & Biotechnology, Shanghai Jiao Tong University, Shanghai, CHINA
E-mail: jiandy@sjtu.edu.cn

Keywords: Extracellular contractile injection systems, Shewanella psychrophila WP2, deep-sea sediment, Killing activity, hydrogen peroxide

Extracellular contractile injection systems (eCISs) are widely distributed in bacteria and archaea. They are related to contractile bacteriophage tails and mediate interactions between bacteria and eukaryotes. Besides, recent studies indicated that they eCISs can inhibit the growth of bacteria. Although several eCISs have been characterized in insect pathogens, their presence and ecological function in deep-sea sediment are still unknown. Here, we identified a novel eCIS named SpsCIS from a deep-sea bacterium *Shewanella psychrophila* WP2, which was isolated from deep-sea sediment at a water depth of 1914 m. Interestingly, the production of SpsCIS was significantly induced by hydrogen peroxide, while not by mitomycin C. Moreover, transcriptomic data showed that SpsCIS was produced spontaneously during the whole growth period of S. psychrophila WP2 at low temperature (4 °C), with the highest production at early exponential phase. Both of the non-contractile and contractile sheath structure of SpsCIS were observed by transmission electron microscopy. Moreover, Spot assays indicated that SpsCIS has bactericidal activity on 3 *Shewanella* species. Taken together, we propose that SpsCIS probably play an important role in biogeochemical cycling in the deep-sea sediment.

The high hydrostatic pressure affects microbial nitrogen transformation in hadal trench sediments

Na Yang[1,2], Yu Zhang[1,2,3*]
1. School of Oceanography, Shanghai Jiao Tong University, Shanghai, CHINA
2. International Center for Deep Life Investigation, Shanghai Jiao Tong University, Shanghai, CHINA
3. State Key Laboratory of Ocean Engineering, Shanghai Jiao Tong University, Shanghai, CHINA
E-mail: zhang.yusjtu@sjtu.edu.cn

Keywords: hadal trench, high hydrostatic pressure, nitrogen cycling, denitrification, DNRA

Hadal trenches, most typically characterized by high hydrostatic pressure (HHP), are one of the most extreme environments on our planet[1-3]. The HHP as a key environmental factor influences redox reactions usually mediated by microorganisms to a greater extent[4-7]. Previously, a fully functional benthic nitrogen cycling has been found in hadal trench sediments[8-13]. However, how the HHP further drives the microbial nitrogen metabolism largely remains unknown. Therefore, the study of hadal microbial nitrogen metabolism in the context of HHP is necessary and important for evaluating element cycling in the deep biospheres and deeply understanding life processes in extreme environments. Here, we investigate the microbial nitrogen transformation and rate in a continuous high-pressure bioreactor maintained under different hydrostatic pressures (0.1, 40, 70, 90 and 115 MPa), combining the metagenomic and metatranscriptomic analyses. Compared with initial microbial communities, the dominant groups changed significantly, from *Pseudomonadaceae* and *Rhodobacteraceae* to *Halomonadaceae*, *Thalassospiraceae* and *Shewanellaceae* after continuous high-pressure incubation. Compared with 0.1 MPa, for the first step of nitrate reduction, nitrite accumulated, meanwhile Nar and Nap genes also highly expressed at 70, 90 and 115 MPa; for nitrite further reduction to ammonium, NirB gene expression was highest at 115 MPa and NirD gene expressed highly at 70 and 115 MPa, NrfA gene expressed highly at 90 and 115 MPa, simultaneously ammonium was detected at 70, 90 and 115 MPa; for nitrite further reduction to NO, N_2O and finally to N_2, the expression of NirS and NosZ genes increased with increasing HHP (highest expression at 115 MPa) and Nor gene highly expressed at 70, 90 and 115 MPa, meanwhile the gas products N_2 reached the highest at 115 MPa and N_2O concentration increased significantly 70, 90 and 115 MPa; which indicates that HHP is likely to promote the denitrification and DNRA pathways, while further tests are required to validate metabolic rates from continuous high-pressure incubations. The key genes involved in anammox pathway were not identified and expressed suggests that anammox is not a major player in the nitrogen cycling in the trench sediment. Our findings reveal differences in the distribution of nitrogen metabolism pathways at different high hydrostatic pressures and deepen our understanding of microbial elemental cycling in hadal trench sediments.

E-mail: fengpingw@sjtu.edu.cn

Keywords: Mariana trench, Anaerobic microbial metabolism, Organic matter mineralization, Element cycling

The Mariana Trench underneath the oligotrophic west Pacific open ocean has recently been shown as a hotspot for organic matter early diagenesis, supporting active microbial communities in the trench sediments. Quantitative estimation of microbial activities is required in the Mariana Trench to evaluate their contributions to deep-sea organic carbon mineralization and element cycling. Previous microbial diversity surveys on the surface sediment layers (< 50 cm) have suggested that aerobic microbes play significant roles in organic matter mineralization in the deep trench sediments. The oxygen consumption rate is also generally applied to indicate hadal microbial processes. However, it remains elusive if and to what extent anaerobic microbes, whose metabolic potentials are closely associated with the cycle of C, N, and S, take part in OM mineralization under this high hydrostatic pressure extreme sedimentary environment. Here, we carried out geochemical measurements, early diagenesis modeling, and 16S rRNA gene amplicon sequencing for gravity cores, comparing the trench sites, including the deepest bottom (~10,500 m) and southern slope (~8,300 m) of the Mariana Trench and the reference abyssal site (~4,500 m). A clear zonation of microbial communities between the trench and reference sediment cores was observed. Compared to the reference abyssal plain, the organic matter mineralization rate was estimated to be ~20 times higher in the slope and ~50 times higher in the bottom sediments, and 1/3 of the organic matter mineralization was contributed by the anaerobic microbial lineages as calculated by geochemical modeling. The microbial nitrogen cycling processes differ primarily in the two trench sites. The bottom sediments enriched in both denitrification and dissimilatory nitrite reduction to ammonium (DNRA) groups. In contrast, the slope sediment showed a close coupling of aerobic nitrification and anaerobic denitrification processes. Nevertheless, denitrification almost exclusively drives the fixed nitrogen loss in both sites, distinguishing the Mariana Trench from other trenches wherein anaerobic ammonium oxidation (anammox) is the predominant nitrogen sink from the benthic ecosystem. These results combined geochemical and microbial profiles to shed light on the essential role of anaerobic microbial processes, contributing to the enhanced organic matter early diagenesis and the C, N, and S cycling in the Mariana Trench.

The geochemical indicators of hydrothermal alteration of MORBs and its implication for potential polymetallic sulfide mineralization

Xing Yu[1*], Hang Hu[1], Peng Zhou[1], Xiqiu Han[1], Xucheng Xu[1]

1. Key Lab of Submarine Geosciences, Second Institute of Oceanography, Ministry of Natural Resources, Hangzhou, Zhejiang, CHINA

E-mail: yuxing@sio.org.cn

Keywords: MORB, hydrothermal alteration, sulfide deposit, major and trace element, Carlsberg Ridge

Hydrothermal alteration of submarine mid-ocean ridge basalts (MORBs) is a normal phenomenon that can be evidenced by sampled rocks. The byproducts of this process may be the sulfide mineralization. The polymetallic sulfide can be a source of metals that related to people's everyday life. However, locating these sulfide deposits underneath the water is quite difficult. Is there any chance that we can investigate the composition of altered basalt samples and give a judgement about the potential of nearby sulfide mineralization?

By systematic study of the altered basaltic samples close to existing known hydrothermal vents (HV), we may find any traces of sulfide deposit. Take the samples from Carlsberg Ridge Tianxiu HV for example, the samples can be classified into three types: the normal MORBs, the slightly altered basalts, the intensely altered basalts. The systematic comparisons of mineral composition, major and trace elements between them implies the mobility and variations of specific elements. The loss on ignition (LOI) is positively correlated with the intensity of hydrothermal alteration. With the increasing extent of alteration, elements K, U, Zn, Cu, and Co become more enriched, whereas the Ca, Mn, Ba, Sr, Th and Y gradually decreased. A lot more elements varied differently at different alteration stages, e.g., MgO, Al_2O_3, Na_2O, Li, and Fe. While plotting all the data from Tianxiu HV, some indicators can be suggested as the distinguish basis for potential intense hydrothermal alteration as well as the sulfide mineralization, i.e., $Zn+Cu+Co>500CaO+MnO*100<15Rb+U>2Sr+Th*1000<250$. These simple approximations may give a quick review of the potential sulfide deposits located close to the highly altered basalts, which would be more easily sampled than the sulfide itself. This would greatly improve our efficiency while we explore the vast seafloor for sulfide ore deposits.

Effects of Mineral on Taxonomic and Functional Structures Microbial Community in Tengchong Hot springs

Fangru Li[1], Weiguo Hou[1*], Shang Wang[2], Hailiang Dong[3]
1. Institute of Earth Sciences, China University of Geosciences, Beijing, Beijing, CHINA
2. CAS Key Laboratory of Environmental Biotechnology, Research Center for Eco-Environmental Sciences, Chinese Academy of Sciences, Beijing, CHINA
3. School of Earth Sciences and Resources, China University of Geosciences, Beijing, Beijing, CHINA
E-mail: weiguohou@cugb.edu.cn

Keywords: mineral particles, microbial communities, diversity, functional groups, stochastically adhere

Terrestrial hot spring ecosystems, as a representative extreme environment for the co-evolution of minerals and microbes, exhibit a variety of habitat differentiation in sedimental microbial communities. Although diverse mineralogical compositions occur in hot spring sediments, the impact of the single mineral on the diversity and structure of microbial communities remains poorly elucidated. In this study, different mineral particles with various chemistries (i.e., hematite, biotite, K-feldspar, quartz, muscovite, aragonite, serpentine, olivine, barite, apatite, and pyrite) were incubated in two Tengchong hot springs to determine the impacts of minerals on the microbial communities taxonomic and functional diversities. Two hot springs included one alkaline (pH~8.34) with a high temperature (~82.8 ^{o}C) and one acidic (pH~3.63) with a relatively low temperature (~43.3 ^{o}C). After 10-day incubation, the minerals and the surrounding bulk sediment were collected. The 16S rRNA gene high-throughput sequencing approach demonstrated that the mineral-associated bacterial taxa differed from those of the bulk sediment samples in the two hot springs. The relative abundance of Proteobacteria, Euryarchaeota, and Acidobacteria increased in all minerals, suggesting that these microorganisms are apt to colonize on solid surfaces, other than live freely. Generally, the α-diversity indices of the microbial communities on the mineral surfaces were higher than those from the bulk sediment samples (P<0.05), which may be caused by stochastically adhering process on the mineral surfaces during 10-day incubation, unlike that the microbial community in sediment has experienced long-term environmental and ecological screening. The microbial ecological functional groups involving in energy sources, C, N, and S metabolism were predicted using the FAPROTAX database. Chemoheterotrophy increased with minerals incubation, which was dominant in most cultured minerals (the relative contents were 5%~20%). Most notably, the sulfate respiration bacteria (mainly related to Desulfobacterales and Syntrophobacterales) associated with aragonite in the acidic hot spring significantly differed from other minerals, possibly due to the pH buffering effect of aragonite providing more favorable conditions for their survival and proliferation. By comparison, aragonite cultured in the alkaline hot spring highly enriched denitrifying bacteria and promoted the nitrogen cycle within the system. Collectively, we speculated that diverse microbes stochastically adhered on the surface of minerals in the water flows and the physical and chemical properties of minerals drove the enrichment of certain microbial communities and functional groups during the short-term incubation. Taken together, these findings thereby provide novel insights into mechanisms of community assembly and element cycling in the terrestrial hydrothermal system associated with hot springs.

Keywords: Thermophilic Microorganism, chemoautotrophy, carbon fixation pathway, high-throughput sequencing

Volcanoes and geothermal hot springs are hydrological conduits that connect the subsurface, the surface, and the atmosphere, where fluids and gases, mainly the greenhouse gas CO_2, are released from the deep crust and even the mantle while experience a number of geological processes during upward migration. Hydrothermal fluids contain H_2S, H_2, Fe^{2+}, and other reducing components, which may be oxidized by chemoautotrophic microorganisms as they reach the surfaces, and some inorganic carbon may be fixed into biomass and other organic carbon by microorganisms meanwhile. Previous research shows that chemosynthesis plays an important role in carbon cycling in deep-sea and terrestrial hot springs, but terrestrial hot springs often have geochemical complexity because of uneven land surface topography, gradients of temperature and spring water chemistry. Thus, terrestrial hot springs provide an excellent place to more easily study the carbon budget in aquatic systems. In this study, seven hot springs with different and irregular physical and chemical parameters were selected in Tengchong Volcano Geothermal National Geopark, Yunnan Province, to explore the carbon fixation capacity and community structure of chemoautotrophic microorganisms in hot springs, and discuss the energy sources and influencing factors of carbon fixation through in-situ cultivation with $NaH^{13}CO_3$ and metagenomic sequencing technology. The results showed that the rates of carbon fixation by chemoautotrophy were far lower than those by photosynthesis, and chemoautotrophy was inhibited by light potentially caused by that the ultraviolet radiation in the sun light has a negative impact on carbon-fixing metabolism. Among high-temperature hot springs (79.3-88.7 ^{o}C), *Aquificae* is the dominant phylum; reductive citrate cycle and reductive acetyl-CoA pathways were the dominant carbon-fixation pathways; and the hydrogen oxidation was a major energy source. In the mid-high temperature springs (54.3-72.5 ^{o}C), the microbial diversity was higher; and there were six carbon fixation pathways among which the reductive citrate cycle is the main carbon-fixation pathway. Hydrogenation, iron oxidation, sulfide oxidation, sulfur oxidation, and thiosulfate oxidation were the potential energy sources. In acid springs (42.8 ^{o}C, pH=4.5), *Proteobacteria* accounted for 80%, 3-Hydroxypropionate bi-cycle was the main chemoautotrophic carbon fixation pathway, and the oxidation of sulfite might the major energy source. The above results revealed the response relationship between the carbon fixation capacity of hot spring microorganisms and environmental factors, which is helpful to deeply understand the carbon cycle process of the hot spring system, and comprehensively understand the carbon budget of hot spring ecosystem in global volcanic regions

Temporal and spatial evolution of bacterial communities in Wocan hydrothermal-plume influenced zone, Carlsberg Ridge, Northwest Indian Ocean

Qian Xie[1], Xiqiu Han[1*]

1. Key Laboratory of Submarine Geoseciences, Second Institute of Oceanography, Hangzhou, Zhejiang, CHINA

E-mail: xqhan@sio.org.cn

Keywords: hydrothermal-plume, microbial diversity, tempora-spatial evolution, high-throughput sequencing, Indian Ocean

Hydrothermal-plume influenced zone includes the areas within and underneath the hydrothermal plume. The structure of microbial communities in the hydrothermal-plume influenced zone evolves temporally and spatially. However, due to the difficulties in observation and sampling, the diversity of microbes and how they evolve with the time and space is less investigated. During Chines DY49-5 cruise in 2018, a sediment trap mooring system was deployed approximately 300 m southeast of the Wocan-1 hydrothermal vent field (6°22N, 60°31'E), Carlsberg ridge, Northwest Indian Ocean. Eighteen months later, a total of 42 hydrothermal plume samples were retrieved from the 40 m and 300 m above the seafloor, respectively. In this paper, we used Illumina Miseq high-throughput sequencing technology combined with in-situ turbidity anomaly data to study the diversity of bacterial communities within and beneath the neutral buoyancy plume, respectively, and how they evolved with the time, with the aim to understand the factors causing the spatial and temporal heterogeneity of the microbial communities. Our results showed that the bacterial communities in the samples were dominated by γ-Proteobacteria, Camplylobacteria, α-Proteobacteria, Bacteroidia, Clostridia and Desulfobulbia. The relative abundance of Camplylobacteria increased when the hydrothermal venting was more active as suggested by the high turbidity anomaly, while the relative abundance of γ-proteobacteria and α-proteobacteria were on the contrary. Spatially, γ-proteobacteria was more abundant within the hydrothermal plume, while Camplylobacteria was more abundant beneath the hydrothermal plume. We conclude that the studied area has been affected by the dynamics of hydrothermal plume from Wocan-1 hydrothermal field. When the hydrothermal influence was stronger, the relative abundance of Camplylobacteria was higher. The samples collected beneath the neutral buoyancy plume contained more Camplylobacteria than those collected within the neutral buoyancy plume, suggesting that the abundance of sulfide particles is likely the main factor causing the spatial and temporal heterogeneity of bacterial communities in the hydrothermal-plume influenced zone.

Biodiversity, biomineralization and metabolic potentials of the neutrophilic, microaerophilic iron-oxidizing Zetaproteobacteria in seafloor hydrothermal environments

Mingxue Sun[1], Lei Su[1], Jiangtao Li[1*]
1. State Key Laboratory of Marine Geology, Tongji University, Shanghai, CHINA
E-mail: jtli@tongji.edu.cn

Keywords: hydrothermal vent, Fe-oxidizing bacteria, Zetaproteobacteria, ultrastructures.

Iron is one of the main components of deep-sea hydrothermal activity products and an important driving element for the chemoautotrophic microbial ecosystem at hydrothermal vents. The neutrophilic microaerophilic iron-oxidizing bacteria, represented by Zetaproteobacteria, is the main drivers of biomediated Fe^{2+} oxidation in hydrothermal vents and their surroundings. Fe-oxidizing bacteria acquires the energy necessary to maintain their metabolism through Fe^{2+} oxidation, while secrete organic matter to precipitate the oxidized insoluble iron (oxides or hydroxides) outside the cell, forming microstructures with twisted stalks, hollow sheaths, branching hollow tubes and other special morphological features. They accumulate into iron-rich oxides/hydroxides which are widely distributed on the seafloor. More and more studies have shown that the *cyc2* gene encoding cytochrome-porin is the key gene of Fe^{2+} oxidation by Zetaproteobacteria, while *c*-type cytochrome or other periplasmic cytochromes are the main electron transport carriers in Fe^{2+} oxidation. Metagenome-based studies revealed that Zetaproteobacteria also generally possesses multiple functional genes and metabolic pathways closely related to nitrogen, sulfur, hydrogen and arsenic cycling, suggesting its potential role in these elements cycling process. In this presentation, we systematically summarize the diversity and physiological characteristics of neutrophilic microaerophilic iron-oxidizing bacteria found in hydrothermal environments, as well as the microstructure records of their biomineralization, key genes and electron transport pathways that mediate Fe^{2+} oxidation. It is helpful to comprehensively and systematically understand the role and contribution of these microorganisms in the migration and enrichment of key ore-forming elements, the maintenance of vent ecology and the mineralization of microorganisms in submarine hydrothermal vents.

Designation of a mathematical modeling framework for microbial-mediated dissolution, migration and precipitation of metallic elements in hydrothermal systems

Peng Hu[1*], Haoyang Zeng[1], Zhiguo He[1]
1. Ocean College, Zhejiang University, Zhoushan , zhejiang, CHINA
E-mail: pengphu@zju.edu.cn

Keywords: numerical modelling, hydrothermal foam, metallic elemation, migration

While the dissolution, migration and precipitation of metallic elements in hydrothermal systems are strongly mediated by microorganisms, there has been rare mathematical modelling work that appropriately consider this process. Potential reason may include the limited quantitative understanding on the microbial-mediated process, and the potential knowledge gaps between what can be used in a numerical model and the main outputs from experimental and field works on the micro-mediated process. Here a modeling framework for microbial-mediated dissolution, migration and precipitation of metallic elements is designed, based on which the potential knowledge gaps are discussed. Moreover, the Hydrothermal Foam, which was originally developed by Guo et al. (2020, Geoscientific Model Development), is further extended to consider migration of metallic elements. Using this extended open-source code, physical factors that may affect the migration rate of metallic elements are numerically investigated using an idealized single-pass hydrothermal system. These factors include the regions for the rock-seawater chemical interactions, the permeability distribution of the domain, as well as the temperature of the magmatic chamber.

Keywords: Iron metabolism, Zetaproteobacteria, Virus

Deep-sea hydrothermal field is considered as one of the most productive ecosystems on Earth. Chemolithotrophic primary production supported by sulfur-oxidizing has been well documented, yet iron-oxidizing process were usually overlooked in spite of the fact that iron is the most abundant source of energy for chemolithotrophy. Zetaproteobacteria, the typical marine neutrophilic iron-oxidizing bacteria, is still under-researched partly because of the difficulties of culturing this clade. In addition, very limited information is available for the viruses of Zetaproteobacteria. In this study, we firstly resolved the genomic compositions of four complete Zetaproteobacteria prophages from reference genome database. By expanding to Zetaproteobacteria inhabiting metagenomes in global scale, we identified 649 potential Zetaproteobacteria viruses. The virus-host infection network revealed a distinct interaction pattern between Zetaproteobacteria and their viruses. The viruses of Zetaproteobacteria showed high host specificity. The discovery of viral encoded iron-oxidizing marker gene (*cyc2*) indicates that viruses may boost the growth of their hosts by promoting iron oxidation. Moreover, ferric uptake regulatory protein (*Fur*) was found widespread in viral genomes identified from Fe (II)-rich hydrothermal deposits. This study sheds light on the relationships between viral infections and deep-sea iron metabolism.

Mineralization of Alvinella tubes at hydrothermal vents on the East Pacific Rise

Yejian Wang[1*], Litao Luo[1], Xiqiu Han[1]
1. Key Laboratory of Submarine Geosciences, Second Institute of Oceanography, MNR, Hangzhou, Zhejiang, CHINA
E-mail: yjwang@sio.org.cn

Keywords: tubeworm, mineralogy, multilayered tubes, sulfide mineralization, weathering oxidation

This paper presents a comparative study of the mineralized *Alvinella* worm-tubes at seafloor hydrothermal vents along the East Pacific Rise. Our study found that worm-tubes mineralization begins in the outer layer of the tubes and is characterized by single or multi-layered concentric colloform pyrite bands as mineralized walls. There are structural differences in the tube-worm mineralization, influenced by the rate of mineral precipitation. For example, tube mineralization is accelerated, its wall thickens, and the number of concentric layers decreases and the spacing becomes smaller. In addition, a small amount framboidal pyrite polycrystalline polymers occur in the colloform pyrite bands, indicating a potential intermediate pathway for the conversion of nano-micron crystalline sulfide minerals to colloform pyrite during the mineralization stratification phase. This process is mainly controlled by the difference in fluid metal ion concentration gradient confined by the organic worm-tubes. On the contrary, the worm-tubes with relatively slow mineralization rates are mostly characterized by a high number of concentric layers, and have a tendency of gradually increasing oxidation and gradually thinning colloform pyrite from the inside to the outside. This feature is related to the oxidation of Fe-Si-rich hydrothermal fluids and the weathering oxidation of low-temperature seawater, respectively. Additionally, we found that sphalerite band developed in the middle layer of the tubes has the effect of isolating seawater oxidation, which can effectively limit the development of seawater oxidation to the inner wall. These findings provide a new perspective for understanding the biological-mineral interactions and their weathering processes in seafloor hydrothermal vent sites.

Iron sulfide minerals formation by thermophilic iron-reducing bacteria Anoxybacter fenmentans DY22613 via sulfur-mediated electron shuttling

Xiang ZENG[1*], Yuemei Zhao[1], Tong Yu[1], Zongze SHAO[1]
1. Key Laboratory of Marine Biogenetic Resources, Third Institute of Oceanography,Ministry of Natural Resources,, Xiamen, Fujian, CHINA
E-mail: zengxiang@tio.org.cn

Keywords: Iron sulfide minerals, Iron reducer, Thermophilic, Deep-sea hydrothermal vents

Iron sulfide minerals are common in the natural environment and play a key role in maintaining the oxygenation of Earth's atmosphere over geological timescale. Sulfate reducing microorganisms have been recognized as an important player for sedimentary iron sulfide mineral formation reactions in low-temperature environments. Yet, the role of biotic processes in the formation of iron sulfide minerals is poorly understood, especially in hydrothermal vents. A novel piezophilic, thermophilic, anaerobic, fermentative iron-reducing bacteria of class *Clostridia*, named *Anoxybacter fermentans* DY22613^T, was isolated from East Pacific Rise hydrothermal sulfides. It can enzymatically reduce elemental sulfur and degrade cysteine to hydrogen sulfide with final concentration 3.6 and 2.5 mM, which accordly enhanced the growth and impacted iron reducing process. Scanning electron microscopy and X-ray diffraction revealed that iron sulfide minerals produced in the presence of strain DY22613 exhibit unique morphology and aggregate differently than abiotic minerals formed in media without cells. The transformation of iron oxides including goethite and akaganeite to Mackinawite (FeS) and Marcasite (FeS_2) occurred two days of incubation with live cells to two months with dead cells. Minerals precipitates containing Fe and S are visible at the surface of cells and extracellularly. These results implied that the potential role of *A. fermentans* DY22613^T in situ in deep-sea hydrothermal sulfids is coupling iron and sulfur cycles, contributing iron sulfide mineral formation.

The Characteristics of Metal Elements in Mussel from Wocan-1 Hydrothermal Vent of Northwest Indian Ocean

Huangxu Wan[1,2], Jiqiang Liu[1*], Xiqiu Han[1]
1. Key Laboratory of Submarine Geosciences, Second Institute of Oceanography, Ministry of Natural Resources,, Key Laboratory of Submarine Geosciences, Second Institute of Oceanography, Ministry of Natural Resources, Hangzhou, Zhejiang, CHINA
2. School of Earth Sciences, Chengdu University of Technology, Chengdu, Sichuan, CHINA
E-mail: liujq@sio.org.cn

Keywords: Mussel,Distribution of metal elements,Rare earth elements,Rare earth elements pattern,Wocan-1 hydrothermal field

The deep-sea mussel, *Bathymodiolus marisindicus*, collected from the Wocan-1 hydrothermal vent of the Northwest Indian Ocean were choose to study the characteristics of metal trace elements during their lifetime in vent system. The content of trace and rare earth elements (REEs) in the mussel shell and tissue were determined using LA-ICP-MS and ICP-MS respectively. Furthermore, the distribution and relationship of metal elements of mussel shell, tissue and sediment, as well as the ecological and chemical characteristics of REEs were explored. The results show that Fe (284.2μg/g), Mn (4.2μg/g) and Zn (12.0μg/g), and Fe (717.6μg/g), Cd (15.0μg/g), Cu (361.9μg/g), Mn (13.0μg/g), Pb (19.4μg/g) and Zn (230.2μg/g) are mainly enriched in the mussel shell and tissue of Wocan-1 hydrothermal vent, respectively. The trace elements are more enriched in mussel tissue than shell. The trace and REEs contents of the mussel of Wocan-1 hydrothermal vent are correlated with the elements contents of the sediment of the hydrothermal field. The total rare earth elements (ΣREE) of mussel shell and tissue are 0.45μg/g and 0.33μg/g, respectively. Both light and heavy rare earth elements (L/HREE) show the fractionation, and LREE (La~Eu) contents are higher than those of HREE (Gd~Lu), which are 0.27μg/g and 0.26μg/g, 0.18μg/g and 0.07μg/g, respectively. Therefore, the LREE is significantly enriched in the mussel shell and tissue, and the mussel shell is more enriched with HREE than the tissue. The REEs distribution pattern shows positive anomalies for La and Eu, negative Ce anomalies in mussel tissue, and positive anomalies for Gd, Eu, Pr and Ho, negative anomalies for Sm and Dy in mussel shell, which further indicate the REEs are selectively enriched for the mussel shell and tissue. The δEu and δCe of the sediment of the Wocan-1 hydrothermal field were 0~3.00 and 0~1.00 (excluding 1)(Qiu et al.,2021), and the δEu and δCe of the mussel shell and tissue of the hydrothermal vent are 3.95 and 4.52, 0.94 and 0.33, respectively. The δEu and δCe values of mussel shell, tissue and sediment are all greater than 1, while the δCe values are all less than 1, indicating that the REEs in the mussel of hydrothermal vent are homologous with those in the sediment of the hydrothermal field, and the REEs in mussel are affected by the seawater and hydrothermal fluid. The distribution and enrichment characteristics of trace and rare earth elements in the mussel of hydrothermal vent are investigated in this paper, which will provide a technical and theoretical basis for further study of hydrothermal geochemical characteristics recorded by organisms of hydrothermal fields.

The seafloor hydrothermal sulfides could serve as energy source for the metabolic growth of chemolithoautotrophs. The activities of the microbes could mobilize and transform the elements in the sulfide minerals and as the consequences that sulfide minerals got weathered and new minerals formed. In order to understand the characteristics and processes of the seafloor microbial weathering, we deployed various types of hydrothermal sulfide samples near the Wocan-1 hydrothermal field to conduct an in-situ incubation experiment for a period of 18 months. In this study, we observed and analyzed the samples before and after the experiments using SEM and Fourier infrared spectroscopy (FT-IR). Our results show that brownish, yellowish and greenish secondary minerals formed on the surface and fissures of the sulfide slabs. Abundant microbial structures in the size from 0.5 μm to 50 μm and dissolution pores in the size of individual cells were observed. The polysaccharides and amide functional groups increased significantly in the samples dominated by chalcopyrite and sphalerite after the experiment, indicating that the activity of microorganisms produced rich extracellular polymer (EPS) on the surface of sulfide samples. While carboxylic acid (-COOH) group and phosphate group (P=O) increased in Cpy-rich samples after the experiment, suggesting that the specific adsorption of carboxylic acid groups(-COOH) to Cu ions (and phosphate groups (P=O) to Zn ions. The findings provide strong evidence for the role of microbes on the oxidation of seafloor sulfides.

Microbial iron metabolic feature in Longqi hydrothermal vent chimneys, Southwest Indian Ridge

Yingwen Zhong[1], Yuehong Wu[1*], Xuewei Xu[1]
1. School of Oceanography, Shanghai Jiao Tong Uiversity, Shanghai, CHINA
E-mail: yuehongwu@sio.org.cn

Keywords: Southwest Indian Ridge, hydrothermal vent, iron oxidation, siderophore, metagenome.

Deep sea hydrothermal vents are responsible for discharging at least one third of iron into oceans[1], which significantly influence primary production in water columns and sulfide deposition in subseafloor. The ultra-slow spreading Southwest Indian Ridge (SWIR) is hot zone for future polymetallic sulfide exploration[2] as deep subsurface detachment and hydrothermal circulation system formed large deposition of sulfide minerals[3]. Meanwhile, it is also known as important component in global deep-sea ecosystems with unique and prospering macrofauna[4]. Thus, research in iron biogeochemistry is significant for both understanding chemosynthetic ecosystems in hydrothermal regions and providing guidelines for future environmental conservation.

To study microbial iron functional feature in SWIR, metagenomic sequencing and binning were utilized to revealed the microbial composition and metabolic potential in two active hydrothermal vent chimneys. In addition to autotrophic iron-oxidizing Zetaproteobacteria, 22 MAGs from 12 uncultured bacterial phyla such as KSB1, SAR324, Gemmtimonadota, Eisenbacteria and Calditrichota were detected with iron-oxidizing enzyme Cyc2, which suggested potential chemoheterotrophic iron-oxidizing microorganisms inhabiting in hydrothermal vent chimneys. As for iron transport and storage, 66% of MAGs contained siderophore transport potential while 59% of MAGs encoded Fe(II) ion transporter *feoABC* or *futABCD*. Ferritin-related genes responsible for cellular iron storage and iron mineral transformation were carried by 66% of MAGs from 30 bacterial phyla and 6 archaeal phyla. To sum up, our study revealed strong microbial metabolic potential involved with iron oxidoreduction, transportation and storage in active chimneys, which indicated intensive flow of iron between hydrothermal vent environment and microbial communities and might be responsible for mineral biotic oxidation.

