The Qaidam Basin is an excellent place to study Chineses Cenozoic lacustrine carbonate rocks, especially lacustrine microbialites. The lower Ganchaigou Formation of Oligocene in Western Qaidam Basin is a set of lacustrine microbialites with large scale, multiple types and close relationship with oil and gas. Based on the detailed anatomy of the Oligocene microbialites in Xichagou and Liangdong areas of Qaidam Basin, it is found that the microbialites formed in the stage of rapid lake transgression and developed on the hard basement such as glutenite and siltstone. In the late stage, the microbialites gradually died out due to the shrinkage of the lake basin. Lacustrine microbiolites consist of thrombolites and stromatolites, and alternate compound types with strong lateral ductility and outcrop of several kilometers. Other carbonate particles include peloids, ooids, biodetritus and aggregate grains. Under the microscope, the thrombolites are characterized with clotted structure and cryptocrystalline cohesive framework, with abundant bioclasts and a small amount of peloids. The stromatolite shows slow undulant features, with typical alternating light and dark lamina. Microbial laminae and clots experienced fabric-selective dolomitization and are preserved as cryptocrystalline and microcrystalline textures. A large number of framboidal pyrite and cryptocrystalline and microcrystalline dolomite particles exist in the form of intergranular mosaics, indicating the role of their sulfate-reducing bacteria in dolomitization. The systematic macro-micro characteristics of lacustrine microbialites in the Upper Ganchaigou Formation of the Oligocene in the western Qaidam Basin will further help understand the types and formation mechanisms of lacustrine microbialites, and guide the Cenozoic oil and gas exploration and the study of reservoir rock types and characteristics.

Controlling effect of lake salinity on the development of carbonate rocks: A case study of paleogene in western Qaidam Basin

1*

1. , , , , CHINA
E-mail: dingyh_04@163.com

Keywords: carbonate rock,palaeosalinity,the upper member of lower Gaichaigou formation,Paleogene,Yingxiongling structral belt,Qaidam Basin

In order to comprehensively evaluate the oil and gas exploration prospects of Paleogene Oligocene lacustrine carbonate rocks in the middle and eastern segments of Yingxiongling tectonic belt in western Qaidam Basin, and predict favorable exploration zones and exploration targets, this paper takes the upper member of Ganchaigou Formation (E32) as an example. Based on the comprehensive analysis of core observation, drilling / logging data and three-dimensional seismic data, combined with the analysis results of rock thin section, chloride ion content, whole rock mineral analysis, gypsum rock distribution and geochemical sensitive parameters, the paleosalinity and carbonate sedimentary evolution of E32 in this area are studied in detail. It is considered that lake salinity is the main control factor of lithologic change and development degree of carbonate rocks. The results showed that : First, the water in the lake changed from brackish water and salt water to saline water, the salinity was increased continuously from early to late in the upper member of lower Gaichaigou formation. The salinity was decreased from Yingxi to Yingdong area in a plane, which resulted the gypsum-salt rock developed poorly. Second, the mineral composition complex and the lithology multiplicity of the carbonate in Yingxiongling area, the lithology changed in each region obviously. In the longitudinal direction, the carbonate rock developed in the early better than in the late, and in a plane, the carbonate rock distributed mainly in the Yingxi and the north of the Yingzhong area, secondly in the south of the Yingzhong area, thirdly in the Yingdong area.

E-mail: 360324567@qq.com

Keywords: Dolomite intercrystalline pores, Qaidam basin, Unconventional oil and gas reservoir, Fluid occurrence

The study area is located at the northwest end of Qaidam Basin. The exploration target horizon of the study area is the Paleogene Lower Ganchaigou Formation, which is a set of shore-shallow to semi-deep lacustrine sediments. The rock composition is characterized by the mixed deposition of argillaceous, carbonate and clastic particles. The main reservoir types are micro- and nano-scale dolomite intercrystalline pores. A large number of intercrystalline pores were formed during the process of penecontemporaneous dolomization (Zhang et al. 2021). Samples were taken from the drilling cores at a sampling depth of 3100m-4050m.

The petrologic characteristics, pore types, pore distribution and pore structure were studied by multiple methods, including thin section analysis, SEM, EPMA, mercury-injection test and NMR. The distribution characteristics of the movable fluid and the change of the centrifugal process were analyzed by means of NMR and centrifugation. Observation under the scanning electron microscope found that the diameter of dolomite crystals was 1 μm to 5 μm, and there was oil distribution in the intercrystalline pores, but the pore was poor connectivity. The pore throat distribution range of the samples with carbonate intercrystalline pore in the lower Ganchaigou Formation of Yingxi area in the process of mercury injection was 11 nm to 220 nm, and the pore throat distribution range in the process of mercury ejection was 40 nm to 1500 nm.

The relaxation time was positively correlated with the pore throat radius. The relaxation time <1ms corresponded to micropores, the relaxation time between 1-10ms corresponded to small pores, the relaxation time between 10-100ms corresponded to mesopores, and the relaxation time >100ms of the corresponding large holes. Through saturated fluid state NMR test, it was believed that the pore throat radius of intercrystalline pore developed samples was 0-160nm, he movable fluid accounted for 13.7%. The NMR imaging of the fluid-saturated sample with intercrystalline pores showed that the fluid in the sample was distributed in a planar shape. The total amount of fluid decreased less during the centrifugation process. The NMR relaxation spectrum changed significantly during the centrifugation process. The peak value of the NMR relaxation spectrum before centrifugation was between 1 ms and 10 ms, and the peak value of the relaxation spectrum after centrifugation was about 1 ms. Before centrifugation, the relaxation time of the fluid distribution in the intercrystalline pores was 0.1ms-10ms. The proportion of fluid distribution was maximum in 1ms-10ms, and the proportion was 50.81%. During centrifugation, the maximum reduction of fluid was in the 1ms-10ms, and it accounting for 75.2% of the total reduction. The fluid in dolomite intercrystalline pore was mainly distributed in micro and small pores, The proportion of fluid in micro and small pores was 84.23%, and the fluid which could be drove out in centrifugation process was mainly distributed in small and medium pores.

The Indicative Significance of Cenozoic Formation Water Distribution on the Sedimentary Evolution of Lacustrine Carbonate in the Western Qaidam Basin

Yanfang Gao[1*]
1. Basin Experimental Research Center, Research Institute of Petroleum Exploration and Development, Northwest, PetroChina, Lanzhou, Gansu, CHINA
E-mail: gaoyanf@petrochina.com.cn

Keywords: formation water, saline lake basin, lacustrine carbonate rocks, geochemical indicators

As an inevitable product of the evolution of saline lake basins, lacustrine carbonate rocks have become an important field of oil and gas exploration, the formation water that occurs in lacustrine carbonate rocks has unique geochemical characteristicsand the research on the chemical composition of formation water has important guiding significance for the sedimentary evolution of lacustrine carbonate rocks and oil and gas exploration. Through chemical analysis of nearly 300 water samples from the Paleogene-Neogene in the western Qaidam Basin, the relationship between various characteristic ions, calcium and magnesium coefficients, desulfurization coefficients, and metamorphism coefficients in formation water were comprehensively compared. The geochemical means of the sedimentary evolution of salt rocks have played an important role in clarifying the differential sedimentary characteristics of salt lakes in the western Qaidam Basin. The results showed that: 1.The hydrochemical characteristics of the saline lake basin are obviously different from east to west, showing the characteristics of high in the west and low in the east. The salinity parameter is inherited, which is consistent with the migration law of the deposition center. 2. The vertical change of the sedimentary paleoenvironment is staged, the “salinization degree” is different, and the sedimentary distribution characteristics of the Paleogene-Neogene lacustrine carbonate rocks are quite different. 3. The variation law of formation water chemical characteristics further reveals the source and evolution of fluids in the basin, provides more dynamic information for the determination of the basin salinity center, and also provides a strong basis for clarifying the distribution law of favorable lacustrine carbonate reservoirs and source rocks.

Evolution characteristics of lacustrine carbonate gravity flow deposits

wang ai ping[1*], jian gong wang[1], ping zhang[1], jia jia guo[1], xiang li[1]
1. Research Institute of Petroleum Exploration & Development–Northwest, PetroChina , Lanzhou, Gansu, CHINA
E-mail: zhgsywap@163.com

Keywords: lacustrine carbonate, gravity flow deposit, saline lake, salt lake

In order to clarify rock characteristics of lacustrine carbonate gravity flow in the western Qaidam Basin, we studied lacustrine carbonate rocks of the upper segment of the Xiaganchaigou formation (E) of Oligocene through various approaches, such as drilling data, core analysis, thin-sections observation, seismic and geochemical tests, to define sedimentary characteristics, depositional model and genetic mechanism in the western Qaidam Basin. In this study, there are three different types of gravity flow deposits and associated sedimentary models are recognized, Including steep slope with high gradient (more than 3°), Ordinary slope with medium gradient (2°-3°) and gentle slope with low gradient (less than 1°). It was found that the syn-sedimentary fault is the main trigger mechanism for the formation of gravity flow deposits, and during the formation period of the Es sequence, sedimentary environments in the western Qaidam Basin are salinized lakes so that lacustrine carbonates mixed with terrigenous detrital minerals, clay minerals, and evaporite minerals are formed. A large number of carbonate gravity flow sediments developed in the salt lacustrine slope zone. The results showed that: 1) Based on the core and thin section, 8 types of carbonate gravity flow sedimentary facies can be identified. They are included in deformed carbonates, breccia carbonates, limy carbonates with breccia, coarse gravel carbonates, fine gravel carbonates, packstone, wackstone, turbidite. The single-layer thickness of breccia carbonates and limy carbonates with breccia is mainly 1-2 m, with the maximum of tens of meters; the single-layer thickness of deformed carbonates, coarse gravel carbonates and fine gravel carbonates is mainly tens of centimeters, with the maximum of 1-2 m; the single-layer thickness of packstone, wackstone and turbidite is mainly mm-cm scale. 2) The formation mechanism of lacustrine carbonate gravity flow deposits include three processes: initiation, transportation, and resedimentation. The sedimentary facies and lithofacies are controlled by creep deformation, in-situ fracture, debris flow, granular flow and turbidity current. 3) Through the restoration of paleogeomorphy, five typical geomorphic units are figured out, including uplift zone with low gradient (in front of Kunlun Mountain, the slope angle is 1°-4°), fault terrace belt (the slope Angle is 2°-5°), Uplift belt with high gradient (in front of Altun Mountain, the slope Angle is 3°-7°), Slope belt (the slope Angle is 0-2°) and depression area (the Slope gradient is generally less than 1°).

Analysis of the types and characteristics of platform margin belts and the differences of reefs developed in different platform margin belts: Taking Changxing Formation on both sides of Kaijiang- Liangping Trough in Sichuan Basin as an example

mingtao zuo[1*]
1. , , , , CHINA
E-mail: zmt199204@163.com

Keywords: the Sichuan Basin, the Changxing period, the structure of platform margin, reef, sedimentary characteristics

Up to now, the exploration and research on the Changxing Formation of the Upper Permian in the Sichuan Basin have been carried out for more than 70 years, and fruitful results have been achieved. However, with the continuous deepening of basic geological research and the degree of exploration and development, it is gradually revealed that there are certain differences in the reef reservoirs of the Changxing Formation on both sides of the Kaijiang- Liangping Trough in the Sichuan Basin, and it is preliminarily recognized that there are differences in the structural characteristics of the platform margin belts. But, these understandings are mainly aimed at the macroscopic research of platform margin belts, and there is no systematic research and comparison on the structural characteristics of different platform margin belts and the development law of reefs. Based on this, this paper takes five typical 3D seismic explored blocks on both sides of the Kaijiang-Liangping Trough as the key research areas, takes 35 drillings data and 4,142 km2 seismic data as the research basis, and tries to summarize the themorphological characteristics of platform margins, the external morphological characteristics and internal structural characteristics of reefs in different areas through the geometric morphology of platform margins and different characteristics of reefs. In addition, The differences in sedimentary characteristics and distribution laws of reefs are studied. The results show that: (1)influenced by sedimentary palaeogeomorphology and differential fault activities, three types of platform margin belts were developed in the Changxing period on both sides of the Kaijiang-Liangping Trough: steep slope platform margin belt controlled by faults, steep slope platform margin belt controlled by sedimentary palaeogeomorphology, and gentle slope platform margin belt controlled by sedimentary palaeogeomorphology; (2)the reefs developed in different platform margin belts show different sedimentary characteristics. Among them, the two types of platform margin belts, "steep slope platform margin belt controlled by faults" and "steep slope platform margin belt controlled by sedimentary palaeogeomorphology", have a narrower horizontal distribution, and the reefs are characterized by "the growth law of large sedimentary thickness and mainly aggradational sedimentary texture". In contrast, platform margin belts such as “gentle-slope platform margin belts controlled by sedimentary paleogeomorphology” have the characteristics of significantly wider horizontal distribution, and the reefs are characterized by "the growth law of multi-row reefs development, thinner sedimentary thickness, and obvious migration";(3)The various sedimentary textures in different platform margin belts at study area are controlled obviously by comprehensive factors, which includes the scale of synsedimentary faults and the differences of sedimentary paleogeomorphology. The development characteristics of reefs in different platform margin belts are further influenced by comprehensive factors such as the differential structural characteristics of platform margin belts, synsedimentary differential sagging, sea-level change, paleoecological environment, and other factors.