Possible contribution of microbial activity to the active black smokers on the mid-oceanic ridge: Constraints from the micro-texture and in-situ sulfur isotope of pyrite in EPR 1-2°S hydrothermal field

Xingwei Meng[1,2], Xiaohu Li[1,2*], Xianglong Jin[1,2], Fengyou Chu[2]
1. School of Oceanography, Shanghai Jiao Tong University, Shanghai, CHINA
2. Key Laboratory of Submarine Geosciences, Second Institute of Oceanography, Ministry of Natural Resources, Hangzhou, Zhejiang, CHINA

Keywords: Sulfur isotopes, Pyrite, Microbial activity, Sulfide chimney, East Pacific Rise

Deep-sea hydrothermal vent systems have wide-ranging gradients of organic matter contents, redox potential, pressure, and temperature, which provide habitats for a large number of extreme microorganisms. Seafloor hydrothermal deposits are usually interpreted to precipitate abiogenically in the sediment-covered back-arc setting, but rarely occur in the hydrothermal systems on the sediment-starved mid-oceanic ridge. Thus, the role of microbial activity on the sulfide precipitation in the sediment-starved mid-oceanic ridge remains poorly understood. We study the micro-textural and in-situ sulfur isotope analysis of the pyrite varieties across the active black smokers at the EPR 1-2°S hydrothermal field using SEM, EPMA, and NanoSIMS. The petrographic observations show that the anhedral/colloform pyrite with a rounded or semicircular shape under an optical microscope can be identified as likely relics of sulfidized fauna on the surface zone of the black smoker. Their sulfur isotopes results are characterized by the near and negative $\delta^{34}S$ (−0.51 ~ 1.08‰, mean: 0.08‰, n = 4), which is in contrast to the other chimneys with elevated $\delta^{34}S$ values in the outer wall associated with the thermochemical sulfate reduction (TSR) of ambient seawater sulfate (Bluth and Ohmoto, 1988; Meng et al., 2019). The outermost sulfide surface formed by the rapid quenching of H_2S-rich fluids during fluid-seawater mixing in a low-temperature environment is suitable for biological survival. The pyrite would be oxidized by seawater and then produce chemosynthetic energy to support bacterial survival as well as bacterial reduction (Mccollom and Shock, 1997). We hypothesize that the low $\delta^{34}S$ values of anhedral pyrite (low to −0.51‰) are most likely related to the incorporation of 8 ~ 24% of bacterially reduced sulfur. This study let us reconsider the possible contribution of bacterial activity to the growth of mature chimneys on the mid-oceanic ridge.

Calcium and copper isotope signatures in hydrothermal sediments as proxies for hydrothermal actives in mid-ocean ridges

Wang Jian Qiang[1], Chen Xue Gang[1*]
1. , , , , CHINA
E-mail: chenxg83@zju.edu.cn

Keywords: Calcium isotopes, Cooper isotopes, Hydrothermal activity

Hydrothermal sediments, which inherit or record the characteristic of sources and geochemical signals of hydrothermal activities, are one of the essential sinks of hydrothermal output (German and Seyfried, 2014; Stein and Stein, 1992). Hence, hydrothermal sediments can be exploited to detect and locate new hydrothermal fields and calculate material fluxes from any particular vent field by mineralogical and geochemical characteristics (Cave et al., 2002; German et al., 1999; Huang et al., 2017; Liao et al., 2019). As sensitive indexes, unconventional stable metal isotopes have been widely used as mineralization tracers in seafloor hydrothermal circulation and new proxies for the marine material circle (Little et al., 2014; 2017; Schmitt et al., 2003; Zhu and Macdougall, 1998). In this study, we explore the mineralogy, geochemistry, $\delta^{44/40}$Ca and δ^{65}Cu variation characteristics of a near-vent sediments core in the Tianxiu hydrothermal field, identify material sources, quantify the contribution of hydrothermal plume calcium (Ca) and copper (Cu), and then assess the activity intensity's evolution trend of the hydrothermal field. The primary material sources of Ca in the Tianxiu sediment core are hydrothermal calcite and bioclastic. The $\delta^{44/40}$Ca of bio-calcite is significantly correlated with its precipitation temperature. According to the $\Delta^{44/40}$CaBio-Seawater = 1000ln(α) that the $\delta^{44/40}$Ca (0.57 ± 0.065‰, 95% confidence interval) of marine biogenic calcite is controlled by the surrounding seawater's temperature (2 ℃ to 7 ℃). Additionally, during hydrothermal circulation, the $\Delta^{44/40}$CaCal-HydFluid of hydrothermal endmember calcite in the altered basement follows a $1/T^2$ (T: temperature in Kelvin) relationship. On the other hand, hydrothermal Cu is derived from hydrothermal plume Cu precipitation and Cu-enriched hydrothermal minerals in the altered basement detrital. During early high-temperature hydrothermal processes, preferentially formed ^{65}Cu-enriched sulfides, causing the subsequent derived hydrothermal plume significantly enrich ^{63}Cu. The δ^{65}Cu of hydrothermal sediments is significantly correlated with its hydrothermal products. In this paper, the estimated δ^{65}Cu of the hydrothermal plume endmember is -0.51 ± 0.20 ‰ (95% confidence interval), and its formed significant ^{65}Cu-depleted hydrothermal precipitation (oxide/hydroxide). Hence hydrothermal plume may provide a critical source of light Cu isotopes entering seawater and metalliferous sediments. In general, the $\delta^{44/40}$Ca value of hydrothermal calcite records the hydrothermal reaction field precipitation temperature, which may be closely related to the intensity of hydrothermal activity and has to be constrained in future studies. While Cu isotopic composition is affected by sources and redox, thus it is more complex to use δ^{65}Cu as an exploration proxy to investigate hydrothermal activity intensity.

Particle Transport and Deposition Released by Horizontal Buoyant Jets in Stratified Fluids

He Zhi guo[1*], Zhang Han[1]

E-mail: hezhiguo@zju.edu.cn

Keywords: Sediment transport, Sedimentation, Stratified Fluids, Buoyant Jet

Particle-laden buoyant jets are ubiquitous in coastal and ocean environments. Here, we reveal the propagation and mechanism of particles with different sizes, densities, and concentrations horizontally transported by buoyant jets in the stratified fluid, using a computational fluid dynamic model fully coupled with a discrete element method. Particles with a large settling velocity deposit quickly after moving forward in a short distance horizontally and associate with a narrow particle accumulation band on the bed. The lateral probability distribution of deposited particles in this pattern is Gaussian-like. The proportion of particles settled near the source is positively related to their density. Particles with a medium settling velocity are driven up by the buoyant flow and then settle. The lateral probability distribution of deposited particles in this pattern deviates from the Gaussian distribution because particles at the head of the deposition area are not subject to the constraint of the jet boundary layer during settling and form dispersed depositional fan on the bed. The length of the deposition area is independent of the volume fraction of particles, while the maximum rise height of particles will decrease with the increase of the volume fraction. Particles with a small settling velocity can remain suspended until the jet rebounds. In this pattern, particles diffuse from the inside of the jet near the neutral buoyancy layer. During the diffusion process, partial particles are recaptured due to the inward flow field caused by the entrainment of the jet.

E-mail: xqhan@sio.org.cn

Keywords: hydrothermal sulfide weathering, Alcanivorax, autotrophic Fe(II)-oxidation, element exchange, deep-sea hydrothermal field

Seafloor weathering of hydrothermal sulfides is a common phenomenon. Yet the role of microorganisms during the process of seafloor weathering is not well studied. In this study, we carried out an experimental study on the interaction between the microbes and hydrothermal sulfides, simulating the water chemistry of bottom seawater of Wocan hydrothermal field, Carlsberg Ridge, in the presence of hydrothermal sulfide particles and Alcanivorax sp. MM125_6 at 28 ℃ for 3 months. Strain Alcanivorax sp. MM125_6 was isolated from Wocan hydrothermal field which has potential of autotrophy and Fe(II)-oxidization. Our results show that after experiment, the water chemistry and pH value changed significantly in the presence of microbes, but insignificant in the absence of microbes. For example, compared to abiotic experiment, the concentrations of Fe, Zn, Cu and Pb in the medium in the presence of microbes increased 6.7-35.2, 1.2-1.5, 2.3-4.3 and 15.3-53.7 fold, respectively. The surfaces of the hydrothermal sulfide grains were colonized by abundant cells as revealed by Fluorescence microscopy images. Scanning Electron Microscopy analysis revealed the presence of extracellular polymeric substances and microbes with the shape of short rods. Besides, particulate iron-oxides, and irregular polygon pits on the surface of sulfide grains were also observed in the biotic experiment, but not in the abiotic experiment. Our findings suggest that Alcanivorax played an important role on the weathering/oxidation of hydrothermal sulfides, and the metabolism of Alcanivorax could accelerate the process of seafloor weathering.

Bioturbation enhanced petrophysical properties in the Ordovician carbonate reservoir of the Tahe oilfield, Tarim Basin, China

Yongbin NIU[1*]
1. Institute of Resources & Environments, Henan Polytechnic University, Jiaozuo, Henan Province, CHINA
E-mail: niuyongbin@hpu.edu.cn

Keywords: Bioturbation, Carbonate reservoir, Diagenesis, Ordovician, Tahe oilfield, Tarim Basin

Bioturbation plays an important role in enhancing the reservoir capacity of tight reservoirs. This study aims to understand the alteration mechanism and effects of bioturbation on oil and gas reservoirs, to clarify the key control factors and constraints influencing the production of bioturbation. The petrophysical characteristics of bioturbation and host sediments in carbonate rocks, such as mineral composition, pore spaces, porosity and permeability, were studied based on the detailed observation and description of the Ordovician cores from the Tahe oilfield. The effect of bioturbation on petrophysical properties of carbonate rocks were carefully analyzed. The results show: (1) Two types of bioturbation, *Thalassinoides*-like burrows and *Planolites*-like burrows, mainly occur in the Ordovician cores of the Tahe oilfield, ranging from the Lower–Middle Ordovician Yingshan Formation to the Middle Ordovician Yijianfang Formation. The burrow-fills are mainly composed of dolomite with subhedral and euhedral crystals. The host sediments mainly consist of micrite. (2) The pores in the host sediments are poorly developed and are incapable of forming effective reservoir spaces. However, well-developed intercrystalline pores among dolomites and microfractures in bioturbated sediments with better connectivity can form effective pore spaces. The results of porosity and permeability show that the host sediments without bioturbation are characterized by poor porosity and permeability. However, with the increase of bioturbation intensity, the porosity of the bioturbated sediments firstly increases and then decreases, whereas the permeability increases all the time. (3) Multiple burrows overprinted in the Ordovician carbonate rocks, forming a large-scale bioturbated carbonate rocks with lateral continuity and vertical connectivity, due to the suitable sedimentary setting, ecological conditions, favorable spatiotemporal sediment matching, and abundant organism-substrate interaction. Subsequently, diagenesis (particularly dolomitization and dissolution) has played a positive role in altering the rock fabric and improving the petrophysical properties of bioturbated carbonates.

Thalassinoides ichnofabrics of Lower Cambrian Longwangmiao Formation (Stage 4, Toyonian) on the Yangtze Platform, South China: Improving paleoenvironmental interpretations

Zisang Huang[1*], Xingzhi Wang[1], Tang Ruifeng[1]
1. School of Geoscience and Technology, Southwest petroleum university , Chendu, Sichuan, CHINA
E-mail: hzs515@163.com

Keywords: Cambrian, Thalassinoides, Carbonate platform, Paleoenvironment

The analysis of Thalassinoides ichnofabrics in the Cambrian Stage 4 Longwangmiao Formation in the Middle and Upper Yangtze Block of South China is conducted to promote the understanding of the paleoenvironment of this period. Thalassinoides ichnofabrics are divided into three types (banded, mottled and grid) according to their morphology, bioturbation index, abundance and related parameters.

The completeness of ichnofabrics gradually increases from banded to grid, the scale of burrows expands, and the structure transitions from two-dimensional to three-dimensional. Malacostracans, phyllocarids and enteropneusts are the most likely burrowers. The findings reveal that frequent changes in paleoenvironmental conditions are the dominant factors for generating the various Thalassinoides ichnofabrics. The changes in depositional rate, substrate properties and nutrient levels affect the behavior and building pattern of the burrowers, thus leading to the diversity of Thalassinoides ichnofabrics. In the early Longwangmiao period, many incomplete Thalassinoides burrow systems were built in the substrates with terrigenous detrital minerals, revealing the significant environmental pressure on the burrowers. In the following period, the Thalassinoides burrows went into complete three-dimensional boxworks. At the end of the period, bioturbation almost disappeared, which indicates that burrowers were difficult to survive in the harsh environment.

Behavioural imprint of the Ordovician Radiation: evidence from Middle–Upper Ordovician deep-sea trace fossils in western Inner Mongolia, North China

Ruo-ying Fan[1], Rui-wen Zong[2], Yi-ming Gong[1*]
1. School of Earth Sciences, China University of Geosciences, Wuhan, Hubei, CHINA
2. State Key Laboratory of Biogeology and Environmental Geology, China University of Geosciences, Wuhan, Hubei, CHINA
E-mail: ymgong@cug.edu.cn

Keywords: bioturbation, deep-marine environment, ichnodisparity, Great Ordovician Biodiversification Event, Late Ordovician, North China Craton

Trace fossils are unique evidence of the body plan and behavioural complexity of animals. Major radiation periods in the Phanerozoic were associated with not only changes in biodiversity, biomass, and ecosystems but also transformations in the relatively implicit, behavioural world. Here we report on a diverse ichnoassemblage from the Middle–Upper Ordovician deep-marine deposits of Inner Mongolia, North China, totalling 24 ichnogenera (including two undetermined forms). They include *Alcyonidiopsis*, *Bifasciculus*, *Bifungites*, *Chondrites*, *Circulichnis*, ?*Cochlichnus*, *Dendrorhaphe*, *Diplocraterion*, *Halopoa*, *Gyrophyllites*, *Monofungites*, *Multina*, *Nereites*, *Paleodictyon*, *Phymatoderma*, *Ptychoplasma*, *Rhizocorallium*, *Sinusichnus*, *Taenidium*, *Thalassinoides*, *Trichichnus*, *Zoophycos*, bag-like trace, and closed ring trace. They are attributed to 21 architectural designs, encompassing 13 subhorizontal structures, 3 subvertical structures, and 5 complex structures. Highly regular and complex burrow systems have been discovered, i.e., the branched circular pattern of *Circulichnis sinensis*, elaborate radial graphoglyptid tunnel system *Dendrorhaphe racemosa*, sinusoid mazework *Sinusichnus sinuosus*, and the boxwork bag-like trace consisting of highly symmetric horizontal galleries and numerous semi-equidistant vertical shafts. The occurrence of these complex trace fossils suggests distinct behavioural complication and novelty in deep-sea communities during the Middle–Late Ordovician. We speculate that along with the onshore–offshore displacement of ichnofauna and significant expansion of deposit-feeding structures possibly driven by accelerated competition in the shallow-marine niches and aided by ameliorated deep-sea benthic food level, there was underlying behavioural evolution towards more delicate, geometric, and efficient feeding patterns. The Late Ordovician may represent the early peak not only in ichnodiversity but also in ichnodisparity and behavioural complexity of deep-sea ichnofauna, which probably reflect the complex interplay of biodiversity, biomass, and ecological changes during the Ordovician Radiation.

A large crustacean burrow system from the Lower Devonian of the northwestern Yangtze Platform, South China

Xiaole Zhang[1*], Jianbo Liu[2], Yi Wang[1], Honghe Xu[1]
1. Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences, Nanjing, Jiangsu, CHINA

E-mail: xlzh@nigpas.ac.cn

Keywords: Trace fossil, engineering, crustacean burrow, Early Devonian, paleoecology

By means of digging and turning over the substrate, bioturbation may have both direct and indirect effects on bottom sediment characteristics. These activities, also known as engineering, promote the remobilization of sediment grains and nutrient cycling, changing the physical and chemical features of the local even global environment. Burrows also provide potential living space for co-habitants and thus largely increases the complexity of benthic community. Crustacean burrows especially have a chance to produce these effects for their higher complexity in burrow architectures, larger sizes and nature as deep-tiered systems. However, records of crustacean burrows during the earlier periods of Paleozoic are scarce. Here we report an unusually large (segments up to 58 mm across), three-dimensional burrow system from the Lower Devonian Pingyipu Formation on the northwestern Yangtze Platform, South China. The burrow system is characterized by horizontally-developed networks, with vertical shafts connecting to the sediment-water interface. The burrow surfaces are characterized by scratches including ridges and bundles of ear-shaped striae, allowing an assignation to *Spongeliomorpha* aff. *S. chevronensis* Muñiz and Mayoral, 2001. Analysis of their morphological features, especially the scratches reveals that the trace maker could be a colony of large, unknown crustacean with thoracic appendages decorated with acute seta or denticulations. The burrows represent both the earliest known and some of the largest *Spongeliomorpha* in geological history that may be comparable to their modern analogues in both morphological and functional aspects. The well-documented presence of large trace fossils produced by infaunal crustaceans shows that, the factor causing more dramatic impacts in substrate properties as observed later may has already present during the Early Devonian.

Early Triassic trace fossils from South China marginal-marine settings: Implications for biotic recovery following the end-Permian mass extinction

Li-Jun Zhang[1*]
1. Institute of Resources and Environment, Henan Polytechnic University, Jiaozuo, Henan, CHINA
E-mail: Ljzhanghpu@gmail.com

Keywords: Ichnology, Ichnodisparity, Ichnodiversity, Biotic recovery, Longmendong section

The Longmendong section is one of the few Early Triassic sections containing fluvial to marine deposits in South China. No trace fossils have been recorded in the fluvial deposits, but a total of 26 ichnospecies are reported from the Lower Triassic Dongchuan, Feixianguan and Jialingjiang formations in this section. This ichnofauna represents brackish-water conditions during the late Dienerian to Smithian, and fully shallow-marine settings in the Spathian. Several ichnologic metrics, such as ichnodiversity, ichnodisparity, ichnoabundance, bioturbation intensity, burrow size, and depth of bioturbation, have been analyzed in order to evaluate the role of environmental and evolutionary factors. Although the upward increases in ichnodiversity, ichnodisparity, burrow size and bioturbation intensity may be linked to the biotic recovery after the end-Permian mass extinction, environmental controls also play an important role in this case. Transgressive-estuarine successions typically show a vertical decrease in the salinity stress, showing the passage of brackish-water ichnofaunas to more diverse associations showing more marine affinities. However, the vertical increase in depth of bioturbation cannot be explained by environmental controls alone, instead most likely reflecting the phase of biotic recovery. Overall, ichnologic data suggest that the brackish-water ecosystem was less impacted by the end-Permian mass extinction than the fully marine realm. The shallow, fully marine benthos completely recovered in the Spathian as is the case for other areas in South China. This study underscores the importance of a careful evaluation of sedimentary facies and environmental conditions as a pre-requisite for interpreting evolutionary mechanisms of biotic recovery.

3D BURROWS OF THE POLYCHAETE ON A TIDAL FLAT OF THE YELLOW RIVER DELTA IN CHINA: IMPLICATIONS FOR THE ICHNOFOSSILS POLYKLADICHNUS AND ARCHAEONASSA

Yuanyuan Wang[1*]
1. Henan Polytechnic University, Institute of Resource and Environment, Jiaozuo, Henan, CHINA
E-mail: hpuyyw@163.com

Keywords: 3D, Perinereis, analogous fossil, Polykladichnus,Archaeonassa

Abundant biogenic sedimentary structures produced by Perinereis aibuhitensis (formerly Nereis) occur in tidal flats of the Yellow River Delta in China. The burrows of Perinereis are visible as vertical tubes and irregular strings in slabbed cores. The cores were studied by X-ray radiography, computed tomography and VGStudio MAX to obtain three-dimensional images of the burrows and their inner structure. The burrows are vertical to steeply oblique, Y-shaped tubes with multiple branches. They are considered as analogues of the trace fossil Polykladichnus. Some gutter-like surface traces are similar to the trace fossil Archaeonassa. Perinereis burrows and trails occur mainly in the mixed flat, less frequently in the mud flat or sand flats. Potentially abundant occurrences of some analogous fossil burrows and trails (Polykladichnus, Archaeonassa) could mark position of the intertidal zone

Response of the macrobenthic trace maker community to palaeoenvironmental conditions during Termination V and MIS 11 at the western Mediterranean Sea: surface conditions affecting deep-sea settings

Javier Dorador[1*], Alba Gonzalez-Lanchas[2,3], Francisco J. Rodríguez-Tovar[1], Francisco Javier Sierro[2], José-Abel Flores[2]

2. Department of Geology, University of Salamanca, Salamanca, SPAIN
3. Department of Earth Sciences, University of Oxford, Oxford, UNITED KINGDOM
E-mail: javidr@ugr.es

Keywords: Ichnology, Mediterranean Sea, Surface production, Benthic conditions, Pleistocene

The Marine Isotope Stage (MIS) 11 is an interesting climatic period as it is considered a long and extremely warm interglacial on the Pleistocene. Additionally, its late part records suborbital-scale instabilities associated with Heinrich-type (Ht) events at Iberian latitudes. These climate changes have been registered and analyzed from coccolithophore records at the OPD Site 977 at the western Mediterranean Sea, showing intense variations on surface primary production that could affect deep-sea conditions. Here, we propose the study of the ichnological content and sediment color to analyse the trace maker response and palaeoenvironmental conditions along this period. Then, we integrate the obtained information with previously studied high-resolution coccolithophore data to check if there is a relation between surface and deep-sea conditions. The trace fossil assemblage is characterized by *Chondrites*, *Planolites*, *Scolicia*, *Thalassinoides* and *Zoophycos*, showing notable differences in abundance and diversity along the cores. Ichnological content was integrated with sediment color data and high-resolution coccolithophore records, showing that trace maker communities were mainly affected by oxygen levels and surface organic productivity. First, during Termination V (i.e., right before MIS 11), an intense upwelling caused high surface organic productivity, which increased the deep organic matter accumulation. This, together with the poorly deep-water removal, generated an Organic Rich Layer and a low degree of bioturbation. However, during MIS 11 the surface organic productivity was stable and moderate, causing a lower organic matter content in the deep-sea setting and better oxygen conditions for the macrobenthic trace maker community. This is recorded by a higher degree of bioturbation and lighter sediments. Ht events 3 and 2 are also registered and characterized by a higher ichnodiversity and abundance. These periods are dominated by low surface organic productivity, but intense deep-water circulation, which increase the deep-water removal and oxygen level. The study of palaeoenvironmental conditions from ichnological content, and the integration with additional proxies, show a clear example of the transference of surface conditions to deep-sea settings.

Ichnological analysis of the Rambla de Tabernas section (Tabernas Basin, SE Spain), a preliminary approach to improve characterization of a turbiditic system

Jose Fernando Cabrera-Ortiz[1], Francisco J. Rodríguez-Tovar[1], Javier Dorador[1*]
1. Department of Stratigraphy and Palaeontology, University of Granada, Granada, SPAIN
E-mail: javidr@ugr.es

Keywords: Turbidites, Trace fossils, Paleoenvironment, Ichnofacies

Tabernas Basin is a Neogene basin of the Betic Cordillera (SE Spain), with an exceptional exposure of continental and marine sediments (Serravallian – Messinian), and a remarkable presence of well-developed turbiditic deposits. These deposits have been mainly studied focusing on sedimentological and tectonic aspects, but other features, as the ichnological content, especially relevant in this facies, has not been studied in detail. Here we present a preliminary study of one of the most representative turbiditic sections from the Tabernas Basin, the *Rambla de Tabernas* section, allowing interpretation of palaeoenvironmental conditions and differentiation of sub-environments in the turbiditic system. The *Rambla de Tabernas* section is a 50 meters long section mainly composed of brownish and olive grey compacted mudstone interbedded with fine- to medium-grained sandstone moderately to poorly sorted. Lithological information, together with sedimentary structures (e.g., parallel and cross laminations) allows differentiating some Bouma turbiditic sequences. Regarding ichnological content, a trace fossil assemblage composed of 14 ichnotaxa is observed, with a pre-depositional traces represented by ?*Circulichnis*, *Cosmorhaphe*, *Desmograpton*, *Helminthorhaphe*, *Megagrapton*, *Paleodictyon*, and *Urohelminthoida*, and a post-depositional association with *Chondrites*, *Ophiomorpha*, ?*Palaeophycus*, *Phycodes*, *Planolites*, *Scolicia*, and *Thalassinoides*. This assemblage can be assigned to *Nereites* ichnofacies, commonly associated to turbiditic deposits. On this general ichnofacies context, variations in trace fossils distribution and Bioturbation Index along the section, allow to differentiate between the *Paleodictyon* ichnosubfacies and *Ophiomorpha rudis* ichnosubfacies, associated to different sub-environments of the turbiditic system. Intervals dominated by *Cosmorhaphe*, *Helminthorhaphe*, *Paleodictyon* and *Urohelminthoida*, assigned to the *Paleodictyon* ichnosubfacies, can be related to the distal part of the turbidite lobe deposit (fan fringe). Those characterized by a major presence of *Ophiomorpha*, *Scolicia*, *Thalassinoides* and *Chondrites*, and a higher abundance, assigned to the *Ophiomorpha rudis* ichnosubfacies, represent a more proximal area within the turbiditic system. This preliminary study supports the usefulness of the ichnological analysis to improve the interpretation of these turbiditic deposits, providing additional information of scientific relevance about depositional sub-environment into the turbiditic system, but also of economic importance considering the interest of these deposits as potential analogues to reservoir facies.

Keywords: lacustrine, marine, delta, trace fossil, Paleocene, Lishui-jiaojiang Sag

In this study, integrated ichnological, sedimentological, geochemical, and seismic analyses of the Lower-Middle Paleocene succession (Yueguifeng and Lingfeng formations) were undertaken to provide insights into the reservoir and source rock predictions in the Lishui-jiaojiang Sag of the East China Sea Shelf Basin. Our studies have revealed that the Lower Paleocene Yueguifeng Formation, the chief source rock in the Lishui-jiaojiang Sag, is actually characterized by a package of mixed coarse-grained and fine-grained deposits in a lacustrine setting. During the accumulation of the Yueguifeng Formation, there existed a predominant clastic influx from the west via the gentle-slope delta system while the local clastic supply from the steep-slope fan system in the east cannot be overlooked. Despite a lack of core samples of the Yueguifeng Formation, the geochemical and paleontological evidences suggest its depositional transition from independently segmented freshwater lakes to a partially closed bay condition. Thereby, the distribution of good-quality lacustrine source rock of the Yueguifeng Formation exhibits significant heterogeneity.

The ichnofossil assemblages and sedimentary structures revealed by core samples have shedded lights on the paleoenvironments and stratigraphic evolutions of the Middle Paleocene Lingfeng Formation. Two facies associations (delta front and prodelta), recorded by an overall transgressive transition from *Skolithos* to *Cruziana* ichnofacies, are interpreted from the cores. The delta front deposits, characterized by intensely bioturbated sandstones with thinly interbedded mudstones, exhibit a low-diversity trace fossil suite of *Ophiomorpha* and *Thalassinoides*. The prodelta deposits, in contrast, document a high abundance and diversity of marine trace fossil assemblage of *Asterosoma*, *Chondrites*, *Ophiomorpha*, *Planolites*, *Phycosiphon*, and *Thalassnoides*. In addition, the presence of high-frequency interbedded sandstone and mudstone features attests to the influence of storm-generated currents during depositions.

Paleopedologic, ichnologic, and sequence-stratigraphic characterization of the early Miocene Khari Nadi Formation, Kutch basin, Gujarat state of India

Krishanu Chatterjee[1*], Sudipta Dasgupta[1], Seema Singh[2], Ayush Srivastava[1], Mohuli Das[1]

Keywords: Paleosol, Khari Nadi Formation, mollisol, Termitichnus ichnofacies, micromorphology, Kutch basin

The presence of multiple well-developed paleosol horizons and their associated continental ichnofacies in the Aquitanian Khari Nadi Formation (KNF) testify a number of subaerial-exposure episodes having significant duration to produce them. This observation apparently contradicts the previous understanding in the literature of an overall deepening of the basin during the Aquitanian Age. Mesoscopic field observation reveals that the intervals toward the base as well as toward the top of the formation demonstrate the most prolific development of paleopedogenetic features, e.g., soil horizonation, formation of peds, mottling, presence of fossilized plant-root traces (i.e., grey rhizotubule and surrounding yellow-brown rhizocretion). The diagnostic redoxiomorphic features with well-developed mottling indicate substantial water logging and characterize the paleosol horizons to be “gleyed” (Mollisol) with a skewed prominence of the B-horizons. The mesoscopic observation has also been substantiated by the micromorphological studies providing evidences of the presence of micro-structures (peds), various types of voids (planes, channels, chambers), characteristic coarse-fine distribution (c/f ratio), and b-fabric with a copious number of intrusive pedofeatures (e.g., coating, hypo-coating, quasi-coating, Fe-Mn nodule) and matrix pedofeatures (e.g., degree of impregnation and development of redoxiomorphic feature).

Extensive termite activity, superimposed on the softground shallow- and marginal-marine ichnofacies associations, has been documented. Its ichnodiversity is restricted and includes ichnogenera Vondrichnus and Termitichnus – both showing several of their ichnospecific preservations. High bioturbation intensity and low ichnodiversity of the isopteric trace fossils along with the association of root traces characterize the Termitichnus ichnofacies that supports the paleopedological features of mollisol development, elucidates a warm and humid Aquitanian paleoclimate and a very shallow paleo-water table, and concur with the earlier paleobotanical studies suggesting a closed tropical evergreen forest. Organism-paleosol interaction has also been found in micromorphological study indicative of trace producers. Delineation of burrow wall and grainsize alignment along it (i.e., fine-grained coating and long-axial alignment of coarse grains parallel to the wall) are the two criteria to distinguish burrows from the surrounding matrix.

This novel integration of the paleopedology and ichnology strongly evidences multiple low-order Aquitanian regressions in the Kutch basin culminating at least twice toward the lower and the upper ends of the interval. Such sharp high-frequency baselevel fluctuations must have been superposed on a previously suggested 3rd-order early Miocene transgression.