Tectonic inversion of cratonic platform margin and its control on petroleum system—A case study of carboniferous in the eastern margin of PreCaspian Basin

Yuan Xiaoyu[1*]

1. Reservoir Description Institute, Northwest Branch of PetroChina Exploration and Development Research Institute, Lanzhou, Gansu, CHINA

E-mail: yuan_xy@petrochina.com.cn

Keywords: Tectonic inversion , Carbonate platform,PreCaspian Basin,Carboniferous

The PreCaspian Basin is a super petroliferous cratonic basin developed on the Kazakhstan plate. Its eastern margin is adjacent to the Ural orogenic belt, and southeastern margin adjacent to the Tethys fold belt (Volozh et al.,2003; Jin Zhijun et al., 2007). Since the late Paleozoic, the southeastern margin of the PreCaspian Basin has experienced a geological history of stable cratonic platform deposition, evolution of Ural orogenic belt and closure of the Paleotethys Ocean, resulting in the present complex tectonic and sedimentary setting (Alexander, A.C, 1999; Liang shuang et al., 2013).

In this paper, the tectonic evolution process of the Carboniferous system in the eastern margin of the PreCaspian Basin is reconstructed by the structural interpretation of the 2D and 3D seismic data and the combination of well-log and seismic data. Based on seismic facies analysis and layer flattening techniques, the favorable sedimentary-diagenetic facies zones such as platform reef, clastic beach and weathered karst zone were identified in comparison with the classical carbonate platform slope deposition models, and the tectonic and sedimentary model in the eastern margin of the PreCaspian Basin was established by structural and depositional reconstruction. The effects of Ural ocean closure and orogenesis on the eastern margin of the PreCaspian Basin is analyzed.

It is concluded that the eastern margin of the PreCaspian Basin underwent slope reversal, fold deformation, strike-slip transformation and differential uplift during the late Hercynian to Indosinian period, resulting in the hiatus, denudation. The hiatus of the Late Carboniferous were favorable to the formation of weathered karst reservoir facies. The tectonic inversion of platform margin carbonate ramp in late Permian was favorable to the formation of limestone shoal lithological reservoirs with updip occlusion. The large strike-slip fault zone is conducive to the formation of fault-fracture compound trap controlled by flower structure, which communicates with deep source rock. The tensional strike-slip fault zone developed in the southern uplift zone is conducive to the formation of fault solution and improves the deep reservoir conditions. Our study reveal the influences of Ural ocean closure and orogenesis on the sedimentation and tectonic deformation of the carbonate ramp of the carboniferous in the PreCaspian cratonic basin, and provide scientific references for the prediction of oil and gas exploration prospects in this area.

Types and differential distribution of Cenozoic lacustrine microbialites in western Qaidam Basin, China

xiujian sun[1*], jiangong wang[1], mingtao zuo[1]

1. Research Institute of Petroleum Exploration & Development Northwestern Branch, Research Institute of Petroleum Exploration & Development Northwestern Branch, Lanzhou, Gansu , CHINA

E-mail: sun_xj@petrochina.com.cn

Keywords: the Qaidam Basin, microbialites, types, differential distribution

As an important type of carbonate rock, microbialites are widely distributed globally, with external morphology and internal structure. The research of microbiolites has always been a hot topic in sedimentology. The Qaidam Basin, with an area of 121,000 km^2, is a Mesozoic and Cenozoic intermountain basin situated in the northern Qinghai-Tibet Plateau. Influenced by the uplift of the Qinghai-Tibet Plateau, a large salt lake developed in the western Qaidam Basin during Oligocene to Miocene, and microbiolites of saline lacustrine were deposited. To clarify the sedimentary characteristics and distribution of Cenozoic microbialites in the western Qaidam Basin, based on the data of outcrops, cores, and thin-sections, the classification, and characteristics of microbialites were carried out to study the differential distribution of different types of microbialites. The results showed that there are four types of Cenozoic microbialites in the western Qaidam Basin, including stromatolite, thrombolite, oncolite, and biogenic grainstone. The lacustrine microbiolites in the western Qaidam basin are mainly developed in the basin margin and shallow water environment, and their distribution is controlled by the combined impact of palaeogeomorphology, sedimentary environment, climate, and hydrological conditions. Based on the analysis of palaeogeomorphology and sedimentary environment, six sedimentary models of microbiolites can be established in high energy coastal zone, high energy steep slope zone, low energy deep water zone, low energy fault zone, low energy gentle slope zone, and low energy deep water uplifts zone in the western Qaidam Basin. Influenced by the changes in the sedimentary environment, the microbiolites in the western Qaidam Basin are developed in different strata, which are relatively independent. In addition, the thickness of each stratum is relatively thin, and the distribution of microbiolites has obvious migration characteristics. We found that intercrystalline pores, dissolution pores, and fractures constitute the main reservoir space of the microbiolites in the western Qaidam Basin, which are mostly characterized by medium-high porosity and permeability. And they are vertically interbedded with lacustrine source rocks, which can form a high-quality source rock and reservoir assemblage, which will be an important exploration field in the western Qaidam Basin.

Dissolution mechanism and effect of acidic fluid under high temperature and pressure in a deep reservoir: A Case Study from Baiyun Sag, Pearl River Mouth Basin

chengze li[1*], jun yao[1], xiaoyu yuan[1]

1. Oil and Gas Strategic Planning Institute, PetroChina Research Institute of Petroleum Exploration & Development-Northwest, Lanzhou, Gansu, CHINA

E-mail: lichz15@lzu.edu.cn

Keywords: Pearl River Mouth Basin, deep reservoir, high temperature and pressure, acid fluid,dissolution

Deep oil and gas exploration is an important direction of current and future oil and gas exploration. Acidic fluid is the main medium of material migration and energy exchange in petroliferous basins and an important geological condition for the formation of secondary pores. Baiyun Sag in Pearl River Mouth Basin has the tectonic geological background of high temperature and high pressure in deep reservoir, rich in organic acid and CO2 acid hot fluid activity, and the deep clastic rock develops secondary pore zone. Using the water-rock reaction device under high temperature and high pressure, combined with scanning electron microscope(SEM) observation, reservoir physical properties, cast thin section, XRD, ICP-OES test and other methods to carry out experimental study on the diagenetic reaction between deep sandstone composition and acid fluid, which is of great significance for revealing the dissolution of deep clastic rock reservoir and the development mechanism of secondary pores, and promoting deep oil and gas exploration. The experimental results showed the following results: (1) CO2-rich fluid has obvious dissolution effect on potassium feldspar, albite and calcite under high temperature and high pressure. The main dissolution temperature pressure window of the three minerals is between 150℃~300℃ and 45~60MPa.Under the condition of high temperature, the change of pressure affects the solubility of CO2, and then affects the dissolution effect and dissolution strength of sandstone components.(2)Organic acid fluid has obvious dissolution effect on core samples under high temperature and high pressure, nine groups of core samples have ion migration phenomenon and release K+, Ca2+, Na+, Mg2+ and other cations. After the reaction, the porosity of the sample increases by 5.6 % on average. It is concluded that the deep reservoirs in The Pearl River Mouth basin have the potential to develop secondary pores. The content of soluble components in rock and the difference of primary mineral structure are the key factors affecting whether the geological fluid can enter the reservoir. (3) The two experimental results reveal the diagenesis mechanism of secondary pores formed by water-rock reaction of deep source-reservoir combination and hydrothermal rock reaction of deep hydrothermal fluid background, respectively. Using core samples to conduct experiments of water-rock reaction is an effective way to offer basic evidence for areas which has no wells. Under the current tendency of high cost and risk for oil and gas exploration, it is a meaningful way to predict and explore resources in deep reservoir.

Seismic Progradational Reflection Characteristics and Sedimentary Model of Lower Permian Limestone Formation,Eastern Margin of the Pre-Caspian Basin

Yajun Zhang[1*], Jinjin Hao[1], Xiaoyu Yuan[1]
1. Reservoir Description Institute, Research Institute of Petroleum Exploartion&Development-Northwest,Petrochina, Lanzhou, Gansu Province, CHINA
E-mail: zhang_yj@petrochina.com.cn

Keywords: Pre-Caspian Basin,seismic progradational reflection, carbonate rocks depositional model ,lower Permian

The Pre-Caspian basin has rich oil and gas resources in pre-salt carbonate reservoir. In recent years, The Carboniferous sedimentary reservoir in the eastern margin of the basin were studied more , but less on the sedimentary characteristics and depositional model of Permian carbonate rocks. A large number of intra platform progradation reflection structures are found in the 3D seismic data of the lower Permian in the eastern margin of the basin. The progradation direction is roughly distributed along the SE-NWdirection, which is different from the characteristics and direction of Carboniferous carbonate platform progradation, and the relevant research has not been reported in the public literature. Therefore, based the 3D seismic data and combined with the calibration of drilling data, compared and tracked the multi-stage progradation seismic reflection structure of the lower Permian,The Arsse stage sedimentary filling sequence , and the sedimentary model are established to clarify the evolution process of the carbonate rocks of the lower Permian. The main conclusions are as follows: The ancient landform of Arsse stage controls the development of two types of carbonate rocks in this area:In the early stage of Arsse ,under the control of inherited ancient landform of Carboniferous, the limestone shoal deposits were developed in the western low convex zone ,and the lithology is algal limestone and bioclastic limestone, while the shelf facies calcilutyte is developed in the eastern part In the middle and late Arsse stage, with the intensification of the Ural orogeny, the southeast part of the study area was gradually uplifted, forming a low and gentle slope paleogeomorphology distributed in the SE-NW direction, and limestone formation with multi-stage S-shaped oblique progradation was developed. The multi-stage progradation developed in the middle and late Arsse stage is mainly controlled by tectonic uplift and slow decline of relative sea level in highstand stage, and continuously migrates along the sedimentary slope break of platform margin. Favorable reservoir facies such as algal limestone, cohesive granular limestone and biological skeleton limestone are developed on the foreset slope break and its continental side. The foreset slope break of each stage is identified by using of seismic reflection structure to find the development facies belt of reservoir rocks, which is helpful to the next step of fine reservoir prediction and the implementation of exploration targets in this area; At the same time, the above analysis of sedimentary process based on seismic progradation reflection structure provides a certain reference for studying the detailed process of Ural tectonic movement of Arsse stage in Lower Permian.

Abstract:With the rapid development of tight oil and shale oil, the study of lacustrine carbonate rocks has received more and more attention. Many theories and models of marine carbonate rocks cannot be completely copied to lacustrine carbonate rocks. In recent years, the Qaidam Basin has made many breakthroughs in the exploration of lacustrine carbonate rocks. Therefore, a systematic summary of the sedimentary distribution characteristics of lacustrine carbonate rocks has been carried out to point out the direction for further exploration of favorable zones. Influenced by paleogeomorphology, paleoclimate, paleo-source and paleo-salinity, the western Qaidam region forms four types of carbonate rocks: algal lime dolomite, granular lime dolomite, micrite lime dolomite and lime shale. Dolomitization is the basic condition for the formation of reservoirs. Various dissolution and tectonic actions can transform the reservoirs to different degrees, and high-efficiency reservoirs can be formed. Along with the migration of the lake basin, different types of carbonate rocks were developed in the Paleogene and Neogene in the western Qaidam, with a superimposed area of up to 8000km2. Carbonate reservoirs and high-quality source rocks are inter-distributed, with the characteristics of source-reservoir coexistence and source-reservoir integration. The cumulative thickness of favorable source-reservoir assemblages is 300-800m, which is the main area for intra-source oil and gas exploration in the basin. At present, the scale of Yingxiongling shale oil reserves has been confirmed, and the next step will continue to expand the blank area of Yingyingling sag. In addition, the carbonate rocks in Xiaoliangshan sag and Zhahaquan sag are also worthy of risk exploration and are expected to achieve greater breakthroughs.

Formation mechanism and controlling factors of microbial reservoir in Dengying Formation, Sichuan Basin

Chen Gengxin[1*]
1. Basin Experimental Research Center, Research Institute of Petroleum Exploration & Development,PtroChina, LanZhou, GanSu, CHINA
E-mail: 94186318@qq.com

Keywords: Microbialite, Reservoir Space, Karst, Sedimentary Geomorphology

The Dengying Formation of Sinian is the most important gas bearing formation of Precambrian in Sichuan Basin. Based on the macro and micro data of drilling cores and outcrop samples, combined with the corresponding geochemical data, the characteristics, formation mechanism and main control factors of microbial dolomite reservoir of Dengying Formation in Sichuan Basin are studied in detail. It is considered that: the rock types of dolomite reservoir of Dengying Formation mainly include algal thrombolite dolomite, algal dolarenite dolomite, algal stromatolite dolomite, etc; The reservoir space is divided into five categories, among which the main reservoir space of Dengying Formation is lattice (residual) pore-cave, intragranular (solution) pore, intercrystalline (solution) pore, small and medium-sized solution pore cave and fracture. Lattice (residual) pore cave and intergranular pore are mainly affected by the sedimentary structure of microbialite. Algal thrombolite dolomite and algal dolarenite dolomite have the best porosity and are most developed in the platform marginal zone. In intra-platform zone, they are mainly stromatolite, laminated and mud crystalline dolomite, and the primary pores are relatively undeveloped; Small and medium-sized karst caves are developed in scale and are the most important reservoir space. Three kinds of karst processes coexist in penecontemporaneous stage, early diagenetic stage and burial stage, among which the early diagenetic stage is the most important. The microstructure of microbialite is the internal cause of selective dissolution. It has obvious characteristics of facies control and geomorphic control on the plane. Vertically, the water resisting layer and high-permeability layer are superimposed in multiple cycles to form a complex karst cave system; Multi-stage structural fractures improve the seepage capacity of Dengying Formation reservoir, and there is an obvious negative correlation between gas production and distance from fault; Dengying Formation has a complex diagenetic history. Diagenesis such as compaction, cementation, filling and siliceous metasomatism are important factors for reservoir damage; Sedimentary geomorphology and syn-sedimentary faults control the favorable sedimentary facies belt, and then control the favorable lithology and the development of primary pores, and affect a series of karstification in the later stage, which is the fundamental control factor of reservoir development of Dengying Formation.