Endobenthic colonization of Cambrian fan delta deposits associated to basement uplifted blocks in southwestern Saskatchewan, Canada

Andrei Ichaso Demianiuk[1*], Luis Alberto Buatois[1], María Gabriela Mángano[1], Patty Thomas[2], Don Marion[2]
1. Geological Sciences, University of Saskatchewan, Saskatoon, Saskatchewan, CANADA
2. North American Helium Inc., NAH, Calgary, Alberta, CANADA

Keywords: Cambrian, fan delta, Basal Sandstone Unit, Earlie Formation, trace fossils, Canada

In southwestern Saskatchewan, middle Cambrian strata of the Basal Sandstone Unit (BSU) and the Earlie Formation are found in subsurface resting on the Precambrian basement. In the studied area, these units record deposition from fan delta wedges to embayment settings accumulated within the context of an epeiric sea, formed during a transgressive event that covered the western margin of Laurentia during the Paleozoic (Slind *et al.*, 1994). In recent years, the economic interest in Saskatchewan's Cambro-Ordovician rocks has increased after the discovery of large amounts of helium in the southwestern regions of the province (Yurkowski, 2016). This led to the development of different exploration and production projects. Core material — recovered by North American Helium (NAH) from eight wells drilled at the flanks of tectonically uplifted Precambrian blocks in southwestern Saskatchewan — from helium-bearing rocks comprised in the BSU and the Earlie Formation was logged in detail. Sedimentologic and ichnologic analyses reveal that environmental stressors, such as coarse grain-size, rapid deposition, and very high hydrodynamic energy, have direct impact on bioturbation intensities and trace fossil distribution in fan deltas. Basal and proximal subaerial fan delta deposits are dominated by very coarse-grained sandstone and boulder conglomerate that are devoid of bioturbation. Subsequent transgression led to landward migration of the fan-delta system and the accumulation of subaqueous mid- to distal-fan sandstone deposits on top of proximal facies. Mid-fan and fan toe deposits reveal subaqueous conditions, and they are characterized by coarse- to medium-grained sandstone and mudstone facies displaying rapid bioturbation events in between sedimentation episodes, when environmental stressors were ameliorated. Transgressive embayment deposits accumulated after the abandonment of the fan delta system once it was completely flooded during Earlie Formation times. Proximal to distal bay deposits consist of various glauconite-rich, coarse- to very fine-grained sandstone and mudstone facies with interbedded carbonate rocks. These embayment deposits display high levels of bioturbation intensity, reflecting stable environmental conditions that favored endobenthic colonization. The presence of bioturbation in both subaqueous fan delta and transgressive deposits provides further support to the view that Cambrian levels of biogenic mixing were high in the absence of extreme environmental stressors. Our study underscore the importance of evaluating sedimentary facies changes to assess the impact of environmental factors prior to making evolutionary inferences.

Ichnofossils from the Late Permian to the earlist Triassic at Meishan, South China and their environmental implications

Ding Yi[1*]
1. College of Environment and Life Sciences, Weinan Normal University, Weinan, Shaanxi, CHINA
E-mail: dingyi@nwu.edu.cn

Keywords: end-Permian, mass extinction, ichnofossil, Meishan, redox evolution

The end-Permian mass extinction (EPME) was one of the most devastating biotic crises in the Phanerozoic (Erwin, 2006). Over 80% of marine species were annihilated in this catastrophe (Stanley, 2016). Previous studies of this mass extinction have mainly concentrated on geochemistry and body fossil records. Meishan section is the Global Stratotype and Point for the Permian–Triassic boundary in South China, yeild abundant ichnofossils. A High-resolution investigation of ichnofossils from the Meishan section reveals the presence of *Arenicolites* isp., *Chondrites* isp., *Diplocraterion* isp., *Palaeophycus* isp., *Planolites* isp., *Skolithos* isp., *Thalassinoides* isp., *Zoophycos* isp.. Ichnofabric index and ichnofossil assemblages in the Meishan section provide an opportunity to detect the palaeoceanic redox evolution in the Permian–Triassic transition. Before the EPME (Beds 1 to 24d), the sediments are strongly bioturbated (ii=5–6), representing a high oxygen level. During the EPME interval (Beds 24e to 27), both high inchnofabric index (ii=4) and low ichnofabric index (ii=1–2) occurr in this interval, indicating a fluctuation of oxygen level. During the post-EPME interval (Beds 28 to 30), the ichnofabric index distinctly dropped, no bioturbation can be observed. The ichnological data suggest that the bottom waters were not permanently anoxic, but interrupted by aerobic periods during the Permian–Triassic transition.

Keywords: bioturbation, burrow halo, substrate lithification, firmground, hardground

Burrowing organisms in the early Cambrian are often known for disturbing the microbial mat dominated seafloor, promoting the cycling of nutrients and oxygen and creating a mixed, loose layer in the substrate. Here we provide new insights on the influence that bioturbation had in modifying substrates in the Cambrian. Dense, morphologically complex burrows with thick diagenetic halos are manifest at several horizons in the Houjiashan Formation (Cambrian Stage 4) of North China. Fragmented burrow parts with their diagenetic halo indicate early and preferential lithification starting from the burrow margins and affecting the surrounding matrix. With increasing amount of bioturbation and the development of diagenetic halos, as well as depleted d13C values within the micrite halos suggest that these originally open conduits (i.e., burrows) facilitated the gradual consolidation and lithification of the soft substrate and transformed it into a firmground and, locally, incipient hardground. The possibility that bioturbation drives and expedites substrate lithification during the Cambrian may be a plausible explanation for the widespread occurrence of consolidated carbonate substrates and their subsequent erosion and reworking during this geological period.

Resilience of infaunal ecosystems during the Early Triassic greenhouse Earth

Xueqian Feng[1], Zhong-Qiang Chen[1*]
1. State Key Laboratory of Biogeology and Environmental Geology, China University of Geosciences, Wuhan, Hubei, CHINA
E-mail: zhong.qiang.chen@cug.edu.cn

Keywords: soft-bodied animals, trace fossils, ecosystem engineering, ichnodiversity, trophic-group amensalism

The Permian-Triassic mass extinction severely depleted biodiversity, primarily observed in the body fossil of well-skeletonized animals. Understanding how whole ecosystems were affected and rebuilt following the crisis requires evidence from both skeletonized and soft-bodied animals; the best comprehensive information on soft-bodied animals comes from ichnofossils. We analyzed abundant trace fossils from 26 sections across the Permian-Triassic boundary in China, and report key metrics of ichnodiversity, ichnodisparity, ecospace utilization, and ecosystem engineering. We find that soft-bodied animals recovered first in deeper marine habitats, and infaunal ecologic structure was well established in the early Smithian. Decoupling in diversity between deposit feeders and suspension feeders in carbonate ramp-platform settings implies that an effect of trophic group amensalism could have delayed the recovery of non-motile, suspension-feeding epifauna in the Early Triassic. This differential reaction of infaunal ecosystems to variable environmental controls thus played a significant but heretofore little appreciated evolutionary and ecologic role in the overall recovery in the Early Triassic hot ocean.

Softground and firmground opportunistic Thalassinoides (-Gyrolithes) ichnofabric and paleosol ichnofabric of the early Miocene Chhasra Formation, Kutch basin, Gujarat state of India

Ayush Srivastava[1*], Sudipta Dasgupta[1], Seema Singh[2], Mohuli Das[1], Krishanu Chatterjee[1]
1. Department of Earth Sciences, Indian Institute of Technology (IIT) Bombay, Mumbai, Maharashtra, INDIA
2. Department of Geology, Punjab University, Chandigarh, Punjab, INDIA
E-mail: 194063007@iitb.ac.in

Keywords: Paleosol, Chhasra formation, Kutch basin, Mixed siliciclastic-carbonate, Thalassinoides ichnofabric, Termitichnus

The Burdigalian Chhasra Formation (CF) of Kutch basin exemplifies a mixed-siliciclastic-carbonate depositional setting manifested by recurring alternations of carbonate and siliciclastic facies. The CF consists of the lower Claystone and the upper Siltstone members. The Claystone Member (an obvious misnomer) is characterized by the intercalated deposition of thick bioclastic carbonate, siltstones, claystones, and sandstones. These siliciclastic horizons contain predominantly pedogenized sandy-siltstone intervals, in which often the occurrence of complete paleosol horizonation can be observed (e.g., ~ 4 m thick amalgamated paleosol along the Berwali river).

The paleosol interval has been investigated with the establishment of paleo-pedogenic features (ped structure, mottling, texture, boundaries, presence of nodules, and fossil root traces). Both top and bottom contacts of the interval are sharp. The paleosol layer overlies a swaley-cross-stratified sandstone bed (thickness ~ 90 cm). A molluscan bioclastic packstone bed overlies the paleosol horizon. The section records both shallow-marine and continental ichnocoenoces overprinting each other.

The underlying sandstone shows a monospecific localized and sparce (BI 1) softground *Thalassinoides* ichnofabric. The overlying packstone demonstrates a monospecific softground *Thalassinoides* ichnofabric though with high to complete (BI 4-6) bioturbation obfuscating identification of any/all other softground trace fossils if were present. Both the units do not show any sign of pedogenesis. At and below the contact between the underlying paleosol and the overlying packstone, *Thalassinoides* transforms into firmground *Gyrolithes* forming a compound ichnotaxa into the paleosol.

The paleosol ichnofabric consists of *Vondrichnus*, *Termitichnus*, and other yet unclassified insect traces with the bioturbation intensity varying conspicuously at different subintervals of the amalgamated horizon and also laterally (BI 3-5). The amalgamated horizon is partitioned by the reactivation surfaces, along which lenses of fully-bioturbated (BI 6) siltstones with monospecific firmground *Thalassinoides* ichnofabric can be observed. From the reactivation surfaces downward, this firmground *Thalassinoides* ichnofabric suite is overprinted on the amalgamated paleosol fabric, hence also locally crosscutting its *Termitichnus* suite.

The early Miocene megasequence of Kutch basin, as a whole, and the Claystone Member, in particular, have earlier been reported to be deposited under a sustained 3rd-order (~7 Ma) transgressive systems tract (TST) (Kumar et al., 2009, 2016). The aforementioned facies association can be observed throughout the Claystone Member making its sequence-stratigraphic context further complex with recurring deposition of the upper-shoreface sandy tempestites, the subaerial exposure intervened by brackish incursions, and deposition of bioclastic packstone event-concentration (sensu Kidwell, 1991) beds. Such facies variations could be both autogenic or high-frequency lower-order allogenic. Both ways impart and maintain a set of ecological stresses on the shallow- and marginal-marine infauna making both the softground and firmground ichnofabrics solely dominated by the opportunistic generalist crustacean trace makers with their domichnial, deposit-feeding, and agrichnial ethology and suppressing all other forms.

Ichnological and Sedimentological characteristics of the Oligocene Maniyara Fort Formation, Kutch basin, Gujarat, India

Kanchan Prasad[1*], Sudipta Dasgupta[1]
1. Department of Earth Sciences, Indian Institute of Technology Bombay, Mumbai, Maharashtra, INDIA
E-mail: kanchan.geo@iitb.ac.in

Keywords: high-energy open-shelf, tropical bioclastic carbonate, ichnofabric, Oligocene, Kutch basin.

Along the banks of mostly N-S or NE-SW flowing streams, outcrops of varying thickness (ca. 30-35 m) of the Oligocene Maniyara Fort Formation (MFF) of the Kutch basin is exposed parallel to the present semi-circular coastline of the Gujarat state of India. Earlier works suggest that the formation was deposited during a marine transgressive environment varying from lagoonal to a high-energy open-shelf environment. Biswas (1992) subdivided MFF into four members, viz., the Basal, Lumpy Clay, Coral Limestone, and Bermoti members. The present study intends to construct a novel, comprehensive, and integrated ichno-sedimentological-stratigraphic model for the Oligocene of Kutch. The facies at the three studied sections, i.e., along the Berwali, Kharai, and Waior rivers, unequivocally consist of the alternations of moderate to completely bioturbated horizons of nummulitic grainstone, glauconitiferous shale, calcareous claystone, and thick cemented fossiliferous packstone-wackestone intervals. Numerous distinctive ichnofabric models can be defined based on the ichnotaxonomy, ichno-diversities, individual abundances of trace fossils, overall bioturbation indices, and tiering and inter-ichnotaxa interactions.

The primary sedimentary structure in nummulitic grainstone facies comprises of planar and trough cross-stratification which is disrupted by intense bioturbation of long networks and mazes of Thalassinoides horizontalis and T. suevicus having 6-8 cm diameter. It is the most common type of bioturbation present in the Oligocene of Kutch. Reburrowing by Thalassinoides, making a composite Thalassinoides ichnofabric, can also be observed that indicates multiple episodes of colonization along with changing sea-bottom conditions. The basal glauconitic shale of MFF unconformably overlies the middle Eocene Fulra Limestone, indicating a sharp transgression during the Oligocene. The green shale facies, which host abundant glauconite pellets, is finely laminated and sparsely bioturbated (BI 1) with Thalassinoides. The Coral Limestone Member characterized by Lepidocyclina packstone facies comprises of calcareous claystone in the lower part and hard nodular fossiliferous limestone with abundant coral bioherms in the upper part. The packstone facies exhibit swaley cross-stratification and laminae at places with localized pinnacle corallite bafflestones and trace-fossil assemblage of Thalassinoides, Ophiomorpha, Paleophycus, Psilonichnus, and Chondrites with moderate to intense bioturbation (BI 3-5). A high-energy open shelf environment is suggested for this member. The uppermost Bermoti Member is characterized by the Spiroclypeus packstone facies, which is laterally extensive throughout the onland exposures and is highly fossiliferous. This facies is characterized by a trace-fossil assemblage of Thalassinoides, Skolithos Rhizocorallium and Taenidium with relatively intense bioturbation (BI 5-6). Ichnofabric analysis conducted by correlating the studied sections over the area demonstrates the overprinting of hardground bioerosion belonging to Trypanites ichnofacies (Entobia and Gastrochaenolites) on the former burrows and body fossils (bivalves, echinoids, and gastropods) at specific intervals corresponding to the periods of stagnancy and/or low-net sediment accumulation. Ethologically, they all represent domichnia and fodinichnia groups and indicate shallow-marine conditions which align with previous studies on lithofacies and depositional settings of the area.

Nummipera saraswatii, a new armored ichnospecies, and the Nummipera-Cylindrichnus ichnofabric in a parautochthonous biofabric: A transgressive bank setting from the early Eocene Naredi Formation, Kutch basin, India

Mohuli Das[1*], Sudipta Dasgupta[1], Renzo D'souza[1]
1. Department of Earth Sciences, Indian Institute of Technology Bombay (IIT Bombay), Mumbai, Maharashtra, INDIA
E-mail: mohuli.das@iitb.ac.in

Keywords: Armored burrow, Nummipera saraswatii, Nummipera-Cylindrichnus ichnofabric (NCi), Naredi Formation, Early Eocene Climatic Optimum (EECO), Kutch basin

The ichnogenus *Nummipera* Hölder 1989 is one of the significant ichnogenera amongst ten rare armored burrows, which reflect the ability of marine infaunal producers to assemble and manipulate available clasts defining the burrow architecture. *Nummipera eocenica* has earlier been designated as the sole type species of the ichnogenus *Nummipera* with the ichnotaxobases: vertical to oblique orientation, reinforced wall ornamented with the tests of larger benthic foraminifera (LBF), no branching, lumen containing the host material, and no spreiten. In the *Assilina* packstone facies of the early Eocene (Ypresian) Naredi Formation from the Kutch basin in western India, a distinctively different ichnospecies, *Nummipera saraswatii*, as we propose here, has been documented. The description of *N. saraswatii* along with the ichnotaxobases are as follows: (1) Horizontal to gently inclined (< 25º), tubular, intermittently vertically flattened (circular to elliptical cross-section), straight to feebly curved, and with two different diameter classes, i.e., 1-1.3 cm (narrower) and 2-3 cm (wider); (2) Well-compacted lining with mostly unbroken megalospheric (A-form) tests of *Assilina* sp. that are aligned at 0º to 30º to the burrow axis both towards and away from the lumen. The wall contains either a single armored lining of tests or a complex structure with multiple concentric layers; (3) Lumen both actively and/or passively filled with either (A) passively filled homogeneous host material or (B) alternate coarse- and fine-grained ferruginous-cemented sandy active backfill showing pinch-and-swell (annulated) variation of diameter; and (4-5) No branching or spreiten. It envisages both crustacean and polychaete producers with distinctive burrow morphology and ethology. The wider burrows are interpreted to be produced as domichnia for sheltering or hiding by crustaceans shown by the irregular inner wall reinforced by their appendages with poorly sorted *Assilina* tests and active backfill. Towards upper bedding surface, the wider burrows rarely transform into *Thalassinoides* isp., thereby, forming a compound ichnotaxa and affirming the crustacean-producer interpretation. The inferred polychaete-made narrower traces are passively filled with smooth inner wall lined with well-sorted *Assilina* tests and were possibly used as domichnia for protection, seclusion, and prevention from collapse.

The shallow-tiered *N. saraswatii* occurs in association with the deep-tiered *Cylindrichnus concentricus* in the trough-cross-stratified 30 cm-thick bed of packstone that overlies a 40-80 cm-thick wackestone. Both lithounits consist primarily of *Assilina* although some *Nummulites,* various other benthic foramaminifera, and ostracodes components are present in the wackestone. The low ichnodiversity and intense (BI 5) *Nummipera-Cylindrichnus* ichnofabric (NCi) of the packstone depict a depauperated Cruziana ichnofacies deposited in a parautochthonos biofabric of the shelfal bank setting. The unbioturbated wackestone formed in a back-bank restricted lagoonal setting. The non-repetitive NCi is featured in the *Assilina* packstone bed of Naredi Formation and corresponds to the‘maximum flooding zone'. In the Kutch basin, this demarcates an overall deepening and opening of the restricted eutrophic marine condition transitioning to the oligotrophic shelfal bank during the Early Eocene Climatic Optimum (EECO).

Ichnofossils and paleosol from the early Eocene Naredi Formation (Kutch, India): Proxies for construction of an integrated paleo-depositional and high-resolution sequence-stratigraphic model

Mohuli Das[1*], Sudipta Dasgupta[1], Seema Singh[2]
1. Department of Earth Sciences, Indian Institute of Technology Bombay (IIT Bombay), Mumbai, Maharashtra, INDIA

Keywords: Camborygma, lungfish aestivation burrow, Skolithos, Macanopsis, paleosol, Eocene Kutch basin

Trace fossils and paleosol are the best proxies for integrating a high-resolution sequence-stratigraphic model along with the regional paleo-depositional and paleo-climatic reconstruction. The present study aims to construct the same for the topmost paleosol (continental) interval of early Eocene (Ypresian) Naredi Formation from the Cenozoic Kutch Basin. The investigated lithology is characterized by a thickening up intercalation of laterite and paleosol (silty shale) horizons, developed by cyclic episodes of erosion, subaerial exposure, and deposition.

The topmost laterite soil profile is of detrital (allogenic) origin due to the absence of conventional laterite horizons (parent rock). Petrographic study has led to the identification of hard laterite, soft laterite or mottled clay zones, and saprolite layers as identified from the micromorphological features (*viz*., plinthite, channel voids, monosteriated b-fabric, undifferentiated micromass, along with coatings, hypocoating, and nodules). This secondary laterite occurs at the paleo-interfluves, consisting of highly weathered trapwash deposits from the Deccan Traps. The silty-shale beds show pedogenic features such as fine-grained subangular-blocky ped development, few medium sized indistinct faint mottles, silty loam to silty clay loam texture, common occurrence of medium to coarse root traces, nodules, very weakly to non-calcareous, and prominent bioturbation – all bearing convincing evidence of subaerial exposure and weakly developed paleosol. The boundaries between the silty shale and laterite layers show gradual transition in a wavy to irregular pattern.

The topmost laterite bed is intensely bioturbated (BI 5), in decreasing abundance with root traces, *Camborygma* isp., and a composite ichnotaxa of vertebrate aestivation burrows and *Skolithos* isp./*Macanopsis* isp., respectively produced by crayfish, lungfish, and arachnids. The silty shale beds represent moderate to high bioturbation (BI 3-4) with the paucispecific assemblage of *Camborygma* burrow systems and root traces. Two different ichnospecies of *Camborygma*, *viz*., *C. symplokonomos* and *C. araioklados*, have been identified at two distinguishing colonization surfaces. Ichnotaxonomy and ichnofabric analyses assisted in better understanding of the ethology of the terrestrial crustacean producers, the alluvial stacking patterns, and the depositional environment. The variation of morphological complexity and ichno-abundance of *Camborygma* burrows serve as a crucial tool for the demarcation of sequence-stratigraphic horizons and fluctuation of the paleo-water table due to the low-order allocyclicity.

The investigated interval has been designated as a pedogenized variety of Scoyenia ichnofacies – a characteristic firmground ichnofacies evolving under alternating subaqueous and subaerial conditions. The paleo-pedological and ichnological investigation leads to interpretation of the paleoclimate to be fluctuating between hot humid to arid condition, with seasonal rainfall and intermittent inundation. The depositional setting has been inferred to be a very shallow lacustrine to lagoonal environment. The shallowing-up and drying-up laterite-paleosol horizon was deposited due to the high-resolution or low-order (*i.e*., higher than 5th order) climatically influenced fluctuations in the sequence-stratigraphic context. The top of the aforementioned sequence demarcates the sequence boundary (the Lutetian forced regression), which is a subaerial unconformity separating it from the overlying fully marine Bartonian late lowstand-early transgressive Harudi Formation.

Keywords: Bioherm, carbonate mound, Nummipera saraswatii, Early Eocene Climatic Optimum (EECO), larger benthic foraminifera (LBF), Naredi Formation

The early Eocene (Ypresian) succession of Naredi Formation (NF) belonging to the Cenozoic Kutch basin of western India attributes to an ideal case study of mixed siliciclastic-carbonate depositional system developed in a pericratonic, partly-restricted, marginal-/shallow-marine setting. The lower succession of NF is dominated by argillites, whereas the mid-upper interval consists of the mixed-carbonate-argillite units.

The mixed-carbonate-argillite member belonging to the shallow-benthic zone (SBZ) 11 of NF consists of, from bottom to top, (A) wackestone bed; (B) *Assilina* packstones with *Nummipera-Cylindrichnus* ichnofabric; (C-E) brown, red shale, and greenish-grey shales; (F) semi-consolidated carbonate mudstone-wackestone hosting *Nummipera* bioherms; (G) calcareous brown shale; (H) *Assilina* packstones with monospecific *Thalassinoides* ichnofabric. Beds (A, C-E, and G) are unbioturbated.

The present study focuses on the semilithified carbonate mudstone-wackestone bed (about 1.75 m thick) hosting a discontinuous biohermal interval of intensely bioturbated, sparsely bioeroded, and lithified grainstone mounds (diameter 15-30 cm for each) characterized by nesting of larger-benthic-foraminifera (LBF) tests unlike the host lithology. The bioherm is unique for its accumulation and growth induced by armored burrows. The armored burrows (*Nummipera saraswatii*) have been identified by their characteristic resistant and discrete walls reinforced with bioclasts. An individual *N. saraswatii* is a horizontal to sub-horizontal tube (diameter 1-1.3 cm) with straight to gentle curvature and circular to elliptical cross-section. The burrow wall shows well-compacted smooth inner lining with imbricated, well-sorted and rarely broken A-form tests of *Assilina* sp., aligned parallel to the burrow axis or gently inclined towards and away from it. In each mound, the wall-ornamenting tests define a complex wall structure with multiple concentric layers. The lumen, devoid of any bioclast, is passively filled with micritic cement. Branching or spreiten are absent. N. saraswatii defining the bioherms are interpreted to be produced by the facultative vermiform infauna (e.g., polychaetes) as the gregarious dwelling traces for nesting, protection, reproduction, and possibly agricultural purpose.

The diagenesis of the bioherm initiates concentrically around the *N. saraswatii* burrows at eogenetic stage where the processes are essentially fabric selective along with porosity reduction due to precipitation of carbonate mineral. The cementation progresses from being the Mn-bearing calcite-rich core (marking anaerobic metabolism) abruptly changing into the ferroan calcite-rich rim (aerobic metabolism). Simultaneous compaction and diametric expansion take place consequent to burial and outward cementation, thereby, opening up the tensile septarian gashes oriented perpendicular to the long-horizontal axes of each bioherm. From circumference inward of bioherm, secondary open burrows are observed to recolonize the primary *N. saraswatii* burrows. Sponge borings (*Entobia* isp.) can be observed only at the side circumference of the bioherm outer rim and are absent at their top and interior. The bioherm facies only occurs once in the non-repetitive carbonate mudstone-wackestone facies corresponding to the highstand systems tract (HST) in the oligotrophic open shelf during the Early Eocene Climatic Optimum (EECO). They are interpreted to be formed as the gregarious coven of facultative vermiform armored-burrow producers, where they entrap and accumulate LBFs using mucus, and feed on the suspended and precipitated nutrients through a complex assortment of trophic strategies.

Seismically induced soft-sediment-deformation structures (sand volcanoes) and the ichnological responses from the early Miocene Khari Nadi Formation of Kutch basin, western India

Sudipta Dasgupta[1*], Ayush Srivastava[1], Krishanu Chatterjee[1], Mohuli Das[1]

E-mail: sdasgupta@iitb.ac.in

Keywords: Sand volcano, ichnoseismite, ichnofacies, Khari Nadi Formation, Kutch basin, Miocene

Distinctive sedimentary structures called the soft-sediment-deformation structures (SSDS) are developed by post-burial deformation of unconsolidated sediments. The sand volcanoes can truly typify the SSDS, which indicates particularly paleo-earthquake activities, defining the concept of “seismite”. The Kutch basin has been tectonically active due to the Indian-Eurasian plate convergence since the onset of eastern Gondwana rifting to the later tectonic inversion during the Cenozoic. A series of sand volcanos from the Aquitanian (early Miocene) Khari Nadi Formation are exposed along the Khari River trail near Aida village. The process-sedimentary characteristics are manifested by the sand volcanoes exposed along the transitional stratum separating the shallow-marine deposits below and the non-marine deposits above.

The section consists of four layers, from bottom to top: viz., fine-grained sand (layer I), shale (layer II), medium-grained sand (layer III), and fine-grained sand (layer IV). Preservation of marine trace-fossil assemblages defined by *Psilonichnus* isp., *Thalassinoides* isp., *Ophiomorpha annulata*, and *Planolites* isp. belonging to the Psilonichnus and Skolithos ichnofacies can be documented in the layers I and II with overprinting of deep-tier continental trace fossil *Vondrichnus* isp. coming from the layer IV. The swaley-cross-stratified layer III is a sand bed bioturbated with *Ophiomorpha nodosa* and, the sand volcanoes can be observed in this layer. The base of overlying layer IV is conformable and sharp. The layer III preserves both the marine (*O. nodosa*) and overprinted continental (*Vondrichnus* isp.) ichnofossils along with small-scale synsedimentary faults surrounding the central/axial feeders of the sand volcanoes, resembling caldera-like structures. The fabric produced by the crosscutting relationship of the *O. nodosa* burrows and the faults definitely indicate their syndepositional origin and the coeval occurrence of both liquefaction (the sand volcano extrusion and undulated layers III-IV contact) and brittle deformation (synsedimentary faults). The first generation of *O. nodosa* is disrupted by the faults therefore predates the latter. The second generation of *O. nodosa* burrows cut the faults across, because they were produced after the faulting and liquefaction event. The layer IV contains an intricate three-dimensional network of termite nests (*Vondrichnus* isp., *Termitichnus* isp.) and root traces within the channel-fill fine-grained sand and is devoid of any marine trace fossil. The deep-tier *Vondrichnus* isp. burrows are found to penetrate all the way to layer I and cut across the SSDS and *O. nodosa* in layer III.

Hence, it is proposed that a seismic event resulting in a tectonic upliftment and the consequent shallowing of the basin can be attributed from the development of sand volcanoes, since the horizon (layer III) containing them marks the transition from the marine to continental sedimentary regime – pointing towards a tectonically-influenced allogenic change for the basin. The observed evidences appear to contradict previous works that suggested a continuous rise of base level throughout the Aquitanian and Burdigalian time. We suggest that these two different phenomena belong to two different sequence-stratigraphic hierarchy with the tectonic uplift being a lower-order (higher-resolution) phenomenon within the Khari Nadi Formation sequence.

Keywords: Siphonichnidae, Rosselichnidae, deposit-feeders, trace fossils, bioturbation, ethology

From two opencast lignite mines from the restricted Kutch basin located at Matanomadh and Umarsar in the state of Gujarat, a monospecific and sparse (BI 0-1) preservation of the complex burrows has been studied and is reported herein from the intercalated organic-rich shale intervals between the middle Eocene amber-bearing lignite seams. The ichnotaxon bears the morphological and, thereby, behavioral affinity to both the ichnofamilies Siphonichnidae and Rosselichnidae.

The burrow has a vertical to oblique orientation and circular to elliptical horizontal section. It is characterized by a series of stacked concave-upward laminae and a concentrically lined axial cylindrical shaft, which penetrates through the conical components. Each individual conical laminae represents the trace of the feeding funnel that is radially fine-striated, as it appears, by a tentacular detritus-feeding organism. Bulbous undulations, particularly along the funnel perimeter, can be observed, which might have been produced due to the localized liquefaction by the moving tentacles. The trace-maker might be capable of sequestrating nutrients and waste along the margin of the shaft, as evidenced in the form of alternate concentric muddy and detrital organic linings. At places, the muddy lining can be either bright green glauconitic or bearing mud from the host lithology or dark brown Fe-oxide rich. The innermost lining can frequently be found bearing authigenic mm- to sub-mm-scale pyrite crystals – both equant and framboidal. Elemental maps derived from the X-ray-fluorescence-spectroscopic analysis also show enrichment of Fe-sulfides along the wall of the central shaft. This is indicative of metabolically induced early diagenetic decomposition of organic matter and the subsequent precipitation of authigenic Fe-minerals along the burrow walls. The lumen appear to be either empty or passively filled.

We postulate that the trace maker is a sessile, trophic generalist, and opportunist bivalve that can resort to combining the surface-detritus feeding, agrichnial chemosymbiosis, and possibly also suspension feeding strategies for its survival exploiting an oxygen-depleted and low pH ambient conditions with possible salinity fluctuation. The niche was unfavorable for colonization by any other common dysoxic trace producers, even the deep endobenthos. The empty shaft suggests that the producer occasionally obtained seclusion by sealing the entrance from the extreme events of ambient chemical changes (e.g., drop in pH or salinity) at the sediment-water interface.

The lithofacies association and succession in the mines are contrastingly different from elsewhere in the Kutch basin. Previously, paleontological and geochemical studies assigned the interval to be deposited under the restricted marginal-marine lagoonal and/or embayment condition. The ichnological evidence suggests a hyperstressed ultra-restricted condition prevailing inside the deep paleogeographical interior of the topographic furrows provided by the Deccan lava flows that offered a nascent and highly rugged basement for the newly forming Paleogene sea. The stress factors are primarily due to the extreme chemical variations at the basin floor and fluid-mud activity.