Characteristics of tight lacustrine carbonate reservoir and its oil and gas significance

Wei Yang[1*], Jiangong Wang[1], Xiujian Sun[1], Hongzhe Li[1], Yadong Bai[1]
1. Basin Experimental Research Center, Research Institute of Petroleum Exploration and Development-Northwest (NWGI), PetroChina, Lanzhou, Gansu, CHINA
E-mail: yangwei052@126.com

Keywords: carbonate, tight reservoir, oil displaces formation water, Qaidam Basin

A large area of lacustrine carbonate rocks developed in the Cenozoic strata in the western Qaidam Basin in China, which is characterized by vertical layers and large cumulative thickness. It is the main reservoir of oil and gas. Under the influence of periodic oscillation of lake water and terrigenous detrital material supply, large scale mixing of carbonate rocks is observed. Algal limestone and oval-aggregate limestone are mainly developed in the basin margin and shallow water environment, while organic-rich lamellar limestone is developed in the deep water environment of basin. Although the reservoir is tight, the rock pore throat is small, and the pore structure is complex, the combination of lattice pore, dissolution pore, intergranular pore and microfracture in the reservoir forms the efficient reservoir space of the fine-grained carbonate reservoir, with the porosity ranging from 1.2% to 13.27%, with an average of 6.8%. In order to explore the mechanism of oil enrichment in tight carbonate reservoirs, algal limestone and limestone samples were selected for oil displacing formation water simulation experiments.

The results show that there is little displacement difference between algal limestone and limestone reservoir, and the oil displacement effect is better in high porosity samples. In tight samples, the filling degree is greatly affected by pore connectivity, and both oil and water are difficult to enter and leave the pores, forming low-saturation reservoirs. The breakthrough pressure of crude oil decreases slightly during secondary charging. With the increase of displacement time, the amount of crude oil increases, and the wettability can reduce the displacement resistance in the reservoir and make it easier to be filled, leading to the shortening of oil saturation time. When the oil is injected into the sample containing micro-fractures, the oil migrates preferentially along the fractures, which shortens the oil saturation time and reduces the oil saturation in the core column. Based on the above research results, it can be concluded that the water in the near-high-quality source rock reservoir are strong displaced, the favorable reservoir with high porosity can be fully filled, and the oil saturation is high, which is an important direction for middle-shallow exploration in the northwest Qaidam Basin.

Micrite Envelope Microstructure and Forming Stage Characterization and its Control on Siliciclastic and Carbonate Mixed Reservoir of Bohai Sea Area

Huan Lu[1*], Liming Dai[1], Hao Liu[2], Yanfang Chen[1]
1. Bohai Oilfield research institute, CNOOC Limited, Tianjin Branch, Tianjin China, Tianjin, CHINA
2. Ocean Science department, China University of Geoscience(Beijing), Beijing, CHINA
E-mail: 415365087@qq.com

Keywords: Micrite Envelope Microstructure, Forming Stage, FBI, Mixed Deposits, Bohai Sea area

1. Introduction

In recent years, a large number of large and medium-size mixed deposits with huge discovered reserves were discovered in Bohai sea area. Our research shows that micritic envelopes are pervasively developed and micrite content are correlated well with high quality intervals of the mixed deposition.

2. Methodologies

In order to further clarify the relation of micrite envelope with high quality reservoir forming mechanism, advanced experimental techniques were adopted. Microstructure of micrite envelope was identified and characterized by Focused Ion Beam(FIB) and Electron Probe, and mineral composition of micrite envelope was determined by X-ray diffraction. The C\O isotope characteristics and forming environment of micritic envelope were determined by Laser Micro Samping analysis of carbon and oxygen isotope and Electron Probe. The biogenesis of micrite envelope was analyzed by Focusing Ion Beam(FIB) with Maps. The difference of dissolution ability of micritic envelope and dolomite and calcite is analyzed through reservoir physical simulation experiment.

3. Result

The result shows that micritic envelope can be classified into algal-bacterial perforated, micritic nucleation and micritic texture forming, micrite molding and complete micritization stage based on different tectonic and sedimentary environment. The preservation and dissolution ability of micritic envelope varied significantly.

3.1 In off-shore marine carbonate basement uplift background bioclastic dolomite reservoir which is of calcareous conglomerate and clastic dolomite mixed deposition

Micritic envelope is of algal-bacterial perforated stage, micritic nucleation stage and micritic texture forming stage, which is of the early diagenetic stage. As fungi and algae needed to absorb nutrients and minerals, and search for habitation to hide, they would repeatedly perforate inside and outside of the carbonate particles, resulting in blocky and metasomatism of micrite. Micrite envelope is finally formed in this process. This process was found at the border of bioclasts, as well as of some carbonate lithoclasts, some are dissoluted, some are not. The permeability of micritic envelope provide sufficient fluid exchange with the outside world, which will lead to dissolution of bioclastics. Aboundant bioclastics molds preserved by micrite envelopes and nano-scale micropores in micrite envelopes were observed by high magnification emission scanning electron microscopy, which proves the permeability of micrite envelope.

3.2 In near-shore gentle slope and steep slope background and volcanic basement reservoir which is of bioclastic dolomite and fan delta dolomitic conglomerate mixed deposition.

Micritic envelope experienced micrite molding and complete micritization stage, which is of late diagenetic stage. Micritization often appears as a thin micrite envelope around particles, it prevents the development of cements syntaxial overgrowths and thus preserves reservoir property. During algae growth prcoess, the lattice support structure of micrite envelope can form stable complex which is of acid and alkali resistance. Micrite envelope dolomite will become the crystalline nucleation and provide attachment point for isopachous rim dolomite growth. We can observe that some micrite were transformed into peloids by pervasive micritization which have dirty cores and clear rims. And this stability of dolomitization process is favorable for the preservation of pores.

Carbonate laminites from the Nanzhang-Yuanan fauna in the Lower Triassic Jialingjiang Formation, South China: Origins and Significances

Yajie Chen[1], Yuefeng Shen[1*], Jun Liu[1]

1. School of Resources and Environmental Engineering, Hefei University of Technology, Hefei, Anhui, CHINA

E-mail: yuefengshen@hfut.edu.cn

Keywords: P-T boundary, biomineralization, organomineralization, automicrite, taphonomy

The famous Early Triassic Nanzhang-Yuanan fauna (marine reptile Lagerstätten) has well documented the recovery of marine ecosystems after the Permian-Triassic mass extinction. These marine reptiles were preserved within laminated limestones (laminites) of Lower Triassic Jialingjiang Formation in Nanzhang and Yuanan, Hubei Province, central China. However, the formation mechanisms of these laminites, their indicative depositional environments as well as their significance on the excellent preservation of marine reptile Lagerstätten are still unknown. In this study, field observation in combination with petrographic and diagenetic analysis under normal light, cathodoluminescence, fluorescence and scanning electronic microscopes, as well as geochemical analysis were conducted to solve these problems. Microbially Induced Sedimentary Structures (MISS) and Reticulated Ridge Structures (RRSs) were developed on the surfaces of laminites. These laminites could be divided into two layers, respectively the light particle-rich layer and the dark organic-rich layer. Laminites packages could be classified as straight-dense laminae, wavy laminae and discontinuous laminae. There are abundant organic maters, extracellular polymeric substance (EPS) and framboid pyrites as well as clay minerals preserved within the dark layers, while light layers are rich in calcite crystals with a few celestite and dolomite crystals but rare clay minerals. *In situ* LA-ICP-MS analysis indicates different REE patterns and Ce abnormalities within different laminae. These all indicate a microbial origin of laminites (microbial laminites or biolaminites) deposited in a stagnant, reduced, hypersaline supratidal flat pond environment. Microbial-induced and/or -influenced biomineralization and organomineralization plays a very important role on the excellent preservation of Nanzhang-Yuanan marine reptile Lagerstätten.

Influence of limestone caprock on differential enrichment of Cambrian shale gas in southern China

ZHANG liuliu[1*]
1. Laboratory of Petroleum Resources, Research Institute of Petroleum Exploration and Development Northwest, PetroChina, Lanzhou, PR China, Lanzhou, Gansu, CHINA
E-mail: Zhangliuliu1993@163.com

Keywords: limestone caprock,shale gas reservoirs, Cambrian shale

In recent years, the Silurian and Cambrian shale gas exploration practices in different areas of southern China have shown that the gas material foundation is good, and the organic-rich shale reservoir roof and floor structure with well-developed storage space is the key factor for the evaluation of favorable shale gas reservoirs. It is also one of the main reasons for the differences in shale gas exploration in different regions of southern China.In this paper, the Cambrian Shuijingtuo Formation shale in Hubei area is analyzed by sample observation, mineral analysis, total organic carbon content test, pore structure parameter test and the reported well profile data obtained from the Cambrian Shuijingtuo Formation shale gas exploration gas. The vertical configuration relationship of gas-generation-reservoir-caprock assemblages is studied, and it is found that relatively tight and thin-layered marlstone is mainly developed at the top of the lower organic-rich shale of the Shuijingtuo Formation, and the bottom limestone has certain large pores, and the storage space is relatively small. In comparison, thin-layered and tight limestone caprocks are mainly developed in the lower part of the top of the organic-rich shale in the upper member with high TOC content. The organic pores generated in the process of organic matter cracking, evolution and hydrocarbon generation are one of the main storage spaces for shale gas. The generated fluids dissolve the lower carbonate minerals, making the lower organic-rich shale floor poor in sealing, resulting in high hydrocarbon expulsion efficiency, the fluid pressure in the voids decreases, which is not conducive to the preservation of voids in the shale under the action of compaction; while the upper and lower organic-rich shale roofs and floors develop relatively tight limestone caprocks with good sealing properties, which are shale gas The preservation of shale plays a good role in isolation, and it forms a good source-reservoir-caprock configuration relationship with the organic-rich shale reservoir with high porosity in the vertical direction. Finally, through the optimization of high-quality organic-rich shale reservoirs in the study area, a model for the preservation conditions of high-quality organic-rich shale reservoirs in the Shuijingtuo Formation is summarized. Through the study of limestone caprock, which provides a new way for the evaluation of Cambrian shale reservoirs in southern China.

Deposition Rate of the Paleogene in Yingxiongling Depression, Qaidam Basin and its significance for oil and gas exploration

Pei Zi Wei[1*], WU YUN ZHAO[1], WU YAN XIONG[1], WU ZHI XIONG[1]
1. Research Institute of Exploration & Development, Qinghai Oilfield Company, PetroChina, Dunhuang , Gansu, CHINA
E-mail: pzweiqh@petrochina.com.cn

Keywords: shale,Milankovitch cycles,Deposition rate,organic matter, Qaidam Basin

The Yingxiongling Depression is located in the northwest margin of the West Qaidam Depression in The Qaidam Basin. It is a key area of shale oil and gas exploration in the Qaidam Basin. Due to its proximity to fault XI, the formation is relatively complex, and the sedimentary rate research is weak and rarely discussed Milankovitch cycles was used to identify the layer thickness and the corresponding astronomical period of the cycle. Acycle module in MATLAB was used to identify milankovitch cycle, so as to calculate the deposition rate Spectral analysis and filtering analysis were carried out on GR logging data and measured TOC data of key wells in Yingxiongling Depression. After the deposition rate was demonstrated, the following understandings were obtained :1. The development of shale in Yingxiongling Depression is caused by seasonal water stratification of salt lake, and the growth period of one light and one dark lamella is one year. 2. The deposition rates of shale with different sedimentary structures are different, and the deposition rates of stratified shale are higher than that of lamellar shale. 3. The footwall deposition rate of fault XI is higher than that of the upper one, resulting in a huge difference in deposition thickness. 4. The existence of salt rock will increase the deposition rate; 5. Sedimentation rate is one of the important factors controlling organic matter enrichment and affecting the formation of organic-rich shale.This study provides a new method and means for the future research of stratigraphic analysis, identification of sedimentary cycles with high precision, division and establishment of high-frequency sequence units in the Qaidam Basin.

Analysis of the dolomite genesis in Lower-Middle Ordovician carbonate rocks in the Yingshan Formation, Gucheng Area, Tarim Basin—Evidence from petrography and geochemical data

Baiwen Huang[1*], Shaonan Zhang[1]
1. School of Geoscience and Technology, Southwest Petroleum University, Chengdu, Sichuan, CHINA
E-mail: 1002871538@qq.com

Keywords: Dolomitization, Recrystallization, Geochemical Characteristics

Various degrees of dolomitization are widely present in the Yingshan Formation in the Gucheng area of the Tarim Basin. To determine the origin of the massive dolomites present, a rich combination of tools was well used, including previous research results, core and thin-section samples, cathodoluminescence, carbon (C-) and oxygen (O-) isotopes, strontium (Sr-) isotopes and content, and burial-thermal history data. The results of this analysis successfully reveal three primary matrix dolomites and three special cements, as follows: (1) microcrystalline to very fine crystalline nonplanar-a dolomite (MD1); (2) very fine to fine crystalline planar-s to planar-e dolomite (MD2); (3) medium to coarse crystalline nonplanar-a to planar-s dolomite (MD3); (4) coarse crystalline nonplanar-a saddle dolomite cement (SD) and (5) medium to coarse crystalline calcite cements (C1 and C2). With increasing crystal size of dolomite, the luminescent intensity of matrix dolomites (MD1, MD2, MD3) gradually escalates under cathode rays, presenting uniform very dull to dull red light. In addition, among them, some MD3 shows different luminescent property, as a dull to dull red light internally and a relatively bright but extremely thin red light at the crystal edges; the Sr content (60.35-205.54 μg/g) and $\delta^{18}O$ (-9.45~4.81‰VPDB) decreased gradually and there was no significant difference in $\delta^{13}C$ values (-1.90~0.01‰VPDB). Reference to the estimated range of early-middle Ordovician marine dolomite (Veizer et al., 1999), the Standard conversion formula of PDB/SMOW and Temperature/SMOW (Friedman and O'Neil., 1977), dolomitization and multiple recrystallization of these three matrix dolomites are supposed to occur during burial process under the influence of slightly evaporated seawater and exogenous hydrothermal fluid: MD1 precipitated from the reflux of mildly evaporated seawater. Some of them underwent significant recrystallization to form MD2, and some of them experienced second significant recrystallization to form MD3 in medium-burial environments. Besides, a portion of MD3 was determined to be the product of the third significant recrystallization under the action of mixed hydrothermal fluid of mantle-derived fluid and Cambrian hot brine due to its special cathodoluminescence, high $^{87}Sr/^{86}Sr$ value (0.709105~0.709265) and special associated minerals (saddle dolomite (SD) and autogenic quartz (QZ)). Furthermore, negative $\delta^{13}C$ values (-2.78~-2.01‰), weak cathodoluminescence, different associated minerals, distinct $\delta^{18}O$ (C1: -12.69~-8.73‰; C2: -8.63~-8.03‰) and $^{87}Sr/^{86}Sr$ isotope characteristics (C1: 0.709212~0.709527; C2: 0.708724~0.708995) indicate that C1 and C2 have different origins: C1 was formed in buried formation water of Himalayan period which was close to the CH_4 charging event; and C2 is related to the late Caledonian and early Hercynian orogeny, which was formed by matrix limestone dissolved under pressure solution and reprecipitated in fractures and caves.