Ichnology and sedimentology of the tide-influenced marginal-marine setting within a restricted paleo-embayment during Eocene in the Kutch basin of Gujarat, India

Renzo D'souza[1*], Sudipta Dasgupta[1], Mohuli Das[1], David Rajkhowa[1]

E-mail: renzo.dsouza@iitb.ac.in

Keywords: Trace fossils, ethology, tidal processes, brackish-water ichnofauna, bay-head delta, Kutch

Embayments having a limited connection to the open ocean are among the most stressful marine environments due to a complex and dynamic interaction of various physicochemical factors. These factors include the periodic fluctuations in hydrodynamic energy resulting in the varying salinity, fluid-mud activity, sedimentation-erosion rates, water turbidity, and dissolved oxygen content. The embayments, especially in their furrow-shaped interiors, receive enhanced tidal-energy dissipation; and, in combination with receiving the terrestrial influx, they offer further accentuation of such factors. Such extreme paleoenvironmental conditions, which vary both spatially and temporally within the embayment, drastically limit the benthic colonization of these regions.

Sedimentological and ichnological data from the outcrops exposed between Saran Nani and Jhulrai villages in the western Kutch basin represents a shallow tidal channel-interfluve-bayhead delta complex. The tidal channel deposits are characterized by bi-directional, mud-draped, trough-cross-stratified sandstones that are dominated by *Ophiomorpha-Paleophycus* ichnofabric. The interfluve deposits are characterized by thinly laminated, organic-rich mudstones having a monospecific *Camborygma* ichnofabric.

Facies in the Jhulrai section are arranged in a parasequence recording an overall progradation from prodelta to deltafront deposits separated by an amber-rich transgressive lag deposit that demarcates a flooding surface. The distal prodelta deposits are characterized by thick organic-rich mudstones containing *Chondrites* isp. (BI 0-1). Relatively small scale (2.8 m height; 36 m length), heterolithic-dominated coarsening-upward clinoform foreset with tidal bundles and rhythmites (lenticular to wavy laminae), and low-intensity bioturbation (BI 0-2) and sporadic lateral distribution of trace fossils (e.g., *Paleophycus* isp and *Asterosoma* isp.) characterize the deltafront. The proximal prodelta deposit of the second upper sequence above the flooding surface consists of heterolithic fine-grained-sand and mud intercalation having sparse bioturbation by *Thalassinoides* isp. and *Cylindrichnus* isp. (BI 0-2).

Ichnofauna across these sub-environments display (1) conspicuously reduced ichnodiversity, (2) dominance of infaunal structures, (3) stunted trace fossils, (4) simple structures produced by trophic generalists that point towards highly stressful conditions controlling benthic colonization accentuated by the basin's paleotopograhical constraints in the studied sections as offered by the Deccan Traps basement. The recognition of the above tide-influenced facies association as aided by ichnological analysis helps in refining the transgressive shoreline trajectories developed in an Eocene, tropical, yet, low sediment-supply environment.

Keywords: Fine-grained depositional systems, oxygen, traction structures, bioturbation, Neuquén Basin

In the last decades, new advancements on mud sedimentology triggered a renewed interest on fine-grained depositional systems. Of these, organic-rich systems are of special importance for unconventional reservoir exploration and development. The Upper Jurassic-Lower Cretaceous Vaca Muerta Formation from Argentina represents one of the most important unconventional reservoirs in the world, showing a high organic carbon content. This formation constitutes bottomset and foreset locations of a mixed carbonate-siliciclastic, shelf-margin, subaqueous clinoform system, typically displaying basin and slope environments. However, m-scale successions consisting of laminated, rippled and bioturbated, mixed to calcareous, crinoidal mudstone and fine to coarse mudstone are interbedded in this clinoform succession. These deposits were interpreted as produced by semi-permanent, low-concentration contour currents in drift environments. These drift deposits were recorded in cores from five wells (660.5 m total) located in areas that are currently explored and developed by oil and gas companies. An ichnofabric analysis was carried on these drift deposits in order to understand paleoenvironmental controls on trace fossils.

The contourite drifts record *Crininicaminus* isp., *Lockeia siliquaria*, ?*Lockeia* isp., *Nereites* isp., *Palaeophycus* isp., *Palaeophycus heberti*, *Phycosiphon incertum*, *Planolites* isp., ?*Skolithos* isp., and escape and equilibrium trace fossils. Four different ichnofabrics were observed: the *Palaeophycus heberti*, *Nereites* isp., *Phycosiphon incertum* and Equilibrichnia-Fugichnia ichnofabrics. Locally, m-thick successions showing an upward decrease and then increase in bioturbation index are comparable to bi-gradational successions of contourites. Benthic activity was shown to be controlled by food distribution, oxygenation, hydrodynamic energy and water turbidity. Suspension feeding strategies in trace fossils (Equilibrichnia-Fugichnia ichnofabric) were associated with food being delivered in suspension by higher energy currents, whereas deposit-feeding behavior (*Nereites* and *Phycosiphon incertum* ichnofabrics) was dominant during times of lower energy currents bringing food to the surface sediments. Hydrodynamic energy controlled the preservation of sedimentary structures, precluding bioturbation during high-energy events. Contour currents increased background oxygen levels of bottom and interstitial waters, although these levels may have remained within the upper dysoxia (as suggested by relatively small burrow diameters). Suspension feeding strategies suggest overall low water turbidity. This example supports the fact that intense bioturbation is characteristic of contourites and provides an example of fine-grained, organic-rich contourites showing a high degree of preservation of sedimentary structures due to oxygen deficiency associated with high organic carbon content.

UNLOCKING THE ARCHITECTURE OF THE COLONIZATION WINDOW: ICHNOFABRICS FROM TIDE-INFLUENCED MEANDER LOOP DEPOSITS (UPPER CRETACEOUS OF THE SPANISH PYRENEES)

Davinia Díez-Canseco[1*], Luis A. Buatois[2], Gabriela M. Mangano[2], Jaime Cuevas-González[1]
1. Department of Environmental and Earth Sciences, University of Alicante, Sant Vicent del Raspeig, Alicante, SPAIN
2. Department of Geological Sciences, University of Saskatchewan, Saskatoon, Saskatchewan, CANADA
E-mail: davinia.diezcanseco@ua.es

Keywords: Ichnofabric, bioturbation control, tide-influenced meander loop, colonization window, redbeds

Tide-influenced meander loop deposits from the Upper Cretaceous Tremp Formation (Pyrenees, Spain) show a heterogeneous ichnofaunal distribution that reflects the variety of processes operating along the point bar lateral accretion and overbank colonization surfaces. Of the six ichnofabrics identified, *Taenidium* 1, *Taenidium* 2, and *Loloichnus* ichnofabrics are present in all the outcrops studied, whereas the *Arenicolites-Taenidium*, *Loloichnus-Taenidium*, and *Planolites* ichnofabrics are less common. Ichnofabrics differ, for instance, in bioturbation index (higher in the upper point bar), inferred behaviour (dominance of dwelling or feeding structures), tiering, ichnotaxonomic composition (Díez-Canseco et al., 2016), or the number of superimposed suites. The key factor controlling ichnofabrics is the morphology of the lateral accretion surfaces and its evolution through time, which determine the architecture of the colonization window linked here to the helicoidal pattern and the velocity of the flow in a meander loop and the successive development of point bars.

Calibrating trace fossil models through geologic time: Macroevolution as a factor in applied ichnology

Luis Alberto Buatois[1*], Maria Gabriela Mangano[1]
1. Geological Sciences, University of Sasktchewan, Saskatoon, Saskatchewan, CANADA
E-mail: luis.buatois@usask.ca

Keywords: Applied ichnology, trace fossils, bioturbation, ichnofacies, facies analysis, paleoenvironmental reconstructions

Ichnology has been extremely successful in facies analysis and paleoenvironmental reconstructions. So far, trace fossil models used in applied ichnology (e.g. the ichnofacies model) have largely been viewed as time-independent in the sense that behavioral convergence has been underscored to the detriment of macroevolutionary innovations. For example, the core of the ichnofacies model highlights those animals facing similar problems (i.e. environmental factors) respond with the same set of solutions (i.e. behavior). As a result, studies analyzing secular changes in ichnofaunal composition (Mángano and Buatois, 2016a,b) have captured, for the most part, the attention of those interested in macroevolutionary aspects but not of those working on sedimentologic and stratigraphic analyses using ichnologic tools. However, we argue that calibrating trace-fossil models according to geologic time is fundamental for applied ichnology. The impact of macroevolutionary trends on trace fossil models used for paleoenvironmental reconstruction is seen at a wide variety of temporal and spatial scales. First, and regardless of the recurrent responses of the benthos to fluctuating environmental conditions, evolutionary innovations have played a paramount role in the type of solutions adopted by organisms to environmental challenges (e.g. the diversification of farming strategies in the deep sea during the Ordovician Radiation). Second, increased ichnodiversity through geologic time reflects the emergence of new key characters (i.e. producers), prompting for calibration of the available models to accommodate these secular changes in the taxonomic richness of animal-substrate interactions (see Buatois and Mángano, 2018). Third, temporal increases in depth and extent of bioturbation impact on the nature of substrates, the preservation potential of discrete events, the degree of decoupling between the sedimentary record of environmental conditions and bioturbation episodes, and the likelihood of the generation of firmground suites without associated erosional exhumation, among other issues. Fourth, onshore-offshore patterns of ichnotaxa through geologic time (e.g. Zoophycos) has been historically problematic from an ichnofacies perspective. Fifth, the resetting of the evolutionary clock during mass extinctions provides a cautionary note on the use of available trace-fossil models in the aftermath of mass extinction episodes. We conclude that evaluation of secular changes in trace fossils is an integral part of the conceptual ichnologic toolbox, not only for those interested in evolutionary paleoecology but also for anyone working in sedimentary geology.

Marine ichnofossils as a record of major bio-environmental events in the Phanerozoic

Qingyang Xu[1], Ruoying Fan[1], Yiming Gong[1*]
1. School of Earth Sciences, China University of Geosciences, Wuhan, Wuhan, Hubei, CHINA
E-mail: ymgong@cug.edu.cn

Keywords: Phanerozoic, biodiversification event, trace fossil, responsive mode, bio-environmental event

In this paper, we analyzed the trace fossil records of the major Phanerozoic biodiversification events, including the Cambrian Explosion, the Great Ordovician Biodiversification Event, and the Mesozoic Marine Revolution. The ichnodiversity and ichnodisparity of marine trace fossils show a positive correlation with biodiversity during these three biodiversification events. The intensity and depth of bioturbation both increased distinctly. The feeding strategies and the behavior of marine trace-makers became more complex. The most prominent change in the trace-making behavior during the Cambrian Explosion is the appearance of vertical burrows (or vertical elements in burrows). The shallow-marine ichnofauna expanded to the deep-marine environment during the Ordovician, as represented by the appearance of morphologically complex deep-marine trace fossils. The marine biodiversity reached the highest in the Cretaceous during the Mesozoic, contributing to increased survival pressure, intensified intraspecific and interspecific competition, and further exploitation of the ecological niches for the benthic communities. Characteristic change during this period is the significant diversification of deep-marine graphoglyptids, with the development of multiple morphological types and feeding strategies. Under the influences of the environmental and biotic changes, marine ichnofaunas became more complicated in morphology and ethology and adopted progressively wider environmental distribution during the Phanerozoic. The marine ichnofaunas displayed increasing penetration depth, transferred from two-dimensional to three-dimensional structures, and radiated from the shallow shelf to the deep sea. These features may be attributed to the adaptive radiation of the marine ichnofaunas along with biodiversity increases during the major biodiversification events.

Keywords: T-OAE, trace fossils, molybdenum, euxinia, Early Jurassic

During the Early Toarcian (Early Jurassic), massive atmospheric inputs of volcanogenic CO_2 led to a rise in atmospheric and seawater temperatures, with subsequent worldwide deposition of black shales. This event, known as the Toarcian Oceanic Anoxic Event (T-OAE), was associated with a major biological crisis in marine environments and widespread anoxia/euxinia in bottom-waters. This work integrates ichnological and geochemical proxies to assess redox conditions across the T-OAE, based on a detailed bed-by-bed study of two outcrops from the Asturian Basin (northern Spain), Lastres and Rodiles. These sections consist largely of limestone and light/dark grey marl beds deposited under oxic to dysoxic conditions, alternating with dark grey marls and black shale intervals deposited under suboxic to anoxic conditions. Different ichnoassemblages are present in the dark grey marls deposited during the T-OAE versus before and after that interval, which are mostly laminated with only rare traces. Integrating ichnological data with molybdenum (Mo) content allows assessment of the variable relations between redox conditions and trace maker activity. We recognised several recurring motifs:

A) Within the T-OAE interval, some dark grey marl beds exhibit an absence of bioturbation, indicating oxygen depletion, but low Mo content (< 2 ppm), showing that suboxic rather than euxinic conditions prevailed.

B) Most laminated dark grey marls and black shale beds deposited during the T-OAE exhibit modest authigenic Mo enrichment (mostly 5-18 ppm), consistent with euxinic pore-waters although bottom-waters may have remained suboxic. Contemporaneous trace fossils are absent in these beds, and only scarce, small, light-infilled *Chondrites* and/or *Planolites* occur. They occasionally overprint the primary lamination but do not deform it, indicating their later appearance during deposition of light grey marls.

C) Below and above the T-OAE interval, underlying light grey marls and overlying dark grey marls are bioturbated by contemporaneous trace makers, showing downward-penetrating dark-sediment-filled burrows into light-bioturbated marls, evidencing that trace makers occupied the benthos during the deposition of these dark sediments, thus indicating generalized oxic bottom- and pore-waters. The dominant ichnoassemblage is mostly the same as that in the light sediments, formed mainly by *Chondrites*, *Diplocraterion*, *Thalassinoides* and *Planolites*. In these sediments, Mo content is very low (lower than crustal average), thus in conformance with the ichnological data indicating oxic bottom-waters.

D) The uppermost black shales, which correspond to the last anoxic episode of the T-OAE, are penetrated by light-sediment-filled burrows from overlying light grey marls deposited under oxic conditions, recording rapid re-establishment of an infaunal community following the anoxic event. This ichnoassemblage, which overprints and erases lamination in these black shales, is similar to that from before the T-OAE, dominated by *Diplocraterion*, *Arenicolites*, *Thalassinoides*, *Planolites* and *Chondrites*. Mo content in these black shale beds is mainly 3-5 ppm, indicating weakly euxinic pore-waters before recolonisation.

In summary, this study highlights the usefulness of an integrative ichnological and geochemical approach in more precisely assessing concurrent bottom-water and pore-water redox conditions. The ichnological data facilitate differentiation between oxic/dysoxic and suboxic/anoxic conditions, while geochemical proxies, in particular Mo content, serve to calibrate reducing intensity in anoxic environments.

Ichnology of the Upper Cretaceous Buda Limestone of Texas: Exploring the trace-fossil content of carbonate lagoonal shelf deposits

Fernando Valencia[1*], Maria Gabriela Mángano[1], Luis A. Buatois[1], Juan Carlos Laya[2]
1. Geological Sciences, University of Saskatchewan, Saskatoon, Saskatchewan, CANADA
2. Geology and Geophysics, Texas A&M University, College Station, Texas, UNITED STATES
E-mail: fev986@mail.usask.ca

Keywords: Chalk, Ichnology, Cenomanian, Buda Formation, Gulf Coast

The Buda Limestone is a lower Cenomanian chalk (e.g., Loucks et al., 2019; Valencia et al., 2021), deposited in a broad lagoonal shelf setting developed on the Comanche Shelf of the Texas Gulf Coast Basin (e.g., Martin, 1967, Young, 1972; Valencia et al., 2021, 2022). This formation is an excellent example of a highly bioturbated carbonate succession, with an ongoing debate about its depositional conditions, particularly whether it was deposited above or below storm-wave-base (e.g., Loucks, 2018; Minisini et al., 2018; Loucks et al., 2019; Valencia et al., 2021, 2022). Surprisingly, however, its ichnology has not yet been analyzed. Previous studies on this unit are largely sedimentology-focused, and thus, limited to reporting very few ichnogenera without further analysis of paleoecologic and paleoenvironmental implications (e.g., Reaser and Dawson, 1995; Reaser and Robinson, 2003). Herein, we report an ichnofauna comprising twenty ichnotaxa, which is widely dominated by *Thalassinoides* isp. and *Chondrites* isp. that overall illustrates the *Cruziana* Ichnofacies, with partial overprints of the *Glossifungites* and *Trypanites* ichnofacies. Variable degree of water interchange between the Buda Limestone paleo-shelf with the open sea, accompanied by highly variable physicochemical parameters inherent to lagoonal circulation (e.g., salinity, bottom-water oxygenation), highly influenced the resultant ichnofaunal content of this unit. The ichnologic features of the Buda Limestone from west and central Texas, including (1) dominance of the *Cruziana* Ichnofacies, (2) the common occurrences of overlapping *Glossifungite*s and *Trypanites* Ichnofacies, and (3) the absence of *Zoophycos* isp., suggest shallow-water carbonate deposition in lagoonal waters above SWB.

Infaunal response during the end-Permian Mass Extinction: Evidence from trace fossils

Mao Luo[1*]

1. State Key Laboratory of Palaeobiology and Stratigraphy, Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences, Nanjing, Jiangsu, CHINA
E-mail: maoluo@nigpas.ac.cn

Keywords: End-Permian Mass extinction, Biotic recovery, Early Triassic, Trace fossils

The end-Permian Mass Extinction (EPME) has caused the largest loss of biodiversity in earth's history and re-shaped shallow-marine ecosystems. Although much has been learned about the mechanism and tempo of this event based on body-fossil record, the global infaunal response to the EPME, as represented by trace fossils, remains poorly understood. Here we undertook analyses of secular changes in ichnodiversity, ichnodisparity and tiering structures of trace makers from the Late Permian to the Middle Triassic based on a global trace-fossil dataset. Results show that global ichnodiversity and ichnodisparity maintained their levels during the EPME until Griesbachian, which then decreased sharply in the Dienerian. Notably, the Griesbachian interval exhibits an unusual dominance of shallower tiers. The discrepancy between body- and trace-fossil diversity is interpreted to be the result of taphonomic effects of trace fossils by the resurgence of widespread microbial matgrounds in the Griesbachian. Such dominance of matgrounds aided the preservation of surficial, semi-infaunal and shallow-tier trace fossils. Our study indicates that the EPME strongly affected the sediment mixed layer, allowing the preservation of shallower tier trace fossils. Disappearance of mixed layer combined with widespread anoxia in the earliest Triassic might have intensified substantial removal of sulfate in sea water by enhanced pyrite burial and inhibited its further re-oxidation, therefore impacting sea water sulfate concentrations.

Tide-Dominated Estuarine or Deltaic Deposits? Sedimentological and Ichnological Analysis of Lower Permian Dandot Formation, North Pakistan.

Waqar Ahmad[1*], Murray K Gingras[1]
1. Earth & Atmospheric Sciences, University of Alberta, Edmonton, Alberta, CANADA
E-mail: wahmad1@ualberta.ca

Keywords: Estuary, Delta, Sedimentology, Ichnology

The lower Permian Dandot Formation (Salt range, north-west Pakistan) contains 35-40 m thick tide-dominated estuarine and tide-dominated deltaic, sand-dominated, heterolithic succession. Sedimentologic and ichnologic datasets have been integrated to characterize the depositional system of Dandot strata. The integrated facies analysis allows recognizing a tide-dominated estuarine (estuarine tidal bar, intertidal mud to mixed flat and supratidal deposits) and tide-influenced deltaic succession (prodelta, delta front, distributary mouth bar, and channels). Depositional processes and sedimentary facies in tide-dominated estuaries and deltas are remarkably similar. Common Sedimentological characteristics (spring- neap cycle, single and double mud and mica drapes, soft-sediment deformation structures, syneresis cracks, rare wave ripples, bidirectional paleocurrent, coal seams, and fragments) and ichnological signatures (sporadic bioturbation, low diversity-low intensity impoverished trace fossils suite, the dominance of deposit-feeding traces, and rare occurrence of suspension-feeding traces) indicate several physicochemical stresses, such as fluctuations in hydrodynamic energy, fluctuations in water salinity, turbid water conditions and heightened depositional rates affected the benthic communities of these tide-impacted settings.

Despite similarities in sedimentary facies, there are significant differences in longer-term processes. These include regressive vs transgressive conditions. This results in substantially different facies associations as well as stratigraphic architecture.

The tide-dominated estuarine succession shows a fining-upward trend in vertical profiles, whereas tide-dominated deltas form a coarsening-upward sequence. Typically estuarine deposits are much cleaner and have better sorting than deltaic successions.

The ichnological trend (regular heterogenous trace fossils distribution, variable bioturbation intensity, low diversity, diminutive traces, and characteristic traces fossils) points to several physiochemical stresses (seasonal fluctuations in sedimentary conditions, shifting substracts, turbid water, and anisotropic resources) that affected deposition in the estuarine setting.

Trace fossils in the deltaic deposits are sporadically heterogeneously distributed. The dataset shows an overall upward decreasing trend in bioturbation intensity and ichnological diversity in deltaic deposits. Trace-fossil typically displays comparably more diversity in contrast to estuarine deposits.

New insight of the interactions between early Cretaceous volcanism and lake environment changes from high-resolution coring archive, NE China

Shixi Cai[1], Gangjian Wei[1*]
1. State Key Laboratory of Isotope Geochemistry, Guangzhou Institute of Geochemistry,Chinese Academy of Sciences, Guangzhou, Guangdong Province, CHINA
E-mail: gjwei@gig.ac.cn

Keywords: tectonic volcanism,palaeoenvironment,redox fluctuations,mass mortality events

Tectonic volcanism is a manifestation of the vitality of the Earth, and it has a great impact on both environmental changes and biosphere evolutions. How tectonic volcanism regulates changes in earth surface, however, has not well presented. Here we present continuous high-resolution geochemical records of the early Cretaceous Jiufotang Formation, NE China, where the famous Jehol biota is discovered. Volcanic ash, gravity flow, and soft sedimentary structures related to tectonic volcanism are found in a 160-m shallow-deep lake section. Multiple geochemical analyses including elemental concentrations, XRD, and SEM are performed to trace volcanic ash layers and reconstruct records of changes in paleoredox and paleoproductivity of the lake. We find that the input of volcanic materials significantly improves productivity and consequently results in anoxic environment in semi-deep and deep lake facies of the Jiufotang Formation. U-Mo and Mo-organic carbon show a covariation pattern, suggesting that the water column has undergone dramatic changes in redox states from oxic to anoxic. This is further proved by the existence of manganese-rich carbonate rocks, an indicator of oxidation stages in the bottom water. Numerous soft sedimentary deformation structures were found in the cores, indicating the frequent occurrence of paleoseismicity. We therefore propose a new model of the terrestrial lake basin environment changes: (1) the hypoxia is mainly controlled by high productivity and deepen of the lake basin and (2) relative oxygenated bottom water could be caused by stronger water mixing which was contributed by ancient earthquakes induced mass wasting event or relative lake depth changes. This dynamic environmental interaction among deep lithosphere activity -lake and surrounding environments - redox state provide new insights to the mass mortality and fossil preservation mechanisms of Jehol biota preserved in fine-grained shale is triggered not by pyroclastic flow but more likely fluctuate redox condition of the bottom of the lake.

Reconstructing Late Ediacaran Carbon and Sulfur Cycles in South China

Zheyu Tian[1*], Graham A Shields[1], Ying Zhou[1], Maoyan Zhu[2], Miao Lu[2]

1. Earth Sciences, University College London, London, England, UNITED KINGDOM

2. State Key Laboratory of Palaeobiology and Stratigraphy, Nanjing Institute of Geology and Palaeontology, Nanjing, Jiangsu, CHINA

E-mail: z.tian.17@ucl.ac.uk

Keywords: Sulfur cycle, CAS, South China, DOUNCE/Shuram, OOE

The carbon and sulfur cycles play an important role in governing and regulating oxygen, climate and environmental shifts of the Earth's surface system, with implications for the evolution of life. The South China Craton (SCC) has provided a relatively complete and intensely researched rock record of the Ediacaran Period, which makes it an ideal place to understand redox coupling between the C and S cycles during that interval. Previous studies on the SCC revealed multiple Ocean Oxygenation Events (OOE) after the Marinoan glaciation. To study the best known OOE, which is associated with the late Ediacaran DOUNCE/Shuram carbon isotope excursion and radiation of aerobic biota into the deep marine realm, this study looks into carbonate carbon and carbonate-associated sulfate (CAS) sulfur isotope data from three representative sections (Lianghong, Sishang, and Qinglinkou sections) on the SCC. Sulfate sulfur isotope values show a coupled decreasing trend with the carbonate carbon isotope values (~ -10‰), reaching near modern levels (~ +21‰) during the DOUNCE/Shuram. Moreover, the $\Delta^{34}S_{sulfate\text{-}sulfide}$ and the estimated maximum seawater sulfate concentration show similar values to modern levels. However, after the DOUNCE/Shuram, the sulfate reservoir shrank back to pre-excursion levels and influenced the S cycling pathways, which resulted in a decoupled C-S trend and ocean deoxygenation. The rises and falls of the estimated seawater sulfate concentration show a coupled shift with Sr isotope values, suggesting that the DOUNCE/Shuram was likely to be tectonically controlled, possibly via weathering-derived nutrient input. Global correlation indicates that the CAS sulfur isotope profile can be used as a global chemostratigraphic correlation tool at times when sulfate concentration is relatively high.

E-mail: chaoli@cudt.edu.cn

Keywords: Ediacaran, Shuram, sulfate, isotope compositions

The Ediacaran Period (~635–539 Ma) witnessed the largest negative inorganic carbon isotope excursion in Earth's history (i.e., the Shuram Excursion, SE), which has been interpreted as reflecting the oxidation of marine organic carbon due to rising oxidant levels. The oxidant sources previously hypothesized include atmospheric O_2, local dissolved [O_2], and sulfate deriving from continental evaporites or sulfide oxidation. However, which oxidant being responsible and the mechanism behind still remain elusive. In this study, we investigated the sulfur and oxygen isotope compositions of the carbonate-associated sulfate (CAS) of Ediacaran rocks from three paleocontinents (South China, South Australia, and Tarim). It shows a parallel decrease in both $\delta^{34}S$ and $\delta^{18}O$ of the CAS during the SE from the three localities and a good positive correlation between them. These observations indicate a mixing between two end-member sulfate populations: pre-existing sulfate and newly-supplied sulfate. We interpret that the pre-existing sulfate, subject to vigorous microbially cycling, is characterized by higher $\delta^{34}S$ and $\delta^{18}O$ values, while new sulfate having lower $\delta^{34}S$ and $\delta^{18}O$ values, may have derived from the oxidation of sulfides. Furthermore, our mixing model suggests that a rise of sulfate by ~20 times was supplied to oceans during the SE, resulting in great oxidation of the marine organic carbon and subsequent oceanic ventilation as well as the radiation of the Ediacaran biota.

Spatial heterogeneity in carbonate carbon isotopic values during the Cambrian ZHUCE event on the southwestern Yangtze platform

Xiaojuan Sun[1], Bo Chen[1], Maoyan Zhu[1,2*]

1. State Key Laboratory of Palaeobiology and Stratigraphy, Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences, Nanjing, Jiangsu, CHINA

2. College of Earth and Planetary Sciences, University of Chinese Academy of Sciences, Beijing, CHINA

E-mail: myzhu@nigpas.ac.cn

Keywords: chemostratigraphy, Cambrian, ZHUCE, carbon isotopes, isotope gradient

The sedimentary record of carbonate carbon isotopes ($\delta^{13}C_{carb}$) is the primary window into Earth's ancient carbon cycles and provides one of the best methods for correlation of marine strata. A prominent positive carbon isotope excursion (named Zhujiaqing Carbon isotope Excursion (ZHUCE) on the Yangtze block) is recognized globally at the lower part of Cambrian Stage 2 and has been utilized extensively for chronostratigraphic correlation and environmental reconstruction. However, substantial variability in magnitude and shape of this excursion among different continents and even within a single basin has hampered high-resolution correlations and led to divergent reconstruction of ocean chemistry and carbon cycle. In order to understand the spatial variation and the genesis of the ZHUCE event, sedimentologic, petrographic, and geochemical investigations have been carried out in two sections from Yunnan, Yangtze platform. Petrographic and texture-specific isotope analyses revealed that the mixing of dolomite minerals to limy mudstone has resulted in variations in $\delta^{13}C_{carb}$ up to 1.8‰ and $\delta^{18}O_{carb}$ up to 3.6‰ across individual beds, which together imply that small-scale variability in the ZHUCE may result partly from local diagenetic overprinting. High-resolution and sample screened $\delta^{13}C_{carb}$ profile from the Laolin section reveals a distinct ZHUCE event with its magnitude and stratigraphic distribution different from previous studies in the same section. The shape and trend of the ZHUCE of the Laolin section can be correlated in detail with that of the Xiaotan section regionally and the northwestern Siberia sections globally, whereas the discrepancies in the magnitude and peak-excursion values of the ZHUCE among the sections and regions might be interpreted as the effects of isotope gradients due to stratification of the depositional basins. In contrast, no positive carbon isotope excursion is recognized from time equivalent strata at the Dapengzi section where $\delta^{13}C_{carb}$ values first fall gradually to -3‰ (V-PDB) and then oscillate between 0‰ and -2‰. This is the first record of the disappearance of the ZHUCE event in a stratigraphically equivalent carbonate-dominated sequence. The sedimentologic, petrographic and geochemical data suggest that the disappearance is likely resulted from the generation of ^{13}C highly depleted water mass relative to the open ocean by oxidation of the organic matter in a hydrologically restricted environment, representing an extreme case of marine redox stratification, which is further supported by the rare earth elements and Yttrium data.

Keywords: redox, restricted basin, glaciation, Datangpo, Neoproterozoic

The Cryogenian Period of the Neoproterozoic was characterized by two Snowball Earth glaciations, which were potentially tied to the diversification and proliferation of eukaryotes and culminated with the appearance of animals. The break-up of Rodinia in the early Neoproterozoic resulted in emergence of numerous rift basins marked by dynamic chemical evolution likely controlled by the waxing and waning of the two global climate upheavals and associated eustatic change and nutrient cycling. The Nanhua Basin, as a marginal restricted basin in South China, provides a unique window to the key cause-and-effect relationships with implications for the radiation of complex life. We focus on an exceptional shale sequence—the Datangpo Formation consisting of a lower black shales and upper gray shales/siltstones—which captures the complete Cryogenian non-glacial interval and likely the onset of Marinoan glaciation. Highly coupled total organic carbon (TOC) and total sulfur concentrations in combination with iron speciation and pyrite sulfur data suggest TOC-rich, euxinic deep-water deposition for the lower black shales but TOC-lean, persistently oxic conditions for the upper gray shales/siltstones associated with relatively shallow-water deposition. We argue that this dramatic shift in water chemistry was primarily governed by the extent of restriction for the Nanhua Basin as a consequence of eustatic variation tied to the glaciation events. Specifically, the highstand in the wake of the Sturtian corresponded with elevated nutrient fluxes delivered from the open ocean and the resultant highly productive, euxinic conditions, while the lowstand linked to the onset of the Marinoan was accompanied by reduced nutrient supplies that led to low productivity and ventilated settings. This model of local redox dynamics tied to the hydrological variations is supported by trace metal distribution patterns. Moreover, our data show that the TOC-lean gray shales/siltstones are characterized by a lack of correlation between TOC and total nitrogen contents. Further investigations demonstrate that nitrogen is predominantly bound by clay minerals for these rocks, which suggests that terrestrial delivery, as a potential source of nitrogen dramatically elevated in response to sea-level fall. This study will inform better understanding of the intrinsic relationships among glaciations, eustatic change, nutrient availability, and redox dynamics within the Earth system over this critical transition, along with implications for other climate upheavals in Earth's deep past.

Interaction of Shibantan Biota and environment in the terminal Ediacaran ocean: evidence from I/Ca and sulfur isotopes

Kaiqi Huang[1], Meng Cheng[1*]

1. State Key Laboratory of Biogeology and Environmental Geology, China University of Geosciences (Wuhan), Wuhan, Hubei, CHINA

E-mail: mengcheng@cug.edu.cn

Keywords: dissolved oxygen, superheavy pyrite, sulfate, bioturbation, Dengying Formation, South China

The terminal Ediacaran (~551-539 Ma) was a crucial period in Earth's history that witnessed the first appearance of skeletonized animals and complex ecosystems (e.g., the Shibantan Biota) in the ocean. However, the trigger for such biological innovations and their feedbacks to the environment are still poorly understood. Here, to explore possible interactions between the Shibantan Biota and the oceanic environment, we carried out an integrated investigation of I/Ca along with sulfur isotopes of carbonate-associated sulfate ($\delta^{34}S_{CAS}$) and pyrite ($\delta^{34}S_{py}$) in the Shibantan Member of the Dengying Formation at Wuhe in the Three Gorges area of South China. Our I/Ca profile yields fluctuating values in the range of <0.1 to >1.0 μmol/mol, corresponding to oxygen concentrations between 1-3 μM and 20-70 μM in the water column of the study area. The variably high $\delta^{34}S_{CAS}$ values (+31.8‰ to +55.7‰, mean +41.0±5.2‰) may imply low sulfate concentrations in the terminal Ediacaran ocean, consistent with contemporaneous expansion of seawater anoxia. Superheavy pyrites (i.e., $\delta^{34}S_{py} > \delta^{34}S_{CAS}$) are present in the lower Shibantan Member, concurrent with the appearance of bioturbation in the sediments, suggesting control by microbial sulfate reduction (MSR) in sulfate-limited porewaters followed by preferential re-oxidation of ^{32}S-bearing H_2S under the influence of burrowing organisms. Our study reveals that oxygen levels in shallow-water environments of the terminal Ediacaran ocean were generally low but still sufficiently high to sustain the physiological requirements of the Shibantan Biota. In turn, burrowing activity of infaunal members of the Shibantan Biota may have enhanced sediment porewater oxygenation, thus expanding the ecosystem space available to early animals.

Keywords: banded iron formation, early Earth, iron cycle, green rust, hydrogen escape

Iron in the early anoxic oceans of Archean age is believed to have been oxidized to form banded iron formations (BIF). Previously, it has been proposed that iron was oxidized either by free oxygen, H2O2, microbial oxidation, or photo-oxidation. However, these mechanisms are difficult to reconcile with evidence for the oceans at that time having been largely devoid of dissolved oxygen and oxidants, together with the rarity of microbial remains in BIF and restrictively slow rates of photo-oxidation. I will discuss recent experimental work which shows that ferrous iron readily oxidizes in analogues of Archean anoxic seawater following the precipitation of ferrous hydroxide. Once precipitated, ferrous hydroxide undergoes decomposition to elemental iron that reacts with water at room temperature to form ferric iron and release hydrogen gas. This ferric iron may then be incorporated into green rust, a mixed ferrous-ferric phase that ages into iron minerals commonly found in BIF. Our finding suggests that anoxic iron oxidation may have contributed to the formation of oxide-facies BIF, especially Algoma-type BIF that likely formed in semi-restricted basins where ferrous hydroxide saturation was more easily achieved. Additionally, hydrogen production during ferrous hydroxide decomposition would have contributed to early Earth's oxidation, as a result of hydrogen escape to space, thus switching ferrous iron from an oxygen sink to an oxidation pathway prior to the GOE.

Marine anoxia change as a driver of late Cambrian SPICE Event shown by Ba & U isotopes

Jianlin Zhou[1*], Fefei Zhang[1]

1. State Key Laboratory for Mineral Deposits Research, School of Earth Sciences and Engineering, Nanjing University, Nanjing, Jiangsu Province, CHINA

E-mail: MG20290047@smail.nju.edu.cn

Keywords: Cambrian, SPICE, barium isotopes, uranium isotopes, marine anoxia, marine productivity.

The late Cambrian SPICE event (~500-496Ma) represents one of the largest positive carbon isotope excursions (CIEs) during the Paleozoic, with magnitudes up to +4%. The beginning of the CIE coincident with a rapid trilobite turnover event. The SPICE is considered to be related to increased organic carbon burial, driven either by the expansion of oceanic anoxia or enhanced primary productivity. However, the main driver of the event and its relationship to the concurrent biotic event remains to be explored and constrained. Here, we use Ba isotopes (δ^{138}Ba) and uranium isotopes (δ^{238}U) in carbonate rocks to assess changes in marine primary productivity and marine redox chemistry across the SPICE. Two widely-spaced carbonate sections in China, Duibian A section in Zhejiang Province and Baijiashan section in Liaoning province, have been studied. Our data show a fluctuation of δ^{138}Ba excursions in a range of ~0.4‰ with a negative excursion to -0.2‰ of δ^{138}Ba corresponding to the peak of δ^{13}C, and a negative excursion of δ^{238}U with ~-0.7‰ at the beginning of the CIE. The negative excursion of δ!"#Ba can be interpreted to be caused most probably by marine anoxia, which can be associated with the upwelling of anoxic bottom seawater, while the negative excursion of δ^{238}U correspond to the trilobite turenover event, consistent with the previous results, showing a servere global anoxia event at the beginning of SPICE. Our new δ^{138}Ba and δ^{238}U results provided critical evidence that expanded marine anoxia was likely a primary trigger of organic carbon burial events that led to the SPICE event.

Spatial pattern of the Ediacaran Shuram Event in Huangling-Shennongjia region, Hubei Province, South China

Haodong Gu[1], Jun Hu[1], Meng Cheng[1], Zihu Zhang[1], Chao Li[2,1*]
1. State Key Laboratory of Biogeology and Environmental Geology, China University of Geosciences (Wuhan), Wuhan, Hubei, CHINA
2. State Key Laboratory of Oil and Gas Reservoir Geology and Exploitation & Institute of Sedimentary Geology, Chengdu University of Technology, Chengdu, Sichuan, CHINA
E-mail: chaoli@cdut.edu.cn

Keywords: Ediacaran, Shuram Excursion, South China, Spatial Pattern

The Ediacaran Period (~635-539 Ma) witnessed major changes in Earth's system including rapid early animal radiations, dramatic environmental changes and the largest carbonate carbon isotopic ($\delta^{13}C^{carb}$) excursion in Earth history known as the Shuram Excursion (SE; Li et al., 2018, 2020). Despite of various patterns, the SE has been identified globally in Ediacaran strata (Grotzinger et al., 2011). However, their spatial pattern has not been well documented at present, impeding our understanding of the formation mechanism of the SE. In the region of the Huangling Anticline of Hubei Province (South China), the SE occurs in the upper part of the Ediacaran Doushantuo Formation (also named as "DOUNCE") and increasingly shows various patterns (Zhu et al., 2007; Lu et al., 2013; Li et al., 2017). In this study, we collected high-resolution $\delta^{13}C_{carb}$ data of the Doushantuo Formation from a large number of sections (n=28) in Huangling and its adjacent Shennongjia region. Based on our paleogeographic reconstruction of the Doushantuo Formation in study region (Gu et al., 2021), our results show a clear coupling between the paleo-water depths and the SE pattern in the Huangling-Shennongjia region. In shallow-water platform area, the SE is not obvious, which typically has a $\delta^{13}C_{carb}$ nadir of about 0‰ within thin strata (<30m). In contrast, the SE is prominent in the deep-water continental shelf basins, with the nadir reaching -10‰ lasting within much thick strata (up to 60m). In the mid-depth zone between the two area, the SE pattern falls in between. Our finding demonstrates that a spatial pattern for the SE may have existed in single craton basin, thus providing new insights into the nature of the largest $\delta^{13}C^{carb}$ excursion in the Earth history and its possible relationship with coeval major changes in Earth system.

Keywords: Shuram Excursion, C-S cycles, Sulfate oxygen isotope, H2S reoxidation, COPSE model, Neoproterozoic

Ediacaran carbonate rocks (635-539 Ma) record the largest negative carbonate isotope excursion in Earth history, termed as the Shuram Excursion (SE). This event has been attributed to anaerobic oxidation of oceanic dissolved organic carbon as a result of enhanced weathering inputs of sulfate to the oceans during the amalgamation of Gondwana. However, the effect of carbon-sulfur cycle interplay on the net redox state of the ocean-atmosphere system remains unclear, impeding our understanding of life-environment co-evolution during the Ediacaran. Here, we generate high-resolution records of paired sulfate sulfur and oxygen isotopes and phosphorus concentrations for the SE interval in the Parachilna Gorge (South Australia) and Jiulongwan and Xiang'erwan sections (Three Gorges, South China), and we evaluate these data in the context of COPSE biogeochemical model simulations to explore net long-term redox changes. Our results support widespread H2S reoxidation in shelf areas during the SE, managing net oxygen budget. Varying degrees of H2S reoxidation on different cratons is likely to have led to high spatial heterogeneity in local oceanic redox states as well as in nutrient availability, representing the transition from low-oxygen Proterozoic oceans to more extensively oxygenated and nutrient-rich Phanerozoic oceans that promoted the rise of the Ediacara Biota.

A short-lived oxidation event during the early Ediacaran and delayed oxygenation of the Proterozoic ocean

Bo Chen[1*]

1. State Key Laboratory of Palaeobiology and Stratigraphy, Nanjing Institute of Geology and PalaeontologyChinese Academy of Sciences, Nanjing, Jiangsu , CHINA

E-mail: chenbo@nigpas.ac.cn

Keywords: Dissolved Organic Matter, carbon isotope perturbations,strontium isotopes, sulfur isotopes,uranium isotopes,metazoans

The Ediacaran Period was characterised by major carbon isotope perturbations. The most extreme of these, the 570 Ma Shuram/DOUNCE (Doushantuo Negative Carbon isotope Excursion) anomaly, coincided with early radiations of benthic macrofauna linked to a temporary expansion in the extent of oxygenated seawater. Here we document an earlier negative excursion (the 610 Ma WANCE (Weng'An Negative Carbon isotope Excursion)) anomaly in the Yangtze Gorges area, South China, that reached equally extreme carbon isotope values and was associated with a similar degree of environmental perturbation. Specifically, new uranium isotope data evidence a significant, but transient, shift towards more oxygenated conditions in tandem with decreasing carbon isotope values, while strontium and sulfur isotope data support an increase in continental weathering through the excursion. We utilize a biogeochemical modelling approach to demonstrate that the influx of such a weathering pulse into an organically-laden, largely anoxic ocean, fully reproduces each of these distinct isotopic trends. Our study directly supports the hypothesis that a large dissolved marine organic pool effectively buffered against widespread oxygenation of the marine environment through the Proterozoic Eon, and in doing so, substantially delayed the radiation of complex aerobic life on Earth.

Potassium isotope fractionation during clay adsorption and implications for reverse weathering in the Precambrian

Xinyang Chen[1,2*], Xinyuan Zheng[1], Brian Beard[3], Clark Johnson[3]

1. Department of Earth and Environmental Sciences, University of Minnesota–Twin Cities, Minneapolis, MN, UNITED STATES
2. Institute of Sedimentary Geology, Chengdu University of Technology, Chengdu, Sichuan, CHINA

E-mail: xinyangchen87@outlook.com

Keywords: K isotopes, reverse weathering, clay, adsorption

The Earth's habitability and climate stability are thought to be regulated by a negative feedback between atmospheric CO2 and the silicate weathering in geological timescales. This carbon-weathering feedback can be out of balance in certain geologic periods such as during the Neoproterozoic-early Paleozoic transition during which multiple Snowball Earth episodes occurred. This period is also marked by a substantial rise in atmospheric oxygen levels and a rapid evolution of multicellular eukaryotes, accompanied with significant perturbations in global carbon cycle. Chemical weathering flux controls the delivery and recycling of nutrients that can greatly influence marine productivity and redox conditions. A critical feature of silicate weathering during the Neoproterozoic is that the authigenic clay formation on the seafloor (termed reverse weathering) could have been greatly enhanced prior to the origin of silica-precipitating organisms in the Precambrian. However, the mechanism, extent, and rate of reverse weathering in the Precambrian are still poorly constrained. Models based on integrated C-Si cycle suggest that the enhance reverse weathering could result in warmer climate than if reverse weathering is ignored. Potassium isotope system is an emerging tool to trace silicate weathering as K is a major element that resides mostly in silicates. One outcome of the enhanced reverse weathering is an intensified clay-seawater interaction during which cations such as K, Ca, Na and Mg could be scavenged and adsorbed that alters the biogeochemical cycles of key nutrient elements.

Here we present K isotope results of cation exchange reactions between clay minerals (illite, smectite, kaolinite) and aqueous solutions to constrain the mechanisms and degree of K isotope fractionation. Series of experiments under different conditions were conducted in order to capture various factors that controls the isotopic fractionation of K. The adsorption rate of K on clay minerals is fast and can reach steady state within hours from initial mixing in our experiments. Isotopically light K is preferentially adsorbed onto the clay minerals. Our results indicate that preferential uptake of lighter K isotopes by seafloor clay minerals from the seawater may explain the observation that modern seawater is ~0.6‰ heavier than the bulk silicate Earth. If the reverse weathering was more extensive in the Precambrian than today, the seawater K isotopic composition could have been even higher than modern value due to removal of light K isotopes from clay adsorption. Potassium isotopic fractionation between clay and seawater during adsorption thus can help better quantify the reaction kinetics and refine estimates of reverse weathering fluxes that allows for better assessment of the effect of reverse weathering on Earth's climate evolution.

V isotope evidence for seawater contribution to the early Cambrian polymetallic Mo-V mineralization in South China and widespread oceanic oxygenation

Lin-Hui Dong[1*]

1. School of Earth and Space Science, University of Science and Technology of China, Hefei, Anhui, CHINA
E-mail: dlh0927@mail.ustc.edu.cn

Keywords: Polymetallic mineralization, Metal source, Seawater scavenging, Redox reconstruction, Yangtze Block

The early Cambrian black shales in the Yangtze Block hosts a polymetallic Ni-Mo sulfide layer with extreme metal concentrations, which grade laterally into V-rich shale. It is still controversial whether the source of ore-forming metal elements is seawater or hydrothermal fluid. In order to discriminate the origin of V, we measured the V isotope compositions ($\delta^{51}V$) of the Ni-Mo polymetallic sulfide layer and host black shale samples from Dazhuliushui and Maluhe sections in Guizhou province, as well as the V-rich shale and host black shale samples from the Sancha and Caojiaping sections in Hunan province. The $\delta_{51}V$ values of host black shale and V-rich shale are consistently heavy (from -0.62 to 0.09‰, avg. -0.23‰), indicating V elements are from seawater. But the polymetallic Ni-Mo sulfide ores have relatively light $\delta^{51}V$ values (from -0.77 to -1.33‰, avg. -1.00‰), which likely resulted from the adsorption of Fe-Mn oxides to V. In light of the above observations, we propose a V geochemical cycling model in the continental margin of the Yangtze platform in South China during early Cambrian. Furthermore, based on the $\delta^{51}V$ values of three sets of samples deposited in various conditions and the V isotopic offset between seawater and these sediments, we reconstruct a global seawater V isotope composition ($\delta^{51}V = 0.17\pm0.36$‰) during the early Cambrian, which is consistent with the $\delta^{51}V$ value of modern oxic seawater (0.20±0.15‰). This demonstrates that early Cambrian open ocean may be already in an oxygenated state closed to that of the modern marine. Oxic seawater may provide suitable environment for Cambrian Explosion. Meanwhile, the result of sensitivity analyses imply that the fraction of hydrothermal flux has little impact on the fraction of oxic flux.

The basal Cambrian carbon isotope excursion revealed in the Central Iberian Zone, Spain

Kun Zhang[1*], Graham Shields[1], Sören Jensen[2], Ying Zhou[1]
1. Department of Earth Sciences, University College London, London, UNITED KINGDOM
2. Área de Paleontología, Universidad de Extremadura, Badajoz, Extremadura, SPAIN
E-mail: kun.zhang.19@ucl.ac.uk

Keywords: basal Cambrian carbon isotope excursion, Spain, Ediacaran-Cambrian boundary

The patterns and causes of early metazoan diversification across the Ediacaran-Cambrian transition remain controversial, and geobiological evidence from less well-known sections can help shed light on the issue. Here, we report carbon and nitrogen isotope data from two fossiliferous sections straddling the Ediacaran-Cambrian interval in the Central Iberia Zone, Spain. Carbon isotope chemostratigraphy of both sections reveals prominent negative excursions, which are interpreted to correspond to the global Basal Cambrian Carbon Isotope Excursion (BACE). The Ediacaran-Cambrian boundary is therefore proposed to sit in the upper part of the Villarta and laterally correlative Cíjara formations. Nitrogen isotope data reveal a similar trend to that found from contemporaneous strata of South China, but lower values indicate a change in nitrogen cycling from anaerobic to aerobic in Central Iberia. In Spain, the treptichnids and Treptichnus appeared above the BACE while Cloudinia appeared below the BACE, which is consistent with an emerging picture of macroevolutionary trend through the Ediacaran-Cambrian interval. Integrated geochemical and biotic records suggest that early metazoan evolution across the Ediacaran-Cambrian transition was possibly mediated by complex environment-ecosystem feedbacks.

Floating microbial mats from the Mesoproterozoic Wumishan Formation, North China

Chuxue Zhao[1], Min Shi[1*], Qinglai Feng[1]
1. School of Earth Science, China University of GeosciencesWuhan, Wuhan, Hubei, CHINA
E-mail: shimin@cug.edu.cn

Keywords: Microbial mat, cyanobacteria, Mesoproterozoic

Microbial mats were well established and widespread during the Proterozoic eon, playing a pivotal role in early marine ecosystem. Especially, microbial mats dominated by cyanobacteria are responsible for the oxygenation of the atmosphere and oceans, which may have contributed to the evolution of eukaryotes. The migration of microbial mats from benthic to floating forms is quite common in modern aquatic environments. However, in the Precambrian ocean, well-preserved benthic microbial mats are rich in sedimentary record, while floating microbial mats remain poorly known. This may be caused by lower preservation potential of floating microbial mats due to degradation in water column.

Here, we systematically investigated cherts and silicified microbialites from the Wumishan Formation (~1480 Ma) Jixian Group, North China. The microbial mats in this study are mainly composed of coccoid microfossils that are simple in morphology and uniform in size. They show different degrees of degradation. A few of them are well preserved, but most are degraded severely with only molds left. Moreover, the microbial mats exhibit alternating light-dark laminae. Interestingly, dark layers on the top of the light layer microbial mats (TLMM) and the bottom of the light layer microbial mats (BLMM) are characterized by different types of microbial mats. A “fossils bridge” connecting the two types of microbial mats can be found in the light layer occasionally. These microbial mats are preserved in cryptocrystalline quartz, while microbial mats and “fossils bridge” are surrounded by chalcedony. This phenomenon indicated that microbial mats preserved in-situ forms. Meanwhile, we found hemispherical structures with convex downward in the TLMM. The height and width of these hemispheres are about 0.1-0.4 mm and 0.4-3 mm respectively, and their ratios are relatively constant. After calculations and simulations, we speculated that the hemispherical structure might be caused by the buoyancy of seawater on the floating microbial mats. Our study provides strong evidence for the existence of floating microbial mats in the Proterozoic, promoting the understanding of early shallow marine biosphere.

The origin of the oldest, extremely 13C-depleted calcite: A snowball Earth legacy

Yongbo Peng[1*]

1. International Center for Isotope Effects Research, Nanjing University, Nanjing, Jiangsu, CHINA

E-mail: ybpeng@nju.edu.cn

Keywords: Cold seep carbonate, isotope, snowball Earth

The 635 Ma Marinoan glaciation is the most severe global glaciation in Earth history. After onset of the deglaciation, the Earth system went through a series of dramatic changes. Amid these changes, extremely 13C-depleted limestones (CDLs) stands out as the most unusual geochemical events of all. The origin of calcite is critical for us understanding the carbon cycle and ocean redox condition after the global glaciation, while the origin is lingering debates. The CDLs has been alternatively interpreted as evidence for anaerobic oxidation of methane during early diagenesis or oxidation of methane resulting from late diagenetic interaction with hydrothermal fluids. Here, we pin down the origin of these calcites to a process driven by sulfate reduction coupled with anaerobic oxidation of methane. Our evidence comes from multi-isotope study for the CDLs and in their host dolostones in the basal Doushantuo Formation, including sulfur and oxygen isotopes of carbonate associated sulfate (CAS), multiple sulfur isotopes of pyrite, carbonate and organic carbon isotopes. The low δ13Corg values down to –46‰ with high δ34Spyirte up to +74‰, positive δ34SCAS– δ18OCAS, δ34SCAS–δ34Spyrite correlations and negative δ13Corg– δ34Spyrite, δ34Spyrite–Δ33Spyrite correlations of these limestones are identical to those of the modern cold seep carbonates formed by microbial anaerobic oxidation of methane using sulfate. This basal Ediacaran, CDLs is the oldest known cold seep carbonates, suggesting that that the earliest Ediacaran peak in marine sulfate concentration is a regional and likely transient event.

Biological response to oxic pulses during the Cambrian

Rachel Wood[1*], Andrey Zhuravlev[1]
1. School of Geosciences, University of Edinburgh, Edinburgh, Scotland, UNITED KINGDOM
E-mail: rachel.wood@ed.ac.uk

Keywords: Cambrian, redox, metazoans, evolution

Oxygenation during the Cambrian Radiation interval probably progressed via a series of short-lived oxic pulses, each lasting 1-3 million years (Myr). But the biotic response of metazoans to this episodic oxygenation has not been quantified, nor the causal processes constrained. Here we present high-resolution metrics from benthic metazoan communities on the Siberian Platform over 20 Myr through Cambrian stages 2 to 4 (~530-510 Million years ago; Ma). During the oxic pulse ~521 Ma, we document increased body size, species diversity, and rates of origination. But during the succeeding phase of expanded marine anoxia (~519-516 Ma), metazoan body size reduced, as did diversity driven by increased rates of extinction. A later oxic pulse ~515 Ma shows a further increase in body size and diversity. The Sinsk Extinction event, ~514 Ma, likely driven by widespread anoxia, caused the 'Lilliput Effect' (body size decrease) in some groups, but the 'Brobdingnag Effect' (body size increase) in others. These metrics confirm that oxygenation events created short-lived pulses of evolutionary diversification, with intervening intervals of partial or widespread anoxia notably enhancing extinction rates.

Mechanistic evaluation of sulfur and oxygen isotope fractionation during microbial sulfate reduction

Mingzhe Dai[1*], Xiaobin Cao[1]

1. International Center for Isotope Effects Research, School of Earth Science and Engineering, Nanjing University, Nanjing, Jiangsu, CHINA

E-mail: mingzhedai@smail.nju.edu.cn

Keywords: microbial sulfate reduction, sulfur isotope, oxygen isotope, triple oxygen isotopes

Microbial sulfate reduction (MSR) dominates the organic carbon mineralization in anaerobic sediments globally. Sulfur and oxygen isotope compositions in sulfate have been widely used to trace the MSR process, and many experimental and theoretical investigations have been done to reveal the underlying mechanisms regulating sulfur and oxygen isotope variations during MSR. However, most previous efforts are designed for closed systems, while sedimentary environments are often open. Here we developed a numerical model incorporating the metabolic reactions and diffusion-transport processes to investigate the factors controlling sulfur and oxygen isotope fractionations, especially focusing on the relationship between sulfur and oxygen isotope fractionation relationship and triple oxygen isotope variations. Our results show that the relationship between sulfur and oxygen isotope fractionation, i.e., the slope of 18O and 34S, is inversely correlated with the cell specific sulfate reduction rate, and the triple oxygen isotope fractionation relationship, i.e., the θ value of MSR, cannot be larger than equilibrium θ value 0.524. The implications of our results will also be presented.

How can dolomite Mg isotopes tell the terminal Ediacaran seawater chemistry?

Pan Zhang[1], Kang-Jun Huang[1*], Mao Luo[2], Yaoping Cai[1], Zhian Bao[1]
1. Department of Geology, Northwest University, Xi'an, Shaanxi, CHINA
2. Nanjing Institute of Geology and Palaeontology and Center for Excellence in Life and Palaeoenvironment, Chinese Academy of Sciences, Nanjing, Jiangsu, CHINA
E-mail: hkj@nwu.edu.cn

Keywords: Seawater Mg/Ca, Mg isotopes, Dolomites, Animal biomineralization

Among the key advances in animal evolution, the development of calcified skeletons is one of the most important innovative revolutions since it fundamentally changed the ecological system. A lot of drivers have been proposed, including the increasing predation pressure and variation in seawater chemistry. Regarding the potentially involved environmental contexts, there are still many uncertainties, such as the seawater Mg/Ca variation during this period due to the lack of reliable archives. Therefore, Mg isotopes of dolomites from the lower member of the Dengying Formation, which is right below the calcified fossil-bearing succession, here are investigated to constrain the coeval seawater Mg/Ca variation since the seawater Mg budget can be reflected by seawater Mg isotopic compositions. Results show that the microbialites with well-preserved sedimentary structures are widely developed in dolomites as the matrix, and fibrous dolomite cements with abundant types show delicate growth zones, which both are formed during the syn-sedimentary stage. The geochemical signatures of these components display the primary signals of the coeval seawater and reveal a relatively anoxic shallow platform setting. Furthermore, the correlated elemental ratios and Mg isotopic compositions of these well-preserved components indicate the pervasive mixture of freshwater in the shallow seawater, and the heavier Mg isotopic compositions in the freshwater endmember imply a silicate-dominated riverine input. This enhanced silicate weathering may relate to the extensive dramatic chemical weathering at the late Ediacaran, which may favor the high Mg/Ca ratio and alkalinity in the oceans on the eve of the earliest animal biomineralization.

Synchroneity and causality of biotic and abiotic processes during the Neoproterozoic-Cambrian transition

Xingliang Zhang[1*]
1. Geology, Northwest University, Xi'an, Shaanxi, CHINA
E-mail: xzhang@nwu.edu.cn

Keywords: Cambrian Explosion, Biotic processes, Abiotic processes, Causality, Synchroneity

Surficial Earth is an integrative system of biotic and abiotic components, which is traditionally called ecosystem. Biotic and abiotic components have interacted with each other since life orgin and the ecosystem itself has evolved ever since. The interplay of biotic and abiotic processes crossing the critical trasitions of Earth's history has long been extensively and intensively investegated by scientists from multidisciplines. Increasingly, more scientists have tended toward more abiologically based explanations for biotic events, generally identifying abiotic changes in tectonics, sedimentation, climate, and redox as the planetary drivers of discontinuous biotic change and viewing biotic changes as passive responses to abiotic changes (Erwin, 2015). The explanations, in most cases, are based on the synchroneity of biotic and abiotic changes seen in the studied geological sections or recognized through global stratigraphical correlations. However, the current correlation resolution is generally insuficient to establish the synchroneity. More critically, simultaneously or successively happened events do not necessarily have causal relationships. Here, I review biotic and abiotic events crossing the Neoproterozoic-Cambrian transition (Zhang et al., 2014; Zhang and Shu, 2021; Li et al., 2021) and discuss challenges in defining their synchroneity and causality.

Geological and geochemical constraints on the genetic relationship between the different phosphorus layers in the Zhangcunping area, South China

Maquzong Bai[1,2], Xiangkun Zhu[2*], Zhaofu Gao[2]

1. China University of Geosciences, Beijing, School of Earth Sciences and Resources, Beijing, CHINA
2. MNR Key Laboratory of Isotope Geology, Institute of Geology, Chinese Academy of Geological Sciences, Beijing, CHINA

E-mail: xiangkunzhu@163.com

Keywords: Ediacaran, Doushantuo formation, Phosphorite, Zhangcunping

Worldwide phosphogenic events took place in the immediate aftermath of the Neoproterozoic glaciation period, resulting in formations of some of the largest phosphorus deposits in the word. The Zhangcunping area in Western Hubei represents one of the most significant phosphatized ore belt in China and the Ediacaran Doushantuo Formation hosts two high-grade phosphatic beds known as the lower phosphorite and upper phosphorite beds. In this study, elemental concentration analysis were investigated in association with a detailed petrographic investigation of the different layers to assess the association between the lower phosphorite and upper phosphorite beds and better constrain the redox condition during the formations of the phosphorus deposits in the Zhangcunping area.

The lower banded phosphorite layer overlies the thick organic-rich shales, and is conformably overlain by dolostone, with an erosional surface at the top, following the upper phosphorites interbedded with dolostone. These two phosphorite layers show different petrographic and geochemical characteristics. On the one hand, framboid pyrite can been observed in the lower phosphorite ores, whereas authigenic iron oxide and fossils, such as spherical algae and cyanobacteria-like microfossils, are common in the upper phosphorite ores. On the other hand, these two ore layers have obvious difference in elemental concentrations: 1) The upper phosphorites have much lower Zn, Ba, Cd contents than the lower phosphorites, but higher Cu contents; 2) The lower phosphorites shows slightly "right inclining" REE pattern and no Ce anomalies (average 0.97), while the upper phosphorites show "hat-shaped" REE plots with negative Ce anomalies (average 0.68); 3) The lower phosphorites have a low Y/Ho ratios with an average of 32.92, but this up to around 42 in the upper phosphorite ores. In the sum, the lower phosphorite ores show higher LREE/HREE, lower Y/Ho, no Ce anomalies and upper phosphorites show lower LREE/HREE, higher Y/Ho with Ce anomalies, suggesting that lower phosphorite ores formed in anoxia bottom water condition and the upper phosphorites deposited in suboxic depositional condition. Therefore, our study suggests a transition from a generally anoxia environment to a suboxic environment during the formation of the two phosphorite layers through the Doushantuo Formation.

Global scale production of brGDGTs by benthic marine bacteria: Implication for developing ocean bottom environmental proxies

Wenjie Xiao[1*], Yunping Xu[2], Chuanlun Zhang[1]

1. Department of Ocean Science and Engineering, Southern University of Science and Technology, Shenzhen, Guangdong, CHINA

2. College of Marine Sciences, Shanghai Ocean University, Shanghai, CHINA

E-mail: wjxiaocug@126.com

Keywords: Branched GDGTs, in-situ production, marine sediment, global scale, paleoclimate reconstruction

The in-situ production of branched glycerol dialkyl glycerol tetraethers (brGDGTs) in marine environments has been generally accepted. However, whether it takes place in the water column or the sediments remains elusive. Here, we compiled a dataset composed of globally distributed marine sediments from continental shelves to hadal trenches to address this important knowledge gap. Firstly, a cutoff of ΣIIIa/ΣIIa ≥ 0.92 was applied to distinguish the marine vs. terrestrial signals of brGDGT production. For marine derived brGDGTs, the cyclization of branched tetraethers (CBT) index, related to ambient pH, displays a large variability, suggesting that marine derived brGDGTs in sediments are mainly produced within sediments where the pH of sediment porewater is highly variable, rather than in the water column where pH is relatively constant. This is also supported by good correlations between the bottom water temperature and the methylation of branched tetraethers (MBT') index, between the water depth and the ΣIIIa/ΣIIa index, as well as between the brGDGT-based proxies and sediment redox conditions during glacial/interglacial cycles. We thus propose that the benthic production of brGDGTs in marine sediments is ubiquitous on a global scale, and is largely affected by the ambient temperature and pH. Our findings support that brGDGT-based proxies have potential of recording environmental conditions of the ocean bottom.