Keywords: Kingriali, Petrography, Dolomitization, Porosity enhancement

Multiple episodes of dolomitization of the shallow marine carbonates of the Late Kingriali Formation resulted in regional scale mapable dolostone geobodies in the Kohat and Potwar sub-basins. Except few unaltered patches of the host limestone, more than 90 % carbonates of the studied formation is diagenetically altered by replacive dolomites with associated dolomite cementation. Petrographical and geochemical data interpretation reveals that during the initial stage of dolomitization, the precursor limestone was significantly modified by the fabric retentive replacive dolomite (RD-I) and produced bulk dolostones with non-planar-a to planar-s crystals. Neomorphic recrystallization (RD-II) was observed as overgrowth of the already formed RD-I dolomite crystals during progressive dolomitization. At shallow depth, the seawater enriched with Fe-ions as a result of interacting with Fe-rich beds within the studied formation. The modified seawater actively participated in the formation of ferroan replacive dolomites (RD-III). Stable isotopic composition of the unaltered Echinoderm plates, calcite cement (CC-I) and RD-I demonstrates signatures of δ18O and δ13C within the limit of late Triassic marine seawater or modified seawater. Depletion in the stable oxygen isotopic composition (from -0.99‰ to -3.75‰ V-PDB) interpreted that RD-II and RD-III were formed in a sequence with progressively high temperature fluids than normal seawater. Precipitation of dolomite cements as cavity filling rhombs (DC-I) and crystal overgrowth (DC-II) with highly depleted δ18O values (-5.44 to -7.45‰ V-PDB) interpreting dolomite cementation at higher temperature and greater depth. The highly depleted values of δ18O (upto -9.16‰ V-PDB) and (upto 0.42‰ V-PDB) for δ13C of saddle dolomite (SD-I), indicates the precipitation of SD-I as a cavity filling dolomite at considerable depth. Calcite cementation and calcitization actively participated in the early, middle, and late diagenetic modifications as interpreted from their petrographic and stable isotopic studies. Porosity enhancement is clearly demonstrated by dissolution, stylolization, fracturing and replacement dolomitization. Dolomite and calcite cementation resulted negative impact on the reservoir character and occluded the dolostone porosity to a greater extent.

Formation mechanism of the Upper Ediacaran microbial-dominated dolomite reservoirs in the northern Tarim Basin, China

Pan Tang[1], Daizhao Chen[1*]

1. Key Laboratory of Cenozoic Geology and Environment, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, CHINA

E-mail: dzh-chen@mail.iggcas.ac.cn

Keywords: microbial dolomite, Upper Ediacaran, reservoir property, formation mechanism

The Upper Ediacaran Qigebrak Formation of the Tarim Basin consists of various microbial dolomites and is considered as a potential hydrocarbon exploration target for deeply-buried carbonate reservoirs. However, the formation mechanism of the Qigebrak dolomite reservoirs has not well been understood yet, hampering the predictions of high-quality reservoirs. This work was conducted based on detailed petrological, geochemical, and petrophysical investigations, aiming at understanding the diagenetic processes and influences on the porosity generation and preservation. The microbial dolomites of the northern Tarim Basin can be divided into four types based on different scales (macro- to micro-) of observation: microbial laminite, stromatolite, spongiomicrobialite, and microbial-peloidal wackstone/mudstone. The main diagenetic products consist of three types of dolomite (microbial dolomicrite, early-stage fibrous dolomite cement, and late-stage pore filling dolomite cement), quartz, calcite and bitumen fillings. Pore spaces are dominated by vugs, solution-enhanced pores, microbial framework pores, intercrystalline pores, micropores and fractures. The development of high-quality dolomite reservoirs in the studied area was essentially controlled by three controlling factors: microbial mat deposition, early dolomitization, and meteoric karst leaching. Microbial mat deposits can be considered as the foundation to form framework pores. Furthermore, the early dolomitization increased the resistivity of the studied microbial dolomites toward chemical and physical compaction, during which abundant micropores are generated. The meteoric karst dissolution, which is related to the uppermost Qigebrak Formation unconformity surface, is the crucial controlling factor that enhanced the porosity via forming a large quantity of vugs- and solution-related pores. Results presented here show that the Precambrian deep-buried dolomicrobialites could serve as potential reservoir geobodies targeted for hydrocarbon exploration.

E-mail: dzh-chen@mail.iggcas.ac.cn

Keywords: Lower Paleozoic carbonates, Tarim Basin, Hydrothermal alteration and dolomitization, hydrothermal dissolution, Permian igeneous activity

The Paleozoic carbonates, particularly the Lower Paleozoic (Cambrian to Mid-Lower Ordovician) platform successions in the Tarim Basin overwhelmingly comprise dolostones of variable origins from syndepositional to burial even telodiagenetic processes. Those hydrothermally-altered dolostones commonly occurred in association with either intrusive magmatism (diabases) of Early Permian large igneous province (LIP) (ca. 290 Ma) or related faulting or fracturing. They are characterized by extensive recrystallization of nonplanar-a matrix dolomite mosaics and void- and/or fracture-filling cements of saddle dolomites and other later diagenetic mineral phases. Saddle dolomites generally yield isotopic (C, O, Sr) data similar to those of matrix dolomites, of which some even yield lower Sr isotopic ratios than the matrix dolomites particularly occurring along the intrusive bodies, indicating the hydrothermal fluids were derived mainly from the ambient carbonate formation fluids, locally mixed with basic magmatic fluids. Fluid inclusion microthermometry of saddle dolomites suggest the temperature of fluids responsible for dolomite precipitation was higher than the ambient formation. In this case, the magmatic emplacement of linked to the Early Permian LIP activity could have caused not only the thermal anomaly but also fracturing in the Paleozoic carbonates that were penetrated by the intrusions, enhancing the thermal diffusion and hydrothermal fluid migration (although minor volumes of thermal fluids from the basic magmas) through the fracture/fault systems, thereby resulting in contact metamorphism (or marbleization), recrystallization of matrix dolomites and dolomite precipitation commonly in primary dolostone successions. On the other hand, hydrothermal fluids could have also caused dolostone dissolution, although not extensive, along the faults or fractures probably through retrograde dissolution as the fluid temperature dropped during upward migration. This may account for the voluminous unfilled large voids/cavities in the deep-buried Cambrian dolostones as recovered in the ultra-deep borehole well TS1 (up to 8408 m).