6. School of Geosciences, University of South Florida, St. Petersburg, Florida, UNITED STATES
E-mail: dinghe@ust.hk

Keywords: Mangroves, Taraxerol, Hydrogen isotope, Carbon isotope, Early diagenesis, Paleoreconstruction

Reconstructing past climate change in mangrove swamps contextualizes ongoing and future developments in these globally important ecosystems. Taraxerol, a well-recognized lipid biomarker for mangroves, is a promising target compound for calibration since it is relatively refractory and well preserved in sediments and since mangrove lipid δ^2H and $\delta^{13}C$ values have been shown to respond to salinity changes. Here we investigate the δ^2H and $\delta^{13}C$ values of taraxerol in leaves of two mangrove species (Rhizophora mangle and Laguncularia racemosa) and three dated mangrove cores along a spatial transect from the Shark River Estuary of South Florida, USA, to constrain its applicability for hydroclimate reconstructions. The net 2H discrimination between surface water and taraxerol increased by 1.0‰ ppt-1 over a salinity range of 0.7-32 ppt for both R. mangle and L. racemosa. Although the $\delta^{13}C$ values of taraxerol showed a significant positive correlation with salinity in L. racemosa, the inverse trend was observed in R. mangle. The isotopic signature and spatial trends of taraxerol observed in mangrove leaves were well imprinted in mangrove surface sediments.
In addition, we further tested if the isotopic signal of taraxerol from mangrove leaves could be preserved in sediment cores on a time scale of ca. 300 yrs. No strong evidence of significant diagenetic alteration was observed for δ^2H values of taraxerol. In contrast, an increase up to ~1.1‰ was observed for $\delta^{13}C$, excluding the Suess effect. Considering the consistent salinity-dependent discrimination of 2H to salinity, and no significant diagenetic alteration of taraxerol δ^2H values on centennial time scales, taraxerol H isotopes are a promising proxy for hydroclimate reconstruction in mangrove and mangrove-adjacent systems. However, the interpretation of $\delta^{13}C$ values of taraxerol should be treated with caution since its correlation with salinity may be species-specific and a slight diagenetic enrichment in 13C may occur.

Effect of "plant types" on terrestrial leaf wax biomarkers

Jinzhao Liu[1*]
1. Paleo environment Division, Institute fo Earth Environment, CAS, Xi'an, Shaanxi, CHINA
E-mail: liujinzhao@ieecas.cn

Keywords: Terrestrial biomarkers, Leaf wax, GDGTs, Cellulose, Coupling

Terrestrial biomarkers are widely studied to indicate the paleoclimate and paleoenvironmental signals. However, almost all prior studies focused on the identification of an alternative proxy such as leaf wax, GDGTs, cellulose etc. Each biomarker has inherent strengths and weaknesses, therefore coupled proxy based upon independent biomarkers is desired. In this study, we try to couple more than one biomarker from a suite of samples for implicating paleoclimate (e.g., RH) and paleoelevation. We found that the coupling of leaf wax δ2H values and brGDGTs along arid elevation transects such as Chinese Loess Plateau and Tibetan Plateau would be better to indicate the altitudinal changes, which could reduce and ambiguity and errors derived from single proxy. Additionally, the coupling of three forms of leaf wax biomarkers such as n-alkanes, δ2H and δ13C values could be used to reflect various climate and environmental information. We also try to couple leaf wax δ2H values and cellulose δ18O values, which can be used to indicate the RH variation. The coupling biomarkers will be a hot research direction for biomarker researchers and paleoclimate/paleoenviornmental reconstruction.

Productivity Controls the Deposition of High-Quality Oil Shale in Wushi Sag, Beibuwan Basin, South China Sea: Evidence From Unusual Carbon Isotope of Kerogens

Huan Mao[1*], Xibing Yang[1], Lin Hu[1], Desheng Hu[1], Xinde Xu[1], Zhipeng Sun[1], Daojun Zhang[1]
1. Research Institute, China National Offshore Oil Corporation (CNOOC) -Hainan Limited, Haikou, Hainan, CHINA
E-mail: maohuan@cnooc.com.cn

Keywords: oil shale, carbon isotope, productivity , algae bloom, lacustrine, Beibuwan Basin

Eocene Liushagang-2 section in Wushi sag, Beibuwan Basin has been proved to deposit lacustrine algal-rich oil shales consisting of sapropel kerogens dominated by lamalginites. Our new study reveals that kerogens of Eocene lacustrine oil shales in Wushi sag demonstrate wide-raging $\delta^{13}C_{org}$ values (-30‰~-17.7‰). Oil shales with heavier carbon isotope anomaly ($\delta^{13}C_{org}$ -23‰ to -17‰) are characterized by more organic richness and hydrocarbon potential compared to oil shales with more negative $\delta^{13}C_{org}$ value (-30‰~-25‰).These findings draw attentions of geologists and raise interesting questions about the cause of anomaly and variation of carbon isotope of oil shales in Wushi sag.

In this paper, we integrate carbon isotope of organic matter ($\delta^{13}C_{org}$) and carbonate ($\delta^{13}C_{cab}$) with molecular and fossil results of oil shales to establish the relationship between molecular biomarker and isotopic composition. It is observed that carbon isotopes of kerogens of oil shales ($\delta^{13}C_{org}$) are strongly and positively correlated with abundance of C_{30} 4-methylsterane. This observation suggests that the unusual ^{13}C enrichment of oil shales is possibly related with algae bloom in Wushi paleolake.The parallel and positive shifts of carbon isotope of organic matter ($\delta^{13}C_{org}$) and carbonates ($\delta^{13}C_{carb}$) further support the hypothesis that bloom-related CO_2(aq) drawdown in photic zones contributes to dissolved inorganic carbon ^{13}C enrichment in surface water (perhaps HCO_3^-) that is utilized by phytoplankton during photosynthesis as carbon source, ultimately resulting in the ^{13}C enrichment of oil shales.Thus these oil shales with heavier carbon isotope represent the products of elevated productivity under CO_2-limiting condition in Wushi paleolake. Conversely, the ^{13}C-depleted oil shales were formed during episodes of decreased algal production, when CO_2 concentration in surface water was so enough that uptake of dissolved CO_2 by phytoplankton enhanced algal ^{12}C discrimination. Therefore, we propose that the observed isotope variation ($\delta^{13}C_{org}$) records the change in productivity of surface water that controls the organic richness of oil shales in Wushi sag.The sharp variation of carbon isotope of oil shales in less than 100m intervals implies that productivity of Wushi paleolake was not stable possibly as the result of paleoclimate fluctuation or nutrient availability during the period of Eocene Liushagang-2 .

The deposition model of Eocene lacustrine oil shales in Wushi sag is reconstructed on the basis of their $\delta^{13}C_{org}$ values. At the early stage of Eocene Liushagang-2 period, nutrient influx (Phosphorus) from the surrounding highlands triggered algae blooms in Wushi paleolake. The elevated productivity caused the more oxygen-depleted environment at the bottom of the lake, which is supported by evidence of higher sulfur in oil shales, contributing to form ^{13}C-enriched oil shales with higher TOC content. Subsequently, productivity of the paleolake decreased resulting in the formation of ^{13}C-depleted oil shales with relatively low organic carbon concentration. At the late stage of Eocene Liushagang-2 period, possible changes of paleoclimate triggered the absence of water-column stratification leading to deposition of organic-lean mud shale in Wushi sag.

Carbon and hydrogen isotope variability of microbial fatty acids reveals a wide range of metabolic diversity in various environments

Yiming Zhang[1], Xianyu Huang[1*], Meiling Zhao[1], Ruicheng Wang[1]
1. State Key Laboratory of Biogeology and Environmental Geology, China University of Geosciences (Wuhan), Wuhan, Hubei, CHINA
E-mail: xyhuang@cug.edu.cn

Keywords: carbon isotope, hydrogen isotope, fatty acids, microbial metabolism

The carbon ($\delta^{13}C$) and hydrogen ($\delta^{2}H$) isotope compositions of microbial lipid biomarkers are a useful tool for tracing microbial metabolism in modern environments, and are one of the few ways to reveal past biogeochemical processes in sedimentary settings. Understanding the isotopic fractionation factors associated with expected biogeochemical processes in natural environments is important to ensure the reliable use of these isotopic tracers. However, the $\delta^{13}C$ and $\delta^{2}H$ characteristics of microbial lipids and their fractionation factors remain less constrained in modern natural environments. Here, we investigated the $\delta^{13}C$ and $\delta^{2}H$ characteristics of microbial fatty acids in natural topsoil samples from a subtropical subalpine basin that includes wetland, meadow, and forest habits. The $\delta^{13}C$ values of microbial fatty acids in meadow and forest topsoil were similar and varied from –22‰ to –32‰, while the $\delta^{13}C$ values of microbial fatty acids in wetland topsoil were more depleted (–24‰ to –40‰). The kinetic carbon isotope fractionation factor ($\varepsilon_{FA/bulk}$) between microbial fatty acids and bulk organic carbon ranged from 10‰ to –3‰ in meadow and forest topsoil, indicating the dominant heterotrophic microbial metabolic activity. The $\varepsilon_{FA/bulk}$ of wetland topsoil had a wider range, with the $\varepsilon_{FA/bulk}$ of monounsaturated fatty acids as low as –10‰, suggesting greater variability of microbial metabolism and potential methanotrophic activities on top of the heterotrophy in wetland environments. Consistent with the difference in carbon metabolism between wetlands and meadows/forests, the molecular distribution of microbial fatty acids suggests a distinct microbial community structure, with Gram-negative bacteria more prevalent in wetlands compared with meadows and forests. The kinetic hydrogen isotope fractionation factor ($\varepsilon_{FA/water}$) between microbial fatty acids and source water ranged from –80‰ to –220‰, and had no significant differences in the three environments, indicating similarities in microbial central metabolism in these topsoil environments. Nevertheless, the $\varepsilon_{FA/water}$ values of anteiso fatty acid were lower than those of other microbial fatty acids, especially in wetland environments. This phenomenon may be related to photoautotrophic metabolism or the preferential synthesis of anteiso fatty acids. In summary, these results suggest a wide range of microbial metabolic diversity in various environments and the potential of microbial lipids $\delta^{13}C$ and $\delta^{2}H$ to track biogeochemical processes.

Response of microbial community to depositional environment and climate change in Liaohe Delta since the Last Glacial Maximum

Xiaofang Yu[1], Xiaoxia Lv[1*]
1. State Key Laboratory of Biogeology and Environmental Geology, China University of Geosciences (Wuhan), Wuhan, Hubei Province, CHINA
E-mail: luxiaox@163.com

Keywords: GDGTs, microbial community, sedimentary environment, climate change

Dramatic changes have taken place in global climate since the LMG, which have a strong impact on global environment. As transitional region between sea and land, the estuary delta area is sensitive to sea level change and climate change. The transgression and regression could strongly influence the coastal sedimentary environment. The evolution of sedimentary environment in Liaohe delta (LHD) since 32 ka BP was divided into four stages: fluvial deposition at 32-25 ka BP, lacustrine deposition in flood basin at 25-8 ka BP, shallow sea deposition at 8-5 ka BP and delta deposition at 5-0 ka BP. Here, we analyzed the concentration of iGDGTs and bGDGTs and found that the microbial communities, as the inhabitant, was sensitive to the environment and climate change. In fluvial sedimentary environment, the archaea and bacteria are not abundant. In lacustrine sedimentary environments, the abundance of methanogens decreased/increased with the increase/decrease of dissolved oxygen in the water column. Then rapid increase in the abundance of marine Thaumarchaeota in shallow seas. The abundance of marine Thaumarchaeota in delta depositional environment decreased gradually. Since 1.5ka BP, the delta has gradually transformed into coastal wetland. In the lacustrine deposition stage, the microbial community had obvious response to climate change. The warm climate of B/A stimulated the abundance of archaea and bacteria in the lake. Stable lake evolution and enhanced monsoon precipitation elevate lake water level and decreased DO of water column, which stimulated the growth of methanogens. In YD, global cooling suppressed microbial abundance. The weakening EASM has reduced precipitation amount, and caused lake levels to drop rapidly. Meanwhile, strong wind caused by EAWM increased the water mixing in shallow lakes, which resulted in the water column DO content increasing and further inhibiting methanogens produce.

Evaluation of the wider applications of the alkanol index BNA15 in a global distribution of peat deposits

Zhiguo Li[1], Xianyu Huang[1*], David Naafs[2], Canfa Wang[1], Shucheng Xie[1]
1. School of Earth Science, China University of Geosciences(Wuhan), Wuhan, Hubei, CHINA
2. School of Chemistry, University of Bristol, Bristol, UNITED KINGDOM
E-mail: xyhuang@cug.edu.cn

Keywords: peat,branched fatty alcohols,BNA15,paleotemperature

The biomarker-based BNA_{15} proxy, the degree of branched C_{15} alkan-1-ols over normal C_{15} alkan-1-ol, was recently proposed as a novel terrestrial paleothermometer. It was calibrated using a limited number of Chinese mineral soils. Whether the BNA_{15} ratio can be applied more generally is currently unknown and the calibration of BNA_{15} using modern peat samples so far does not exist. Here we analyzed 129 surface and downcore peat samples from 18 globally distributed peatlands with a broad mean annual air temperature (MAAT) range (-3.2 to 26.5℃) and pH range (3 to 8) to test the wider applicability of the BNA_{15} proxy in peat deposits. Our results show that the BNA_{15} differs significantly between depths within the same peat core, with higher values in the anoxic catotelm in mid/low latitude peatlands and slightly higher in the acrotelm in high latitude/altitude peatlands. Combined with the evidence of the absolute concentration of alkan-1-ols in a peat core retrieved from the Dajiuhu peatland, we suggest that more branched alkan-1-ols are from the acro/catotelm boundary. BNA_{15} has a moderate correlation with the growth temperature in surface samples, which is affected by temperature and water table together. Besides, a positive correlation can be observed between BNA_{15} and MAAT in the catotelm part in Chinese peatlands (R^2=0.95, $p<0.01$), as well as in other peatlands beyond China (R^2=0.99, $p<0.05$), but the slopes and intercepts differ. We find no clear correlation between BNA_{15} and pH in any of the peatlands. The regional difference in the slope and intercept of the correlation between BNA_{15} and MAAT suggests that this proxy is affected by other factors beyond the temperature, e.g. vegetation type, peat nutrient status, and/or microbial community.

5. State Key Laboratory of Organic Geochemistry, Guangzhou Institute of Geochemistry, Guangzhou, Guangdong, CHINA

E-mail: xyhuang@cug.edu.cn

Keywords: Holocene, hydroclimate, biomarker, δD

China experienced significant hydrological changes during the mid-to-late Holocene transition. However, the nature of the hydroclimate anomaly on the southeast coast of China remains elusive. Here, we present a leaf wax record from the Shuizhuyang (SZY) peat deposit on the southeast coast of China spanning the Holocene. The δD values of C_{29} *n*-alkane (δD_{C29}) showed a large positive shift from 4.7 to 3.8 ka with an amplitude up to 24‰. As δD_{C29} changed independent of vegetation proxies and could not be solely explained by variations in precipitation δD values, it is more likely to reflect prolonged drying during the mid-to-late Holocene transition. This prolonged drying is probably to be primarily shaped by a more El Niño-like state over the tropical Pacific Ocean, which would decrease the rainfall on the southeast coast of China by shifting the western Pacific subtropical high (WPSH) more southwestward.

The brGDGT-based paleothermometer; proxy development and application

Bernhard David Naafs[1*]
1. Organic Geochemistry Unit, School of Chemistry, University of Bristol, Bristol, UNITED KINGDOM
E-mail: david.naafs@bristol.ac.uk

Keywords: biomarker, brGDGT, temperature, terrestrial, paleo climate, organic

Branched glycerol dialkyl glycerol tetraethers (brGDGTs) are bacterial membrane lipids. The distribution of brGDGTs in mineral soils, lakes, and peats is correlated with temperature through a decrease in the degree of methylation with increasing temperature. This empirical observation forms the basis of the brGDGT paleothermometer. In my presentation I will present and discuss recent advances in our understanding of the brGDGT-based paleotherometer, including recent culturing successes and molecular dynamics simulations, which together allow us to confidently apply this proxy to reconstruct terrestrial temperature to the geological past. I will also present new data to demonstrate how the brGDGT-based paleotherometer can revolutionize our understanding of the operation of Earth's System in general and the terrestrial realm specifically.

The occurrence of hydroxylated isoprenoid GDGTs in soils and peats: implications for OH-GDGT-based proxies

YI MAN[1], HUAN YANG[1*]
1. , , , , CHINA
E-mail: yhsailing@163.com

Keywords: Hydroxylated isoprenoid GDGTs, soil, peat, temperature,Thaumarchaeota

Hydroxylated isoprenoid glycerol dialkyl glycerol tetraethers (OH-GDGTs), a class of lipids that widely occur in the global marine and lacustrine environments, have been used as tools for temperature reconstruction. However, their occurrence in terrestrial environments is rare. Here, we investigated the downward variation in distribution and concentration of OH-GDGTs in three soil profiles (SP) from Mount Yujiashan in Wuhan, central China as well as the distribution of OH-GDGTs in Chinese peatlands where the mean annual air temperature (MAT) varies from 2℃ to 14.2℃. In soils, the OH-GDGT content showed significant correlations with that of crenarchaeol and decreased with total organic carbon content (TOC), likely in relation to the decreased supply of organic nutrients downwards in these SPs. Crenarchaeol was likely to be produced primarily by Thaumarchaeota Group I.1b whereas OH-GDGTs by Thaumarchaeota Group I.1a based on 16S rRNA gene sequencing. This suggests that Thaumarchaeota Group I.1b and I.1a occupy similar niches in these soils. OH-GDGTs were dominated by OH-GDGT-2 in soils and OH-GDGT-0 was dominant in peats, differing significantly from aquatic settings. RI-OH' showed a significant correlation with temperature in the combined data set of soils and peats, with a different intercept yet a similar slope to that of the global marine data set. Applying the marine RI-OH and RI-OH' calibration to these soils and peats yielded markedly higher temperatures than local MAT, suggesting a different response of terrestrial OH-GDGTs to temperature and (or) a significant bias of RI-OH/RI-OH' towards summer temperature.

Resolving the biosynthesis of tetraether lipids: potential implications for deciphering the sedimentary biomarker record

Zhirui Zeng[1*]

1. Department of Ocean Science and Engineering, Southern University of Science and Technology, Shenzhen, Guangdong, CHINA

E-mail: zengzr@sustech.edu.cn

Keywords: Lipid biomarker, Tetraether lipids, GDGTs biosynthesis, paleoenvironment

Microbial lipids can be preserved for geological time periods within sediments and provide a unique tool that allows the reconstruction of paleoenvironment and paleoecology. A unique group of microbial lipids, glycerol dibiphytanyl glycerol tetraethers (GDGTs), are archaeal membrane lipids that are correlated with archaeal community and environmental fluctuations, leading to the use of GDGTs as taxonomic markers and paleoproxies for studies of microbial ecology and past global climate fluctuations. In our studies, by identifying genes responsible for GDGTs biosynthesis, including GDGT-0 formation, GDGT cyclization, and GDGT caldital head group alternation, we have a better understanding of the biological sources of GDGTs fossils in sediments, that allows GDGTs to become a more reliable taxonomic marker. This genetic basis could also provide insight into the regulation on GDGTs profiles in archaea, and thus establish a more robust correlation between lipid profiles and environmental fluctuations.

Significant contribution of petrogenic organic carbon in the Taiwan Strait

Bingyan Zhao[1], Jianfang Hu[1*], Weisen Liao[1]
1. State Key Laboratory of Organic Geochemistry, Guangzhou Institute of Geochemistry, Guangzhou City, Guangdong Province, CHINA
E-mail: hujf@gig.ac.cn

Keywords: Taiwan Strait, Organic Carbon (OC), Petrogenic OC, Four-end member model

The marginal seas occupy only 20% of global ocean area, but contribute around 80% of organic carbon (OC) burial in sediments, thus, are significant to the ocean carbon cycles and budgets (Hedges and keil 1995; Burdige, 2005; Zhao et al., 2021). The input of terrestrial OC to the continental shelves increases due to the global climatic change and anthropogenic activities, which is an important yet undetermined proportion of global carbon budget. The Taiwan Strait receives abundant terrestrial OC from the Taiwan Island. To better understand the sources and controls on the OC burial in the Taiwan Strait. We measured the lignin and hopanoid molecular biomarkers in the Taiwan Strait. Together with the N/C and δ13Corg data (Liao et al., 2018), we estimate the proportions of OC derived from soil, plant, petrogenic and marine using a four end-member mixing model. The results indicate that the fractional contributions of soil, bedrock, plant and marine OC are 9–28%, 31–61%, 7–31%, and 13–46%, respectively. Petrogenic OC is the main component of the burial OC in the Taiwan Strait, with buried carbon budget up to 0.19×106 t C yr−1. This finding highlights the need for better constrain of terrigenous OC to better understand the carbon cycling and burial in marginal seas with high-standing islands and/or highly eroded mountains.

Metabolism variation of heterotrophs recorded by compound-specific hydrogen isotopes over the past 3000 years in Antarctica

Xin Chen[1,2*]

1. School of Oceanography, Shanghai Jiao Tong University, Shanghai, CHINA
2. School of Earth and Space Sciences, University of Science and Technology of China, Hefei, Anhui, CHINA
E-mail: xinchen1991@sjtu.edu.cn

Keywords: Lipid biomarkers, Hydrogen isotope ratios, Metabolism, Paleo-ecological changes, Antarctica

Hydrogen isotopes ratios of lipids are strongly correlated with metabolism: strongest 2H-depleted in chemoautotrophs, moderately 2H-depleted in photoautotrophs and slightly 2H-enriched in heterotrophs (Zhang et al., 2009; Wijker et al., 2019). These features highlight the potential using compound-specific hydrogen isotopes to provide meaningful insights into the metabolism of modern and ancient microorganisms. Up to now, however, there is no study concentrating on whether such isotope signals can be used to infer the metabolism on geologic times. Furthermore, what environmental factors affect the changes of central metabolic pathways in heterotrophs remain elusive. Here we performed the analysis of the compound-specific hydrogen isotopes in two lacustrine sediment profiles (IIL3 and IIL9) sampled at Inexpressible Island, western Ross Sea, Antarctica. We show that mid- and long-chain n-alkanoic acids all display “inverse” or reduced hydrogen isotope fractionations throughout these two explored sediment profiles, suggesting these compounds are predominantly originated from heterotrophic microbes. Large D/H fractionations indicate the central metabolic pathway of heterotrophs changed significantly during the past 3000 years. Compared with other proxies in the same cores, the central metabolic pathway of heterotrophs is driven by lake/pond productivity, which response to air temperature changes. Our results suggest that D/H variation in heterotrophic lipids has great potential as a proxy for inferring paleo central metabolism, which may provide curial information about ecological changes and carbon cycle on geologic times in Antarctica.

E-mail: xiecug@163.com

Keywords: polycyclic aromatic hydrocarbons,aridification,wildfire-climate-biota

The frequency and intensity of wildfires have a significant impact on landscapes and terrestrial ecosystems. Evidence of enhanced wildfires has been reported from both Permian-Triassic (P-Tr) and Triassic-Jurassic (Tr-J) transitional strata, which considered to be causally related to the Siberian Traps and Central Atlantic Magmatic Province, respectively. However, it remains unclear whether the enhancement of wildfires at sites distal to these volcanic sources was the result of climate change at a global scale (e.g., volcanically induced warming and aridification) or a regional scale (e.g., aridification linked to hydrological cycle changes). Here, we utilize pyrolytic polycyclic aromatic hydrocarbons (PAHs) to generate a high-resolution record of secular variation in wildfire frequency for terrestrial sections in China during the end-Permian (Dalongkou) and end-Triassic (Hechuan and Guangyuan) biotic crisis, with which we compare floral and faunal records of the same sections in order to evaluate wildfire-climate links. Two episodes of increased pyrolytic PAH concentrations and ratios of combustion origin in the subtropical terrestrial Dalongkou section of northwestern China during the P-Tr transition were linked to increased wildfire frequency, one triggered by climatic hyperwarming and the other by aridification, as revealed by spore-to-pollen ratios (S/P). Increased abundances of pyrolytic PAHs of wildfire origin found in the Hechuan and Guangyuan sections were also linked to increased wildfire frequency during the Tr-J transition, probably triggered by regional aridification. Our data demonstrate similar terrestrial ecosystem stresses from climate-induced wildfires outside of their respective regions of large igneous province (LIP) emplacement, as well as major floral turnovers, during the P-Tr and Tr-J events. We also compiled proxy data at a global scale to examine the geographic distribution of wildfires during each boundary event (Fig. 1), revealing a link between wildfire frequency and coal occurrence that was presumably mediated by the geographic distribution of forests. Although volcanism is likely to have been the ultimate cause of climate change during the P-Tr and Tr-J events, we infer that rapid local climate change (aridification) was the main cause of wildfires in South China. These results are highly significant in providing new insights into wildfire-climate-biota relationships in terrestrial systems during the two largest mass extinction events in Earth history.

The impact of Labrador and North Atlantic currents in modulating sedimentation and climate on the northwest Atlantic Ocean during the last 40 ka

Yang Wang[1], Harunur Rashid[1,2*], Jianing He[1], Zhaowu Zhang[1]
1. College of Marine Sciences, Shanghai Ocean University, Shanghai, CHINA
2. Earth and Environmental Sciences, Memorial University of Newfoundland, St John's, Newfoundland and Labrador, CANADA
E-mail: rashid@shou.edu.cn

Keywords: Labrador Current, Sea-Surface temperature, Laurentide Ice Sheet, Scotian Shelf, Newfoundland Basin

The SE Grand Banks and Scotian margin of the northwest Atlantic Ocean is the most dynamic region due to bathing by two distinct seasonal water masses: the equator flowing cold and fresh Labrador Current and northeast flowing warm and salty North Atlantic Current (NAC). Both regions witness dramatic changes in the sea-surface temperature and salinity and seasonal sediment-bearing plume and nutrients primarily derived from the neighboring landmasses and sea-ice melt freshwater. In the modern oceanographic setting, the Nova Scotia margin is mainly influenced by the NAC, whereas the SE Grand Banks is perturbed by a mixture of Labrador Current and NAC. Here we report changes in the sediment dynamics and sea-surface characteristics using five sediment cores, namely 93026-07, 96018-20 and 87003-07 from the Scotian margin and 2001043-027 and 9007-08 from the SE Grand Banks for the past 40 ka. Our data suggest two distinct dichotomies between the Scotian margin and SE Grand Banks in which glacial sediments were found in the upper slope of both regions, whereas the Holocene sediments were only reported from the former. The difference in sediment dynamics reflects erosion and sediment remobilization by the Labrador Current.

Further, the first application of the isoprenoid glycerol dibiphytanyl glycerol tetraethers (GDGTs) proxy TEX86 in these two regions revealed changes in two distinct thermal structures (i.e., sea-surface temperatures). Secondly, the branched GDGTs index (∑IIIa/∑IIa and BIT) and sediment bulk geochemical proxies (CaCO3% and Ca/Ti) were used to assess change in the terrigenous input.

Our TEX^{L}_{86}-derived temperature suggests the opposite trend between the two regions during the early Holocene and deglacial period, in which cooler sea-surface temperatures (SSTs) prevailed on the Scotian margin than on the SE Grand Banks. The difference in the SSTs reflects that the Labrador Current mainly influenced the Scotian margin during the early Holocene and deglacial period. However, it is hypothesized that the SSTs were most likely influenced by a mixture of the Labrador Current and NAC on the SE Grand Banks, which needs to be affirmed by additional proxies.

Quantitative Holocene temperature evolution revealed by lacustrine brGDGTs record from southwestern China

Jie Wu[1], Huan Yang[1*]
1. School of Earth Sciences, China University of Geosciences (Wuhan), Wuhan, Hubei, CHINA
E-mail: yhsailing@163.com

Keywords: Holocene, temperature, GDGTs, southwestern China

Holocene temperature cooling or warming is highly controversial, partly due to the lack of high-quantity temperature record. Here, we present a high-resolution, no seasonal bias and no hydrology affected Holocene temperature record from southwest China. The temperature record showed an overall cooling trend during 10-0 ka BP, accompanying with several centennial scale abruptly cold events. These signals are supported by other temperature records from China monsoon region and global synthesized temperature records. Our result indicates that the seasonal bias might not be responsible for the discrepancy between the large region synthesized results and model simulated results. In addition, we find the human activities in the Anthropocene have not only cause a rapid increase in temperature during the background of a long cooling trend in the Holocene, but also led to a decouple between temperature and precipitation in southwest China.

Seasonal imprint of Holocene temperature reconstruction on the Tibetan Plateau

Can Zhang[1], Cheng Zhao[1*]
1. Lake Sediment and Environmental Evolution, Nanjing Institute of Geography and Limnology, Chinese Academy of Sciences, Nanjing, Jiangsu, CHINA
E-mail: czhao@niglas.ac.cn

Keywords: Seasonal temperature, Holocene, Tibetan Plateau, Insolation, Greenhouse gas forcing

The Tibetan Plateau (TP) is one of the most sensitive areas to global climate changes. Quantitative paleotemperature reconstructions on the TP since the Last Deglaciation provide a prominent opportunity not only for assessing the position, but also for better understanding the mechanism of recent warming. In this study, we first present a well-dated, high-resolution (~70 years), ice-free-season temperature (from March to October, TM-O) record over the past 19 ka from a small alpine lake on the southeastern TP based on brGDGT proxy. Our reconstructed TM-O record displays a long-term ~4 ◦C warming trend during the past 19 ka with a deglacial increase of ~3 ◦C and Holocene increase of ~1 ◦C. To better understand the pattern and mechanism of postglacial temperature changes on the TP, we review 16 published paleotemperature records since the Last Deglaciation. The results show a general warming pattern during the Last Deglaciation but divergent trends of seasonal temperatures during the Holocene with a gradual cooling pattern in summer temperature, an overall warming pattern in winter temperature, annual temperature, and TM-O as well as a warming-cooling-warming pattern in TMJJAS (temperature from May to September). Data-model comparison indicates that the long-term warming trend in deglacial temperatures are primarily driven by rising atmospheric greenhouse gases (GHGs) on the TP. In contrast, Holocene temperature changes are mainly controlled by local seasonal insolation and additional radiative forcing of GHGs on the TP, thereby resulting in divergent patterns of seasonal temperature changes. Our study highlights the necessity of taking into account the seasonal bias when reconstructing temperatures, especially in high latitudes and high altitudes where the freezing occurs.

Enhanced precipitation in the Gulf of Mexico during the Eocene–Oligocene transition driven by interhemispherical temperature asymmetry

Guangsheng Zhuang[1*]
1. Geology and Geophysics, Louisiana State University, Baton Rouge, Louisiana, UNITED STATES
E-mail: gzhuang@lsu.edu

Keywords: Gulf of Mexico, Compound Specific Isotope Analysis, Lipid wax, Eocene-Oligocene Transition

Studies reveal that the sea-surface temperature (SST) of the Northern Hemisphere decreased at a smaller amplitude than that of the Southern Hemisphere during the Eocene–Oligocene transition (EOT). This interhemispheric temperature asymmetry has been associated with intensified Atlantic Meridional Overturning Circulation (AMOC) that may have driven enhanced precipitation and weathering in low latitudes and the subsequent drawdown of atmospheric carbon dioxide. However, no quantitative constraints on paleo-precipitation have been reported in low latitudes to characterize the AMOC effect across the EOT. Here, we present the results of high-resolution (ca. 6 k.y. per sample) isotopic and biomarker records from the Gulf of Mexico. Reconstructed precipitation using leaf wax carbon isotopes shows an increase of 44% across the EOT (34.1–33.6 Ma), which is accompanied by a secular increase in SST of 2 °C during the latest Eocene. We attribute the enhanced precipitation in the Gulf of Mexico to the northward shift of the Intertropical Convergence Zone that was driven by an enlarged polar-tropic temperature gradient in the Southern Hemisphere and an invigorated AMOC. Our findings link changes in meridional temperature gradient and large-scale oceanic circulation to the low-latitude terrestrial hydroclimate and provide paleohydrological evidence that supports CO2-weathering feedback during the EOT “greenhouse” to “icehouse” transition.

Spatial distribution of n-alkanes in the catchment and sediments of Lake Lugu, Southwest China: Implications for palaeoenvironment reconstruction

Jingjing Li[1*]
1. State Key Laboratory of Lake Sciences and Environment, Nanjing Institute of Geography and Limnology Chinese Academy of Sciences, Nanjing, Jiangsu, CHINA
E-mail: jjli@niglas.ac.cn

Keywords: n-Alkanes, Lake surface sediment, Spatial distribution, Water depth, Palaeoenvironment reconstruction

n-Alkanes have been widely used to reconstruct palaeoenvironmental variations in lacustrine environments. However, for robust reconstructions, improving the understanding of the origin of n-alkanes and their distribution within the lake is essential. Therefore, we examined the distribution pattern of n-alkanes in the aquatic plants within Lake Lugu (a deep alpine lake on the southeastern margin of the Tibetan Plateau, southwest China), and terrestrial plants and topsoils in the catchment, to unravel the origin of sedimentary n-alkanes and further investigate the spatial distribution of n-alkanes from surface sediments in this lake. The aquatic plants are dominated by mid-chain C23 and C25, terrestrial plants and soils by long-chain C29, and 76% of the surface sediment samples show C29 predominance. The average chain length (ACL) and the aquatic plant proxy (Paq) values of surface sediments are between those of aquatic and terrestrial plants and soils. Thus, n-alkanes from autochthonous (aquatic plants) and allochthonous (terrestrial plants and soils) sources were apparent in the surface sediments. A substantial spatial distribution of n-alkanes exists within Lake Lugu: the n-alkane concentrations of total, aquatic, and terrigenous origins are concentrated in the northwestern portion of the lake's north basin, which may be attributed to the underwater topography and increased human-induced soil erosion in this area. Similarly, the clear spatial heterogeneity of ACL21-33 and Paq may suggest that the sedimentary n-alkanes comprise a mixture contribution of autochthonous and allochthonous production, which might be the major source of n-alkanes in the lakeshore, and a higher proportion of autochthonous n-alkanes is present in deep water. However, there is no significant correlation between the Paq of sediments and water depth in Lake Lugu; thus, the application of Paq as a lake-level indicator should be used with caution in deep-water lakes similar to Lake Lugu.

Late deglacial methane leak from low latitude northern hemisphere

Mengyuan Wang[1*]
1. School of marine sciences, Sun Yat-sen University, zhuhai, Guangdong, CHINA
E-mail: wangmy36@mail.sysu.edu.cn

Keywords: Glycerol Dialkyl Glycerol Tetraethers, Shenhu hydrate zone, methane leak, late deglacial

Released methane to sea water and atmosphere, marine hydrate dissociation is a vital issue on discussing global climate. Understanding the last glacial and interglacial cycle hydrate leak helps us depict the future. In this study, we take Northern Hemisphere low latitude hydrate zone as an example, trying to reveal the geological records of hydrate leak, especially from deglaciation which is a mirror-like recent period of modern climate. We conduct this work using biogeochemistry proxies from Glycerol Dialkyl Glycerol Tetraethers (GDGTs) and foraminifera stable carbon isotope. Our results from Shenhu hydrate zone in the South China Sea record cold periods methane release during Last Glacial Maximum, that is known to be a result of hydrostatic pressure reduction. Interestingly, we found obvious methane leak in deglacial period. Abrupt intermediate water temperature increase might probably be one of the reasons that trigger this warm period methane release. Northern Hemisphere high latitude (near Arctic) also featured by deglacial hydrate dissociation. However, records from north pole is a little bit earlier. This might be caused by lagged drastic changes in low latitude ocean circulation when global climate abruptly warming up after long cool period. Our study shows that low latitude Northern Hemisphere marine CH4 leakage likely contribute to deglacial and early Holocene warm period air CH4 optimum.

E-mail: Baicy@cugb.edu.cn

Keywords: Gas hydrates, sedimentary processes, sediment physical properties, microbial abundance, South China Sea

As a potential major energy resource, gas hydrates are widely found in sub-oceanic sediments and could play an important role in the future of fuels. Many studies have been applied on gas hydrates reservoir to understand its accumulation as well as potential industrial values, while the characteristics of sediments favoring gas hydrates accumulation are still unclear. Here, we investigate a gas hydrates reservoir in Shenhu area, Pearl River Mouth Basin, South China Sea (SCS), studying reservoir sediments features to understand controlling factors of gas hydrates accumulation. We sampled sediments of drilling site W19 in this area, which has thick, high saturation gas hydrate layers, and analyze sediments' physical properties (including the grain size, mineral composition, and specific surface area), and microbial abundance in the gas hydrate-bearing and adjacent layers. The results show fine-grained turbidite sediments characterized by poor sorting, high foraminifera abundance, and low clay mineral content, are beneficial to gas hydrate accumulation, while suspended sediments characterized by fine sorting, high calcareous ultra-microfossil abundance, and high clay mineral content, are not conducive to gas hydrate accumulation. Based on these results, we propose multiple factors, including the sedimentary processes, sorting, microbial abundance, mineral composition, and specific surface area, has been controlling the gas hydrate accumulation in the SCS and it could potentially reveal the regularity of gas hydrate accumulation on a global scale.

E-mail: dfeng@shou.edu.cn

Keywords: Methane, Anaerobic oxidation of methane, Organoclastic sulfate reduction, pore-water sulfate; Sulfide

Sulfate-driven anaerobic oxidation of methane (SD-AOM) is ubiquitous in sedimentary environments, leaving an imprint in pyrite sulfur isotope ratios. However, the $\delta^{34}S$ values of pyrite alone are insufficient to discriminate SD-AOM signals from organoclastic sulfate reduction (OSR). Here, we investigated the multiple sulfur isotope ratios ($\delta^{34}S$ and $\Delta^{33}S$ values) of pore-water sulfate and sulfide, and authigenic pyrite of two piston cores and one push core from the continental slope of the South China Sea. Multiple sulfur isotope systematics reflect methane fluxes at the site. At a low methane flux site, a positive $\Delta^{33}S_{SO4}$ - $\delta^{34}S_{SO4}$ correlation of pore-water sulfate is observed in the upper, OSR-dominated zone, whereas they are negatively correlated in the sulfate-methane transition zone (SMTZ). At high methane flux site, the whole sulfate reduction zone is dominated by SD-AOM and own a negative $\Delta^{33}S_{SO4}$ - $\delta^{34}S_{SO4}$ correlation typified by different slopes under variable methane flux. The multiple sulfur isotope systematics of pyrite in methane-bearing sediment depend on the relative contribution of SD-AOM and OSR to the sulfide pool. This study provides a revised $\Delta^{33}S$ - $\delta^{34}S$ systematics of sulfide and sulfate minerals for tracing past SD-AOM activity and the different origins of pyrite.

Keywords: Authigenic carbonate, cold seep, AMS 14C, U/Th dating, Gulf of Mexico

Anaerobic oxidation of methane (AOM), mostly taking place at cold seeps, represents the major present-day sink for this important greenhouse gas that generated in marine sediments. This process often leads to formation of authigenic carbonates close to the seafloor along continental margins. Authigenic carbonates from hydrocarbon seeps are thus unique archives of past seepage and associated environmental parameters. Here, we applied accelerator mass spectrometry (AMS) radiocarbon (14C) and Uranium/Thorium (U/Th) dating to carbonates collected at nearly 50 seep sites from the northern Gulf of Mexico continental slope. The resulting ages indicates that carbonate from sites with water depth over 500 m usually much younger than 50 ka whereas carbonates from sites with water depth less than 500 m are often older. Although a wide range of frequencies was observed for gas and fluid expulsion events, it is suggested that enhanced seepage occurred following a sediment loading cycle. Our results highlight that sediment loading can have a strong impact on gas and fluid expulsions affecting slope stability and the carbon cycle.

Keywords: Oil seeps, Oil degradation, Sulfate-reducing bacteria, DAGEs, Gulf of Mexico, Makran accretionary prism

Hydrocarbon seeps are ubiquitous along continental margins and can exhibit varying fluid compositions. Most seeps are dominated by methane, but different contributions of short- and long-chain hydrocarbons, as well as crude oil are common. The Campeche Knolls in the Southern Gulf of Mexico are known for extensive oil seepage, which has an inhibiting effect on life at seeps. However, short- and long-chain hydrocarbons have been shown to be degraded by a range of heterotrophic sulfate-reducing bacteria. Here lipid biomarker and carbon isotope data from authigenic carbonates from the Campeche Knolls in the southern Gulf of Mexico are presented, indicating sulfate-reduction of oil-derived hydrocarbons and associated carbonate precipitation. The carbonates show $\delta^{13}C$ values in the range of -31.3‰ to -21.9‰, agreeing with carbon derived from oil-derived hydrocarbons. The occurrence of a particularly high amount of bacterial non-isoprenoidal ether lipids (DAGEs) with a wide variety of alkyl chain lengths was observed. Additionally, bacterial biomarkers show heavier carbon isotopic signatures than their counterparts at methane seeps. Mixing calculations revealed that a substantial part of the local sulfate reduction is coupled to the oxidation of non-methane hydrocarbons at oils seeps, contributing to authigenic carbonate precipitation. These data imply the possible characterization of bacterial oxidation of oil-derived hydrocarbons in modern and, in cases of moderate to good biomarker preservation, ancient environments, allowing for the estimation of the influence of fluid composition on chemosynthesis-based communities at seeps.

E-mail: joern.peckmann@uni-hamburg.de

Keywords: Bioturbation, burrows, seep carbonates, South China Sea

Seepage is widely distributed along continental margins worldwide, emitting methane and other reduced compounds into seawater or even the atmosphere. Since methane is an energy source on the one hand and greenhouse gas on the other hand, tracing seep activity is of environmental significance. Past seep activity is recorded by authigenic seep carbonates, the formation of which is induced by the high alkalinity produced by sulfate-driven anaerobic oxidation of methane (SD-AOM). Microcrystalline high-Mg calcite, in addition to botryoidal aragonite, is the common sedimentary fabric of seep limestones. The microcrystalline matrix is commonly pierced by burrows, which are subsequently filled by newly formed carbonate cement at later stage of seep activity. Here, we report infilled burrows in seep carbonates from the Shenhu area, occurring as longitudinal, winding and branched fabrics with a width of 400 to 700 μm. The infilled burrows and surrounding matrix are both cemented by microcrystalline seep carbonates. The carbonates in burrows show overall lower relative contents of dolomite, Mg/Ca ratios, and higher carbon isotope values. Since SD-AOM promotes the formation of carbonates with higher $MgCO_3$ contents and results in lower carbon isotope values than carbonates forming from marine dissolved inorganic carbon, the early stages seep carbonate formation in the matrix were more strongly controlled by SD-AOM, whereas the carbonate precipitating in burrows was influenced to a higher degree by marine conditions after the ingress of seawater into burrows.

Keywords: Hydrocarbon seeps, Authigenic carbonate, Diagenesis, Clotted micrite, Trace elements

Geochemical analyses of ancient seep limestones provide information on the chemical composition of seep fluids, facilitating for the reconstruction of the early evolution of chemosynthesis-based faunal communities. However, diagenetic processes often mask the primary composition of seep carbonates, impeding a reliable reconstruction of formation environments. The potential for the preservation of primary element patterns in microcrystalline carbonate, which is typically the volumetrically dominant phase of seep limestones, is poorly constrained to date. This study investigates ancient seep limestones collected from the Blue Mountains of eastern Oregon, USA, where seep limestones are composed of three different carbonate phases, including clotted calcite, banded and botryoidal cement, and equant calcite. Mineralogically, these three carbonate phases are now calcite characterized by low magnesium/calcium (Mg/Ca) ratios. The fibrous crystal habit of the botryoidal and banded cement indicates that the precursor mineral was originally aragonite. However, low strontium (Sr) contents and positive europium (Eu) anomalies of botryoidal cement suggest that this phase was affected by diagenetic alteration. Equant calcite exhibits the largest crystal size and the highest manganese/strontium (Mn/Sr) ratios, suggesting that this phase was the product of later-stage diagenesis, probably having precipitated during progressive burial. High Sr contents and low Mn/Sr ratios of clotted micrite suggest that this phase was less affected by diagenetic alteration, and has the highest preservation potential with respect to the original seep fluid composition. Shale-normalized rare earth elements and yttrium (REY) patterns of clotted micrite are similar to those found for modern seawater, agreeing with a close to primary composition of clotted micrite. Despite of its small crystal size, our study suggests that clotted micrite may have the potential to preserve information on fluid composition.

Keywords: Black Sea, Methane seeps, Trace elements, Carbonate mineralogy

Trace elements are widely used to constrain environmental conditions and biogeochemical processes. Authigenic carbonates in particular are a reliable archive due to their ability to take up and store trace elements over geologic timescales. Here we present new data on the effect of ambient redox conditions on trace element distributions in authigenic seep carbonates forming in different geochemical and hydrographic environments. Carbonates from shallow and deep-sea hydrocarbon seeps of the Black Sea are compared to seepage sites from the northern Gulf of Mexico and the northern South China Sea, revealing that trace element inventories are to some extent site-specific and depend on carbonate mineralogy. Strongly euxinic conditions at Black Sea deep-water seeps favor the formation of low-magnesium calcite, whereas fluctuating redox conditions favors aragonite cement precipitation. The trends in mineralogy are accompanied by distinct enrichments and depletions of specific trace elements including uranium, iron, and manganese. Aragonite cements exhibit lower magnesium to strontium ratios and manganese contents than their low-magnesium calcite counterparts. Moreover, trace elements in Black Sea carbonates are enriched in barium, manganese, zinc, and nickel, and are depleted in iron. The new trace element data suggest that the presence of dissolved sulfide influences carbonate mineralogy, and, accordingly, trace element speciation and content. The results of this study have implications for trace element-based paleoenvironment reconstructions beyond seep environments, and may initiate a reassessment of authigenic carbonates as a trace element archive, in particular for carbonates from ancient and modern euxinic environments.

E-mail: ygzhang@smail.nju.edu.cn

Keywords: Cambrian Radiation, Coupled C-S isotopes, Orbital Cycles, Redox Cycles.

During the Cambrian Explosion, episodic radiations of major animal phyla occurred in concert with repeated carbon and sulfur isotope excursions. These isotope patterns are thought to reflect oscillations in atmospheric O2, which promoted animal diversification events. However, the driver for isotopic and redox variation is unclear. Here we show that these synchronous carbon and sulfur isotope cycles, as well as marine oxygenation pulses, can be driven by long-period orbital forcing and its effects on weathering and nutrient delivery. We use spectral analysis to confirm that the isotope periodicities correspond to the long-period eccentricity obliquity cycles, and then explore the effects of this orbital forcing using a combined climate-biogeochemical model.

The model produces a fluctuating bioavailable phosphorus flux, which results from the varying latitudinal distribution of temperature, which drives pulses of oceanic photosynthetic productivity and organic carbon burial. The model also reproduces the unusual co-variation of carbon and sulfur isotopes, which occurs due to low seawater sulfate concentration and highly variable rates of pyrite burial.

We conclude that the oxygen-driven evolutionary changes in the early Cambrian can be explained by recurrent nutrient inputs to the ocean, which probably resulted from climate change caused by long-period orbital cycles. Such long-period cyclicity may explain other time periods that saw biogeochemical oscillations on these timescales.

The paleoceanic environment and exceptional fossil preservation in the Middle Triassic Luoping Biota from South China

Zhixin Ma[1,2*], Shixue Hu[2], Huaichun Wu[1], Changyong Zhou[2], Wen Wen[2], Qiyue Zhang[2], Jinyuan Huang[2], Xiao Min[2]
1. School of Ocean Sciences, China University of Geosciences, Beijing, CHINA
2. Fundamental geological research, Chengdu Center, China Geological Survey, Chengdu, Sichuan, CHINA
E-mail: zhixinma83@126.com

Keywords: Luoping biota, productivity, exceptional preservation, anoxia, Middle Triassic

The Luoping Biota is a typical representative of the full recovery of marine ecosystem after the Permian–Triassic Mass Extinction (Hu et al., 2011; Chen and Benton, 2012; Benton et al., 2013), yet the paleoenvironment background and ultimate cause of fossil preservation is still not well understood (Bai et al., 2010; Zhou et al., 2014; Ma et al., 2021). Here we presented sedimentary facies and multi-geochemical proxies (TOC, TN, δ13Ccarb, and δ13Corg, P/Al, Cuxs, Nixs, Baxs, MoEF, UEF, and VEF) in Member II of the Middle Triassic Guanling Formation at the Xiangdongpo section from Luoping County, Yunnan Province, to unravel the evolution of sedimentary environment, primary productivity, paleoredox condition and their link to the exceptional preservation of Luoping biota. The abundant exceptional preserved fossils mainly occur in two intervals from intra-platform depression environment, with high productivity and anoxia. Relatively low C/N ratios and distributed Δ13Ccarb-org indicate the source of primary productivity is derived from a mixture of eukaryotic algae and prokaryotic microbes. Based on the results of this study and regional correlation, it is concluded that when the sea level rose, nutrients were supplied to the Luoping area by Megamonsoon induced upwelling from the open ocean, fueled high primary productivity in surface water and oxygen consumption in the water column, causing bottom water anoxia. The lack of oxygen in the bottom water reduced the rate of biomass degradation and bioturbation, promoted the growth of microbial mats, and led to the exceptional preservation of macrofauna fossils.

Terrestrial carbon cycle implications from compound-specific carbon isotopes in Southwest China during the Permian-Triassic mass extinction

Jiaqi Wu[1], Genming Luo[1*]
1. School of Earth Sciences, China University of Geosciences, Wuhan, Wuhan, Hubei, CHINA
E-mail: logming@gmail.com

Keywords: Permo-Triassic transition, Southwest China, compound-specific carbon isotopes

Anthropogenic emissions disrupt modern global carbon cycle perturbated potentially far greater in magnitude and rate than variations in the recent past. The deep-time analogue through the Permo-Triassic (P-Tr) transition, which witnessed the largest mass extinction in Phanerozoic with substantial carbon perturbations and climate warming (Sun et al., 2012), could provide potential insights into the impact CO_2 on ecosystems. This extinction is thought to have been triggered by Siberian Traps large igneous province magmatism (Burgess et al., 2017). Multiple investigations have identified a large negative carbon isotope excursion of 3‰-6‰ in both marine carbonate and bulk sedimentary organic matter during the P-Tr boundary (Korte and Kozur, 2010). However, ultimate trigger mechanisms of the CIE remain dispute and bulk organic $\delta^{13}C$ is mixed signals of organic matter from different sources. The source uncertainty would be removed by compound carbon specific isotope compositions in *n*-alkanes, which offers a more specific proxy to distinguish different organic source and has been employed to interpret carbon cycle and paleoclimate (Diefendorf and Freimuth, 2017). Here, we undertake a survey of *n*-alkanes $\delta^{13}C$ values in a P-Tr boundary sequence ZK4703 in Southwest China. *n*-alkanes $\delta^{13}C$ are more negative but highly correlated with $\delta^{13}C_{org}$, $\delta^{13}C_{cuticle}$ and $\delta^{13}C_{charcoal}$ (R^2 = 0.62, 0.71, 0.64, respectively) published data from (Chu et al., 2020). *n*-alkanes $\delta^{13}C$ shows values around -25‰ in the Xuanwei Formation, then decreased to -30‰~-36‰ in the lowest part of the Kayitou Formation. It is suggested that massive volcanic CO_2 release, and large quantities of ^{13}C-depleted carbon emission from organic matter and methane are triggers of the carbon cycle perturbation as a global control, though some regional controls existed, e.g., effective moisture and methane oxidation. The carbon perturbations presented here would provide insights into the climate of future due to global warming and high greenhouse gases caused by anthropogenic emissions.

Carbon sequestration of the middle Miocene Sunda Shelf facilitated global climate change

Pengfei Ma[1*], Zhifei Liu[1], Han Cheng[2]
1. State Key Laboratory of Marine Geology, Tongji University, Shanghai, CHINA
2. State Key Laboratory of Biogeology and Environmental Geology, China University of Geosciences, Beijing, CHINA
E-mail: pma@tongji.edu.cn

Keywords: Sunda Shelf, Carbon cycle, Middle Miocene, Climatic transition

Extensive land-sea redistribution of the low latitudes could induce significant climatic change at regional and global scales. The Sunda Shelf (SS) exposure has been proven to drive the tropical climatic evolution during the Last Glacial Period by geological records and modeling. However, due to the lack of scientific drilling, its role in much older geological periods remains unclear and has been generally ignored in previous studies, even though periodical flooding and exposure have occurred since at least the early Miocene. To resolve this issue to a certain extent, we compile the sedimentary records of the SS basins during the middle Miocene, which was characterized by a crucial transition from climatic optimum to profound global cooling. Sea level stayed high during the middle Miocene Climatic Optimum (MCO) and dropped in steps along with high-latitude cooling events of the middle Miocene Climatic Transition (MMCT). In this sequence framework, organic carbon amounts of the SS sediments deposited during the two crucial periods were qualified and further used to estimate atmospheric CO2 sequestration considering these immature source rocks had not undergone large-scale hydrocarbon generation and migration. Our results indicated that carbon sequestration took place at the fastest rate in paralic environments during the MMCT. Compared with the MCO, the increased sequestration rate is equivalent to a drawdown of ca. 100 ppm atmospheric CO2 per Myr, accounting for about 30 % of the global atmospheric CO2 decline rate through the MMCT. This study certified that gradual exposure of the SS during the middle Miocene could likely facilitate the climatic transition via altering global carbon cycles.

Keywords: Sulfur isotopes, Framboidal pyrite, Ocean oxygenation, Microbialite, Metazoan reefs, North China

Microbe-metazoan transitions (MMTs), representing a switch from microbe-mediated to metazoan-mediated carbonate production, have been linked to major changes in Earth-surface conditions. The 'late Cambrian MMT' (nomen novum), during which microbial reefs were replaced by maceriate and lithistid sponge reefs, coincided with a sharp rise in atmospheric O_2 levels attributed to the Steptoean Positive Carbon Isotope Excursion (SPICE) at ~497-494 Ma. However, relationships between atmospheric oxygenation, marine redox conditions, and the MMT have not been thoroughly investigated to date. Here, we conducted paired analyses of carbonate carbon isotopes ($\delta^{13}C_{carb}$), sulfur isotopes of carbonate-associated sulfate ($\delta^{34}S_{CAS}$) and pyrite ($\delta^{34}S_{Py}$), pyrite morphologies, and fossil assemblages of two upper Cambrian shallow-marine sections on the North China Platform (Tangwangzhai and Huangyangshan). The sulfur isotopic composition of framboidal pyrite ($\delta^{34}S_{FrPy}$) was calculated from that of total pyrite ($\delta^{34}S_{TPy}$) assuming a varied fractionation with euhedral pyrite based on pyrite morphological analyses. Modelling of S-isotope fractionations ($\Delta^{34}S_{CAS\text{-}FrPy}$) indicates that contemporaneous seawater had low sulfate concentrations (i.e., $[SO_4^{2-}]$sw ~4-6 mM) with locally high spatial heterogeneity during the Rising SPICE (early to middle Paibian), which were the product of massive burial of pyrite (together with organic matter) as a consequence of extensive oceanic anoxia. Immediately following the SPICE, a reduced pyrite burial rate and an increased flux of terrestrially sourced, ^{34}S-depleted sulfate to shallow-marine environments resulted in lower $\delta^{34}S_{CAS}$ values. At that time, $[SO_4^{2-}]$sw rose to a maximum of ~9-16 mM and became more uniform during the Post-SPICE (middle to late Jiangshanian), suggesting a more oxidized condition of seawater and the atmosphere. Rising O_2 levels in both the atmosphere and marine environments triggered the late Cambrian MMT and set the stage for the subsequent Great Ordovician Biodiversity Event.

E-mail: jpzhang@nigpas.ac.cn

Keywords: Nitrogen isotopes, Mo isotopes, ocean redox, climatic cooling, GOBE

The Great Ordovician Biodiversification Event (GOBE) achieved its peak during the Middle Ordovician, likely in association with climatic cooling and a rise of atmospheric O_2. However, unstable redox states developed widely in contemporaneous epeiric seas, challenging previous assumptions about sustained oceanic oxygenation driven by deep-ocean ventilation in the aftermath of Ordovician cooling. Herein we investigate two Middle-Upper Ordovician shale-dominated successions from intra-shelf basin and slope settings of the Yangtze Sea, South China. Negative shifts in bulk $\delta^{15}N$ and productivity proxies reveal temporal changes in the pattern of nutrient cycling under moderate-to-high productivity conditions, which is probably sustained by increased cold and nutrient-rich upwelling in pace with the pulse of climatic cooling. As a result, marine anoxia likely expanded in deep-waters of the Yangtze Sea, as reflected in enrichments of highly reactive iron and redox-sensitive metals (Mo, U). Although moderate Mo abundances (25-50 ppm) and $\delta^{98/95}Mo$ values (+0.4 to +0.8‰) within the euxinic interval suggest the possibility that bottom waters were featured by low sulfide concentrations, the $\delta^{98/95}Mo$ values are comparable to those of coeval euxinic facies (~ +0.6‰). Weak operation of particle shuttle may have also contributed to low $\delta^{98/95}Mo$ values, but this influence is considered quite limited given no consequent correlation between the enrichment of Mo relative to U and $\delta^{98/95}Mo$ for euxinic sediments. Furthermore, modeling results show that low seawater $\delta^{98/95}Mo$ can be produced when sulfidic sinks dominate Mo removal, and suggest the ocean was not such oxygenated as previously assumed for the Mid-Late Ordovician. Our findings thus, for the first time, potentially link the pulse of expanded marine anoxia and climatic cooling to a decline in the species diversity of marine invertebrates following the peak of GOBE.

Analysis of integrated C-S-Fe cycling along the Panthalassic transect across the Pliensbachian-Toarcian

Wenhan Chen[1], David Bryan Kemp[1*]
1. School of Earth Science, china university of Geosciences (Wuhan), Wuhan, Hubei, CHINA
E-mail: davidkemp@cug.edu.cn

Keywords: Toarcian Oceanic Anoxic Event, C-S-Fe cycling, Panthalassa

The early Toarcian Oceanic Anoxic Event (T-OAE; ~183 Ma) (Jenkyns, 1988) was one of the most significant environmental perturbations of the Mesozoic, characterized by a pronounced carbon cycle perturbation, widespread deposition of organic-rich sediments and seawater deoxygenation, as well as a minor mass extinction. Similar climate and environmental perturbations likely occurred across the Pliensbachian-Toarcian (Pl-To) boundary. However, the extent and significance of deoxygenation from the late Pliensbachian to early Toarcian is unclear due to the lack of records, especially deep-water archives outside of Europe. Here, we present high-resolution stable sulfur isotopes of reduced metal-bound sulfur ($\delta^{34}S_{pyrite}$), pyrite sulfur concentrations (S_{PY}), Fe-speciation and trace element concentration data from two Panthalassic Ocean sections across the Pliensbachian–Toarcian boundary (Pl/To) and the T-OAE, one deposited in deep water (Sakahogi section, paleo-water depth >~2.7 km) and the other on a shallow margin (Sakuraguchi-dani section, paleo-water depth likely <~50 m). Marked positive $\delta^{34}S_{pyrite}$ excursions of >10‰ across both the Pl-To and the T-OAE at Sakahogi, and a positive excursion of >20‰ at the onset of the T-OAE at Sakuraguchi-dani are most likely controlled by increased organic matter supply to seafloor and sedimentation rates, respectively, while expanded anoxic/euxinic conditions may have played a significant role in the enrichment of pyrite. Fe-speciation and trace element data from the deep-water site indicate that anoxic/ferruginous conditions characterized the open Panthalassic Ocean from the late Pliensbachian to the end of the T-OAE. This site shows evidence for potentially euxinic pore waters near the Pl-To boundary, and euxinic bottom water across the T-OAE, with a transition towards more oxygenated conditions after the T-OAE. Fe-speciation data from the shallow water site also ostensibly suggest anoxic/ferruginous conditions across the T-OAE, but trace element and sedimentological data indicate oxygenated to possibly suboxic conditions. This ambiguity can be attributed to the upwelling of waters from the deep ocean, which brought ferruginous water to the shelf, whereupon Fe^{2+} was oxidized in oxic shallow waters and deposited largely *in situ*.

Geochemical characteristics of cold seeps in southern South China Sea

Zhifeng Wan[1*], Chongmin Chen[1], Xuewan Wu[1]
1. School of Marine Sciences, Sun Yat-sen University, Zhuhai, Guangdong, CHINA
E-mail: wanzhif@mail.sysu.edu.cn

Keywords: geochemistry, cold seeps, sediment, pore water, southern South China Sea

Cold seep, characterized by active material circulation and methane seepage, is of great importance to reconstruct the paleo-marine environment and trace the origin of life and the occurrence of minerals. Southern South China Sea (SCS) with ample oil and gas resources is an ideal platform for cold seep study, but information and researches on cold seeps here are rather deficient. We studied the geochemical characteristics of sediment cores and pore water combined with seismic profile information in the Beikang Basin, aiming to further understand the nature of cold seeps in this area. The extremely low δ13CDIC of pore water at each core indicates a strong anaerobic oxidation of methane (AOM) function and a major source of biogenic methane. The sulfate methane transition zone can be characterized by profiles of SO42-, the high content of inorganic carbon (DIC) and the corresponding minimum δ13CDIC in pore water. The kink-type depth profiles of Sr, Ba and Ni enrichment factors and Sr/Mg in the sediments of BH-CL37 indicate the depth of the paleo SMTZ, denoting a past enhanced methane flux or the modern weakened cold seep activity. The features of Mo, U and REE constrain the reducing sedimentary environment. Combined with the seismic profiles, we conclude that fluid fluxes and tectonic settings greatly influence the sedimentary environment and geochemistry, leading to the prominenet regional differences in the properties and activities of cold seeps. This study of cold seep in southern SCS proves the variation of cold seep in time and space, stressing the necessity of further region-specific analysis towards different cold seeps; and the complex conditions of SCS do function well in offering multiple types of cold seeps.

Integrated signatures of secondary microbial gas within gas hydrate reservoirs: a case study in the Shenhu Area, Northern South China Sea

Hongfei Lai[1], Haijun Qiu[1], Zenggui Kuang[1], Jinfeng Ren[1], Yunxin Fang[1], Jinqiang Liang[1*]
1. National Engineering Research Center of Gas Hydrate Exploration and Development, Guangzhou Marine and Geological survey, Guangzhou, Guangdong, CHINA
E-mail: 443960317@qq.com

Keywords: hydrocarbon biodegradation, biomarkers, secondary microbial gas, gas hydrate

A series of highly saturated pore-filled gas hydrate deposits were recently discovered in the Shenhu area of northern South China Sea. However, the main hydrocarbon sources of the gas hydrates remain controversial. The main hypotheses include a shallowly buried microbial gas source or a deeply buried thermogenic hydrocarbon source. In this study, an integrated geochemical-microbial-geological analysis of gas hydrate and sediment samples from sites SC1 and SC2 in the Shenhu area was conducted to investigate the possible hydrocarbon sources, and to identify the signatures of the secondary microbial gases in the gas hydrate reservoirs. The results show that the gas hydrates from sites SC1 and SC2 exhibit the geochemical characteristics of secondary microbial gas ($C_1/(C_2+C_3)$ >100, –50.2‰<$\delta^{13}C$-C_1<–47.4‰), and the propane (C_3) component and liquid thermogenic hydrocarbons (C_{15+}) have been severely biodegraded (a strongly elevated $\delta^{13}C$-C_3 value and a high abundance of 25-norhopanes). In addition, we discovered that the in-situ Quaternary marine sediments exhibit relatively low generation potential of primary microbial gas because of the extremely low organic matter richness (total organic matter content (TOC)<0.3%) and low in-situ temperatures (5–18°C). Furthermore, a relatively high abundance of methanogens (~7%–15%) were detected within the gas hydrate reservoir, which may be attributed to the methane generation process of hydrocarbon biodegradation. Moreover, the geological-geophysical interpretations indicate that the distributions of the gas hydrate accumulations and the shallow gas pools are strictly controlled by the effective faults connecting them with the deeply buried thermogenic source rocks. These lines of evidence suggest a significant contribution of secondary microbial methane to sites SC1 and SC2, which further indicates that the main contribution was from deeply buried thermogenic hydrocarbon sources. Our results suggest that the secondary microbial methane within gas hydrates is an important terminal product that has been converted from thermogenic hydrocarbons via microbial degradation, which helps explain why the geochemistry of most of the hydrate-bound gas indicates a microbial origin even though the geological evidence indicates that the gas is mainly sourced from deeply buried thermogenic hydrocarbons.

Keywords: Gas hydrates, authigenic carbonates, petrography, diagenesis

Carbonate formation at cold seeps occurs when methane is anaerobically oxidised by a consortium of methanotrophic archaea and sulfate reducing bacteria, in a process known as anaerobic oxidation of methane (AOM). The methane oxidised can be released from gas hydrates. Gas hydrates have recently received increasing attention due to their potential energy value and possible environmental impact such as greenhouse effects, slope instability etc.

In modern marine settings, seep carbonates commonly occur in close association with gas hydrates. Gas hydrates, however, are not preserved in the geological record. Therefore, hydrate-related authigenic carbonates (clathrites) represent quite specific seep carbonates and they are the only physical archives preserving evidence of the former presence of gas hydrates. Unfortunately, petrographic criteria typical of clathrites in the sediments that no longer contain gas hydrate are ambiguous. In fact, even though gas hydrates are common in modern marine sediments along continental slopes in all oceans and were very likely present at least throughout the Phanerozoic, there are surprisingly few records of ancient clathrites Compaction of cavities originally occupied by ice and/or gas bubbles as well as dissolution of metastable phases of methane-derived carbonates leads to fabric and petrographic changes obliterating or even extinguishing diagnostic features.

To develop petrographic criteria for clathrites, recent methane-derived gas hydrate-fed carbonates precipitated at seep sites of the Hydrate Ridge (Pacific, offshore Oregon) were compared with fossil counterparts. Among the few examples of paleoseep areas in which the former presence of gas hydrates has been suggested are the Piedmont Basin and the Northern Apennines (both Miocene in age and located in Italy) as well as the Outer Carpathians (Oligocene, Poland). The preserved features in the fossil authigenic carbonates depend on the diagenetic path experienced by those rocks, therefore their investigation is fundamental to understand the physical and chemical processes involved in carbonate precipitation. Here, some preliminary observations of these rocks can be shown.

This work was funded by the National Science Centre grant no. 2020/37/B/ST10/01769.

Rising bottom-water temperatures induced methane release during the middle Holocene in the Okinawa Trough, East China Sea

Hongxiang Guan[1*], Lei Liu[1], Yu Hu[2]
1. Key Lab of Submarine Geosciences and Prospecting Techniques, Ocean University of China, Qingdao, Shandong, CHINA
2. Shanghai Engineering Research Center of Hadal Science and Technology, Shanghai Ocean University, Shanghai , Shanghai, CHINA
E-mail: guanhongxiang@ouc.edu.cn

Keywords: anaerobic oxidation of methane (AOM), sulfate-methane transition (SMT), authigenic carbonates, Okinawa Trough, East China Sea

It is not currently well understood how a changing climate controls methane releases in the Okinawa Trough. In this study, a piston core was collected from a seep-impacted area at a water depth of approximately 1000 m from the Okinawa Trough, East China Sea, and was studied using comprehensive analyses of carbon and oxygen stable isotopes, lipid biomarkers, and major and trace element geochemistry. Extremely low δ13C values of total inorganic carbon and organic carbon, increased Methane Index, and molybdenum (Mo) and uranium (U) enrichments at depths of 225–255 cm below the sea-floor (bsf) and 75–142.5 cm bsf were found. Combined with published pore water data, fossil and current sulfate-methane transitions (SMTs) were identified. Mass balance equations were applied to estimate the fraction and content of authigenic carbonates at the two SMTs and their corresponding δ18O values. The calculations revealed that the estimated δ18O values of authigenic carbonates for the fossil SMT (from 4.9‰ to 5.8‰) and the current SMT (from -2.1‰ to 4.4‰) were higher and lower than the theoretical equilibrium δ18O value (4.8‰), respectively. These results suggest that fossil seepage is possibly induced by the dissociation of gas hydrates. The fluids of the current seepage may be derived from the equilibrium between the ambient seawater and the fluids of gas hydrate dissociation. Based on the accumulation of authigenic carbonate in sediments, previously published pore-water calcium and magnesium fluxes, and foraminifera 14C dating, the fossil methane seepage was confirmed to have occurred during the period 8.2 to 4.5 ka B.P., with its SMT depth less than 105 cm bsf, while the present-day methane seepage with a low fluid intensity was estimated to have started before 1.0 ka and formed its SMT at approximately 250 cm bsf. The timing of this fossil methane seepage suggests that the rising temperature of the North Pacific Intermediate Water during the early and middle Holocene mainly controlled the methane release in the Okinawa Trough, whereas the ongoing methane emission was likely induced by decreased pressure driven by back-arc extension. The geochemical data demonstrate past methane release as a response to environmental changes and suggest that the Okinawa Trough gas hydrates were sensitive to temperature fluctuations during the middle Holocene.

Classification of biogenic carbonate rocks

Ya-Sheng Wu[1*]

1. Division of Cenozoic Geology and Environment, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, CHINA

E-mail: wys@mail.igcas.ac.cn

Keywords: Biolith, macrobiolith, microbiolith, framelite, bafflelite

All rocks formed by macroorganisms and microbes belong to bioliths, which are divided into macrobioliths and microbioliths. The macrobioliths are divided into the biolithites, i.e., reef rocks formed by macroorganisms, and the bioallolites composed of the skeletal grains and micrites formed by macroorganisms. The microbioliths are divided into calcimicroliths, ferromicroliths, mangamicroliths, and claymicroliths. The calcimicroliths are divided into microlithites (i.e., the reef rocks formed by microbes), microbialites, and the microallolites consisting of the grains formed from microlithites and microbialites and the micrites formed by microbes. The microlithite includes the framelite with a framework built by in situ skeletons of up-growing benthic microbes, bafflelite, and the filalite having a framework built by the in situ skeletons of soft filamentous microbes. Dendrolite is a specific kind of framelite. The microbialite includes stromatolite, laminate, thrombolite, crustolite, and oncolite. The crustolite is characterized by laminated fabrics encrusting on some skeletons or grains.

The amorphous and crystalline carbonate biomineralization in cyanobacterial biofilms induced by Synechocystis sp. PCC6803 cultured in CaCl2-MgCl2-SrCl2 mediums

Yanyang Zhao[1*]
1. College of Earth Science and Engineering, Shandong University of Science and Technology, Qingdao, Shandong, CHINA
E-mail: zhaoyysdust@163.com

Keywords: cyanobacteria, biomineralization, carbonate, Sr/Ca, Mg/Ca, acidic amino acids

Ca^{2+}, Mg^{2+}, and Sr^{2+} are elements with similar ionic and hydrochemical characteristics, yet the microbial mineralization behavior in their coexisting environments is seldomly introduced [1,2]. In this study, a cyanobacterium *Synechocystis* sp. PCC6803 was used to induce the formation of minerals in mediums with various Mg/Ca and Sr/Ca ratios (Ca^{2+}=0.01 M). The medium hydrochemistry, including cell density, solution pH, and alkalinity, was recorded periodically. The bioprecipitates were characterized with X-ray diffraction (XRD), scanning and transmission electron microscopy (SEM and TEM), Fourier Translation Infrared spectroscopy (FT-IR), and Thermal Gravimetric Analyzer (TGA). The results showed the growth of *Synechocystis* sp. PCC6803 was inhibited by the increased ionic strength, while the final accumulated alkalinity and pH of the medium were not affected. Two crystalline minerals, calcite ($CaCO_3$) and strontianite ($SrCO_3$), were precipitated in the mediums with low ionic strength; those were transformed from the early amorphous precipitates by a dissolution and re-precipitation mechanism. The morphology of the present cyanobacterial strontianite was changed from column to dumbbell shape and finally into a spherical shape. High concentrations of Sr^{2+}, like Mg^{2+}, could prolong the stabilization of amorphous carbonate precipitates. The acidic amino acids (Glu and Asp) in EPS of *Synechocystis* sp. PCC6803 cultured in high Sr^{2+} and Mg^{2+} concentrations were significantly increased, compared to those cultured in medium without Sr^{2+} and Mg^{2+} (p<0.005). The density functional theory (DFT) calculations results showed that the binding between the two acidic amino acids and ion-H_2O complexes ($Ca[H_2O]_6^{2+}$, $Mg[H_2O]_6^{2+}$, and $Sr[H_2O]_6^{2+}$) are all thermodynamically-favored processes. Consequently, lower energy was needed in the subsequent precipitation and the nucleation on the EPS of *Synechocystis* sp. PCC6803. This inferred process was also supported by the appearance of amorphous particles on the EPS of *Synechocystis* sp. PCC6803.

Biomineralization of rhodochrosite induced by halophilic Virgibacillus dokdonensis WLR1 bacteria

Hui Zhao[1], Huaxiao Yan[1], Yanyang Zhao[2], Zuozhen Han[2*]
1. College of Chemical and Biological Engineering, Shandong University of Scicence and Technology, Qingdao, Shandong Province, CHINA
2. College of Earth Science and Engineering, Shandong University of Science and Technology, Qingdao, Shandong, CHINA
E-mail: hanzuozhen65@126.com

Keywords: Rhodochroite, Sedimentary biogenesis, Microbial biomineralization, Halophilic microorganism, Virgibacillus dokdonensis,Intracellular and extracellular biomineralization

Rhodochroite is the main mineral type of manganese ore with sedimentary genesis. Studies have shown that biological action contributes to the formation and deposition of rhodochrosite. Here, biomineralization of rhodochrosite under the action of halophilic Virgibacillus dokdonensis WLR1 bacteria was studied. The biotic rhodochrosite had diversified morphologies, such as spherulite, long rod, butterfly and dumbbell, etc. The EDS results showed that the rhodochrosite contained organic elements such as S and P besides the Mn, C and O elements. FTIR analyses further proved that the rhodochrosite had protein secondary structures such as α-helix, β-sheet, β-turn, and 3(10)-helix. The stable carbon isotope analyses revealed that δ13CPDB values changed from -16.148‰ to -17.827‰, further proving the biogenesis of the rhodochrosite. The intracellular and extracellular rhodochrosite could be formed after ultra-thin sections of WLR1 bacteria were analyzed by HRTEM and SAED. Under the action of WLR1 bacteria, the Mn2+ concentrations decreased from 49.58, 103.02, 157.39, 201.65 mg/L to 9.57, 11.38, 15.05, 19.06 mg/L on 24th day, the Mn2+ precipitation ratios were 82%, 89%, 90%, 91%, and the Mn2+ sedimentation rates were 4, 8, 13, and 17 mg/L/d. The results show that bacteria significantly promote the precipitation of rhodochroite. On this basis, the contribution of bacteria in the process of manganese biomineralization is further discussed. This experiment has enriched the study on the microbial genesis of manganese rich ores deposition.

Keywords: protodolomite, extreme halophilic bacterium, Vibrio harveyi, amino acids, polysaccharides

Bacterial activities have been demonstrated as critical for protodolomite precipitation in specific aqueous conditions, whereas the relationship between the various hydrochemical factors and bacterial activity has not been fully explored [1]. In this study, biomineralization experiments were conducted using a newly isolated extreme halophilic bacterium from salina mud, Vibrio harveyi QPL2, under various Mg/Ca molar ratios (0, 3, 6, 10, and 12) and a salinity of 200 ‰. The mineral phases, elemental composition, morphology and crystal lattice structure of the precipitates were analyzed by XRD, SEM and HRTEM, respectively. The organic weight and functional groups in the biominerals were identified by TG-DSC, FTIR, and XPS analysis. The amounts of amino acids and polysaccharides in the EPS of QPL2 cultured at various Mg/Ca molar ratios were quantified by an amino acid analyzer and high-performance liquid chromatography. The results confirm that disordered stoichiometric protodolomite was successfully precipitated through the activities of bacteria in a medium with relatively high Mg/Ca molar ratios (10 and 12) but it was not identified in cultures with lower Mg/Ca molar ratios (0, 3, and 6). That bacterial activity is critical for protodolomite formation is shown by the significant bacterial relicts identified in the precipitated spherulite crystals, including pinhole structures, a mineral coating around cells, and high organic matter content within the crystal. It was also confirmed that the high Mg/Ca molar ratio affects the composition of the organic components in the bacterial EPS, leading to the precipitation of the protodolomite. Specifically, not only the total EPS amount, but also other facilitators including the acidic amino acids (Glu and Asp) and polysaccharides in the EPS, increased significantly under the high Mg/Ca molar ratios. Combined with previous studies [2], the present findings suggest a clear link between high Mg/Ca molar ratios and the formation of protodolomite through halophilic bacterial activity.

Correlative micro-analytical strategies to elucidate complex formational and diagenetic processes in Precambrian stromatolites

Keyron Hickman-Lewis[1*]
1. Earth Sciences, The Natural History Museum, London, UNITED KINGDOM
E-mail: keyron.hickman-lewis@nhm.ac.uk

Keywords: stromatolites, biogenicity, micro-analysis

Stromatolites are fossilised records of laminated microbial communities. The oldest examples date to almost 3.5 billion years; however, controversy continues to surround these most ancient forms because of generally poor preservation, the lack of retention of syngenetic fossils derived from their architect organisms, and ambiguity surrounding the morphogenesis of simple macrostructures, such as the domical and conical stromatolites that dominate the early Precambrian record. I will present new high-resolution datasets from two Precambrian stromatolite horizons with the objective of demonstrating that multi-scalar, multi-technique characterisation sheds light on the biogenesis, taphonomy, and diagenesis of even simple stromatolitic forms.

1) 3.48 Ga Dresser Formation. Flat-laminated and domical stromatolites of the Dresser Formation are widely considered the earliest convincing morphological evidence for life on Earth but have been heavily altered by iron oxidation. We have conducted sub-micron-scale analyses of these stromatolites coupling morphological evidence from microscopy, laboratory X-ray μCT and synchrotron μCT (resolution = 0.9 μm) with chemical evidence from laser ablation ICP-MS, Raman spectroscopy and SEM-EDX. Our 2D–3D morphological reconstructions highlight numerous biological micromorphologies: undulatory layers, non-isopachous laminations, crestal thickening through domes and vertically oriented fabric elements interpreted as microbial palisade structure. Combined with palaeoenvironmental indicators of shallow marine deposition, these indicators strongly suggest phototrophic dominance of the stromatolite ecosystem. The exceptional preservation of these microfabrics is best explained by early and rapid silicification, as evidenced by the mineralogy and texture of stromatolitic layers, and by strong Eu anomalies in penecontemporaneous chert. These high-resolution data shed new light on Earth's oldest traces of life and reinforce their biogenic interpretation, also providing a taphonomic model for the ecosystem.

2) 790 Ma Skillogalee Dolomite. Flat-laminated and domical stromatolite-like structures of the Skillogalee Dolomite are widely used for Neoproterozoic chronostratigraphy across Australia. We performed spatially correlated microscopy, and Raman and Fourier transform infrared microspectroscopy of rare organic-rich layers within these stromatolites. Organic-rich layers are concordant with the sequence of formation of the stromatolitic macrostructure, suggesting syndepositional growth. They comprise weakly laminated fabrics with evidence of plastic deformation and early diagenetic organic staining, and preserve an archive of microbe–sediment interaction in the form of oriented sediment particles. Raman and FTIR show that the organic fraction comprises aromatic and aliphatic moieties tied to specific microstructures. As in the Dresser Formation, the association of organic-rich layers with silicified domains suggests that early silicification played a role in the preservation of these rare features. The identification of such spatially restricted organic fabrics in contemporaneous and more ancient stromatolites may serve as a means of establishing biogenicity of simple stromatolite morphologies in the absence of microfossil preservation.

New insights on the palaeoenvironments, biogeochemistry and palaeoecology of Palaeoarchaean microbial mat ecosystems

Keyron Hickman-Lewis[1,2*], Barbara Cavalazzi[2], Wren Montgomery[1], Frédéric Foucher[3], Caroline Smith[1], Frances Westall[3]

Keywords: microbial mats, Archaean, geobiology

The Palaeoarchaean (3.6–3.2 Ga) fossil record is dominated by microbial mats that formed in shallow marine settings, suggesting that phototrophic ecosystems were important components of Archaean global biogeochemistry [1]. This presentation describes Palaeoarchaean microbial mats and their local environments using advanced in situ organic–inorganic geochemical approaches, focussing on the Barberton greenstone belt.

Depositional environments of Palaeoarchaean ecosystems. High-resolution optical petrography shows that microbial mats exhibit subtly different growth and deformation phenomena depending upon their substrate: in microcrystalline cherts, mats have undulatory morphologies with well-preserved growth and deformation textures [2]; in sandstone horizons, mats are less well-preserved but show responses to sedimentation phenomena, i.e. trapping, binding and orienting sand grains and forming micro-tufted morphologies [3,4]. 3D visualisations of mats using X-ray μCT corroborate these textural phenomena [5]. Laser ablation ICP-MS shows that the chert phase within which mats occur preserves rare earth element plus yttrium (REE+Y) compositions denoting a complex confluence of marine, hydrothermal and riverine chemistries [6]. This suggests productive microbial biomes in epicontinental settings as early as ~3.5 Ga.

Biogeochemical networks in Palaeoarchaean ecosystems. Correlated micro-analysis of microbial mats yields insights into the communities responsible for the formation of microbial mats in deep time and the mechanisms by which they were preserved. Raman geothermometry of kerogen indicates thermal histories consistent with lower greenschist grade temperatures, reflecting regional metamorphism. FTIR microspectroscopy shows that mat kerogen includes diverse aromatic and aliphatic moieties, including C–H, COOH and other groups [2,3,7]; this richness of preservation indicates extremely rapid preservation and entombment of biomass by silica. Quantifying CH3/CH2 ratios in kerogen has also enabled discrimination between mats dominated by Bacteria and by Archaea [7]. Finally, in situ organic δ13C signatures show a diversity of clustered values that may shed light on the origins of multiple metabolic pathways.

The results of this multi-technique, high-resolution approach to microbial mat palaeobiology demonstrate that advanced analytical capabilities have the potential to re-evaluate our understanding of Palaeoarchaean ecosystems and sustain the validity and significance of authentic biogeochemical signatures in deep time.

Paleobiological Characteristics and its Hydrocarbon Significance of Bioclastic Migmatite in Bohai Sea

Pan Wenjing[1*], Yang Haifeng[1], Wang Qingbin[1], Tian Derui[1], Wang Gaiwei[1]
1. Bohai Oilfield Research Institute, China National Offshore Oil Corporation, Tianjin Branch, Tianjin, CHINA
E-mail: panwj@cnooc.com.cn

Keywords: Bohai Sea,Paleogene,bioclastic migmatite,palaeontology,reservoir

Lacustrine migmatite is widely distributed in the first member of Shahejie Formation of Paleogene in Bohai Sea. The bioclastic migmatite is the high-quality reservoir with good physical properties and high productivity. In this paper, a systematic paleontological study of bioclastic components in bioclastic migmatites is carried out. It is confirmed that gastropods are the most important bioclastic types in the first member of the Shahejie Formation in Bohai Sea. 21 genus and 27 species of gastropods and 19 genus and 74 species of ostracoda are identified. They are mainly miniaturized types suitable for living in a certain salinity and shallow water environment. It is found that the gastropods are easily to accumulate in high energy environment, while the content of ostracods is relatively high in low energy environment combined with paleoenvironmental studies. The analyses of casting thin section, SEM and EPMA show that bioclasts plays an important role in the evolution of migmatite reservoir. The reservoir space is directly provided by the cavity hole of the bioclastic body, the mold hole of the shell, the shielding hole and the differential contraction joint. Early dissolution of bioclasts can effectively improve the permeability of the reservoir, promote dolomitization of the bioclastic enrichment section, and form a high-quality reservoir of bioclastic dolomite. Bioclasts form a stable mud crystal set with the action of microorganism, which plays a supporting role of pore lattice. The physical properties of the bioclastic migmatite mainly composed of gastropods are better than the others, as influenced by the differences of shell composition and various kinds of biological sedimentary environment.

Keywords: Ordos Basin, Late Ordovician, platform margin reef-shoal facies, restricted platform, lagoon.

The paleontology and sedimentary facies of three main Ordovician sections in the southwest edge of Ordos basin, Shijiezigou, Longmendong and Tiewadian, have been studied. It was revealed that the Ordovician in the Shijiezigou section was composed of packstone and wackestone of open platform facies with coral and dasycladacean bioclasts, the Longmendong and the Tiewadian sections are composed of three types of breccia. One is limestone of reef and shoal facies with abundant late Ordovician coral, stromatoporoid and dasycladacean fossils and bioclasts, the second is micritic limestone of tidal facies with bird's eyes structure, and the third is micritic limestone of lagoon facies with cyanobacteria and Tetradiids. The breccia rocks of the three sections are bedded, composed of limestone debris of platform margin reef-shoal facies and restricted platform tidal and lagoon facies without roundness, and contain no sandy silt, and are interpreted as resultant from the conglomerates formed from the erosion of the Upper Ordovician carbonate platform marginal reef and shoal faces and the inner restricted platform facies limestone, deposited by gravity flow. The Upper Ordovician platform marginal facies in the Tazhong platform in Tarim Basin, Xinjiang, consist of reef-shoal facies and open platform facies, and the inner part of the Tazhong platform consists of restricted platform facies and open platform facies. Comparison of the fossils and facies between the Ordos platform and Tazhong platform shows that not only the late Ordovician platform margin reef-shoal facies developed in the southwest margin of Ordos platform, but also the open platform and restrict platform developed behind the reef-shoal facies. The restrict platform included tidal flat facies and lagoon facies, and its range may cover the whole Ordos plate.

Research status and prospect of banded iron formation in early Earth

Zhuofei Sha[1], Aoran Liu[1*]
1. Department of Earth Sciences, Hebei GEO University, Shijiazhuang City, Hebei Province, CHINA
E-mail: Aoranliu@cug.edu.cn

Keywords: banded iron formation,biogenic,microorganism

BIF is a type of banded iron formation widely distributed in the Precambrian, which is the most dominant deposit type in the world. Its formation occurred before and after the Great Oxidation Event, and the deposition of BIF was abruptly terminated after the "Snowball Earth" event. There are two main theories on the genesis of BIF: abiogenesis and biogenesis, and clarifying the genesis of BIF has been an important academic issue in the study of mineral deposits. The theory of continental material weathering and submarine hydrothermal theory are abiogenic, but in recent years, with the advancement of analytical tests, the theory of biogenesis has gradually emerged, and most scholars believe that microorganisms played an important role in the deposition of BIF. The high concentration of HCO-3 in seawater provides a large amount of CO2 for photosynthesis of cyanobacteria, which induces cyanobacteria to aggregate and produce the oxygen required for iron precipitation. Photosynthetic bacteria provide oxygen for the oxidation of iron bacteria, and the oxidation and reduction of iron bacteria is the key to the formation of BIF. Magnetosomes in magnetotactic bacteria degrade to iron or are preserved directly in the sediment to form iron minerals. Since it is difficult to preserve the microbial activity remains, the presence and type of microorganisms can be studied by the distribution pattern of rare earth elements, Fe isotope tracing and other technical means to find the characteristics of microbial activities, which can enrich the research theory of BIF biogenesis and provide information for finding BIF iron ore resources and guiding iron ore exploration. It has both high research value and economic value.

E-mail: gmluo@cug.edu.cn

Keywords: Abiotic synthesized pyrite, nickel partition coefficient, trace metal concentration of paleo-seawater

Trace metals actively participate in various cycles in the ocean and play critical roles in biogeochemical cycles, while it is a big challenge to reconstruct seawater trace metal concentration in deep time. It has been proposed that the trace metal contents in pyrite, through ion replacement or adsorption, may record trace metal characteristics of paleo-seawater (TMsw). However, the partition coefficients of these trace metals between pyrite and water column during pyrite formation have never been figured out, which impedes the quantitative reconstruction of TMsw from trace metal contents in pyrite. For this purpose, we investigated the partition coefficients of Co and Ni between pyrite and water column by doping these elements during the abiotic synthesizing of pyrite under ambient temperature. We observed a close positive relationship between the trace elemental concentrations in the solution and the precipitated pyrite, supporting previous inference. Furthermore, our experiments suggest that nearly all the Ni and Co were sequenced by pyrite, and the amount of pyrite precipitated is a principal factor affecting the concentration of pyrite. In summary, our work demonstrates that the trace metal concentration of sedimentary pyrite cannot be directly converted to trace metal concentration of paleo-seawater, and the abundance of sedimentary pyrite should be considered in order to quantitatively reconstruct seawater trace metal concentration in deep time.

Iron oxyhydrxides in subsurface dolostones: biomineralization and crystal morphologies

Min Ren[1*]
1. Department of Geological Oceanography, Xiamen University, Xiamen, Fujian, CHINA
E-mail: mren@xmu.edu.cn

Keywords: Iron oxyhydroxides, Biomineralization, Nonclassical crystallization, Nanoparticle, Amorphous

Iron oxide/oxyhydroxide precipitation in nature can involve various mechanisms that are dictated by ambient environmental conditions. Amorphous and crystalline Fe oxyhydroxides associated with extracellular polymeric substances (EPS) are commonly distributed in some of void space of subsurface Ordovician dolostone (Jinan, North China Block). These precipitates, dominated by ferrihydrite nanogranules (20–30 nm), acicular goethite nanorods and nanofibers (>200 nm), and various twinned goethite polymorphs (~1–3 mm), display different crystallization stages that reflect the processes of iron mineralization. The development of iron oxyhydroxide involved: (1) biogenic ferrihydrite and goethite nanoparticle formation, (2) ferrihydrite–goethite transformation and development of nanogranule-attached goethite, (3) goethite twinning, and (4) multi-generation overgrowths on twined goethite. The process demonstrates that the Fe was fixed biogenically with crystallization taking place via a nonclassical nanogranule-aggregation pathway. The study sheds light on the complex mechanisms of crystal growth and morphological development associated with iron oxyhydroxide mineralization in geological records. The distribution of the precipitates, concentrated in larger voids ~11 m below ground surface, reflects their sensitivity to ambient conditions such as redox and Fe supply.

The origin of biogenic dolomites from Mesoproterozoic Jixian System in Ordos Basin

Qian Zhang[1], Wenhui Liu[1*], Wenhou Li[1]
1. Department of geology, Northwest University, XI'an, Shaanxi Province, CHINA
E-mail: whliu@nwu.edu.cn

Keywords: Jixian system, dolomite, biogenic

During the development of long earth history, microbial rocks, as a kind of geological record of primitive life activities, have been widely distributed and spanned a wide range of times, dating back to the earliest Paleoproterozoic, while the abundance, distribution range and morphology of the Middle Neo-Proterozoic strata have reached their peaks. Microbial carbonate rocks are not only related to the formation and enrichment of metal deposits, but also important objects for oil and gas exploration. The Jixian carbonate marine formation is well exposed on the western and southern margin of Ordos Basin, and the Longjiayuan, Xunjiansi, Duguan and Fengjiawan formations are exposed from the bottom to top. With good exposure and convenient transportation, it provides abundant material for microbial carbonate petrology and genetic research. Through field section measurements, hand specimen identification, combined with sedimentological, petrological, and geochemical analysis and research, it is concluded that mud-crystalline dolomite, siliceous dolomite, stromatolite and a small amount of sparry dolomite are developed in Jixian system of Ordos Basin. The stromatolites structures present at Jixian system are identified as stratifera, columnar, conical, domal, spheroidal and lobate types, which indicate that the whole period was in a tidal flat with deep local water bodies. Abundant microbially induced sedimentary structures (MISS) have been recognized in these rocks, indicating diversified microbial activities and a high organic production. With the aid of SEM observation, a large number of extracellular polymeric secretions, nanoglobules, polyhedrons, and their aggregates were found in the stromatolite. These filaments and well-preserved spherical bacteria (possibly cyanobacteria) are distributed in the bright or dark layers. Acicular aragonites which were found in some sample suggests authigenic carbonate precipitation from anaerobic oxidation of methane. Silicification protects the microstructure of some microbial mats. At the same time, extracellular polymeric secretions can combine with other elements such as Si, Mg and Ca, making them more suitable for bacterial mineralization and dolomite crystallization, providing some intuitive evidence for the biogenesis of stromatolite in Jixian system.