Comparatively, the Lower Paleozoic limestones, although limitedly distributed, occur on the northeastern flank in the Quruktagh area of Tianshan Mountains, and are dominated by basinal thin-bedded lime mudstones. Subordinate dolostones occur as by light-colored beige, anastomosed dolostone geobodies along the faults and fractures cross-cutting the well stratified limestones. These dolostones comprise matrix dolomite and cement dolomites (saddle dolomites) locally with brecciated and/or zebra fabrics. Isotopic (C, O, Sr) data of dolomites suggest dolomitizing fluids were largely inherited from or buffered by the host formation fluids with elevated temperatures and inputs of Mg and radiogenic Sr from the host limestones through enhanced rock-fluid interactions. The fault- or fracture-prevalent dolomitizing process probably took place during the Hercynian orogeny, as the Tarim block collided with the Tianshan island arc chains to the north and northeast through which the secondary tensional faults and fractures within the overall compressional setting could have acted as the favourable fluid conduits recharged by the Mg-rich fluids expelled from the depths, leading to the dolomitization along the faults/fractures.

Microbial dolomite precipitation mediated by methanogen in a Permian lake, NW China

Wenxuan Hu[1*]

1. School of Earth Sciences and Enginering, Nanjing University, Nanjing, Jiangsu, CHINA

E-mail: huwx@nju.edu.cn

Keywords: microbial dolomite, dolomite nanoglobules, methanogens, biosignature, lake sediments, Permian

Microbes can mediate dolomite precipitation in laboratory experiments, but until now linkage of microbes to ancient dolomites remains poorly constrained. This paradox is usually due to the lack of diagnostic biogeochemical signatures and mineralized microbial remains in the rock record. Here, we report the occurrence of methanogen-mediated dolomite in a Permian non-hypersaline lake from NW China. The clumped isotope (Δ47) temperature provides direct evidence of a low-temperature origin (typically < 40 °C). The extremely positive δ26Mg (up to +0.44‰) and δ13C (up to +19‰) values in the dolomite suggest authigenic precipitation in methanogenic lake sediments. Micron-sized spheroidal bodies, filamentous and sheet-like structures are interpreted as mineralized coccoid archaea and extracellular polymeric substances (EPS), respectively; they exhibit a granular texture consisting of dolomite nanoglobules (mainly 40–100 nm in diameter). A combination of both geochemical and microscale evidence strongly confirms a microbial origin of dolomite induced by methanogens. Moreover, the formation of dolomite is characterized by a non-classical pathway including metabolic incubation, heterogeneous nucleation, and aggregative growth. Dolomite nanoglobules initially nucleated on the surfaces of methanogen cells or EPS, and then merged into larger aggregates. These findings provide valuable clues to decipher the biosignature of ancient dolomites and better understand dolomite formation.

LA-ICP-MS U-Pb Age, SEM and isotope constrain on the origin of Ediacaran dolomite

jie zhang[1*]

1. Marine Petroleum Geology institute, PetroChina Hangzhou Research Institute of Geology, Hangzhou, Zhejiang, CHINA
E-mail: zhangjiecug@163.com

Keywords: Dolomite precipitation, SEM, Microbial mediation, Seawater geochemistry, LA-ICP-MS U-Pb Age analysis

Huge thick succession of dolostone developed in Ediacaran in typical platform sedimentary area of China (Bao, 2019). But lomestone developed around the paleouplift, slope environments (Jin, 2019). Multi-sections study show that these dolostone structures differ from the dolostone with replacement in Phanerozoic and their origins are in dispute with primary or secondary. Because of the flourishment of microbes in PreCambrian, many researchers tended to explain with microbial origin. Many similar microbial proofs like spherulitic dolomites were discovered in the dolostone with microbial structures. However, the surrounding rock are very fine-crystal dolostone and the cements and fillings are pure dolomites with rare calcite. Geochemical data show that they were not replaced from calcite. LA-ICP-MS U-Pb Age analysis result of these dolomites are about 554My, which means that they were penecontemperaneously formed. Modern dolomite experiments and dolomite precipitation in super-salinity environment show that microbes play significant fuction in the dolomite precipitation. But more researches show that the more important function of microbes is that they changed the microenvironment of marine water and the dolomites were easy to precipitate. Or the aragonites were easy to transfer to dolomites. This aragonite-dolomite sea is different with the calcite sea and aragonite sea in Phanerozoic. The flourishment of microbes will change the chemical characteristics of marine water in platform area and lead to widespread dolomite precipitation. However, the restricted microbe scale in non-platform area were insufficient to the widespreas dolomite precipitation.

Keywords: Tarim Basin, Hydrothermal dissolution, Deep-buried carbonate, Dolomite reservoir

Dolomites pervasively occur in the deep/ultradeep buried carbonates, especially in the Early Paleozoic, in the Tarim Basin, NW China. This study focuses on the Upper Cambrian dolomites of SHNP1 well in the Shunnan area, Tarim Basin, which still preserved abundant dissolution pores and/or vugs at depth over 7500 m. Integrated isotopic geochemistry (C, O and Sr) and fluid inclusion microthermometry suggest that dolomite recrystallization and subsequent precipitation were closely associated with fault-related hydrothermal fluids migrated from greater depth. In addition, the diameter of dissolution pores are gradually increasing with progressively burial. This variation also verified that they were formed by upward migration of tectonically driven hydrothermal fluids rather than infiltration of subsurface water with progressive burial. Moreover, the anisotropy of reservoir space revealed by full diameter CT scanning illustrated that fractures induced by hydrothermal dolomitization could significantly improve the quality of carbonate reservoir, particularly of permeability. Hydrothermal-related dolomite reservoir may be extensively present in the deep/ultradeep buried carbonates in the Tarim Basin in view of the occurrence of such phenomenon in the borehole TS1 in the northern Tarim Basin. This study demonstrates the constructive role of hydrothermal dolomitization in improving the property of carbonate in ancient cratonic basin. It thus deserves to pay more attention to the hydrothermal-altered dolomites than ever before during hydrocarbon exploration in the Tarim Basin and elsewhere.

Keywords: Burrow-associated dolomites, Isotopic geochemistry, Reservoirs, Tarim Basin, Lower-Middle Ordovician

The origin and reservoir implications of burrow-associated dolomites (BADs) are still not well defined. The study carried out comprehensive analyses of petrography, fluid inclusion microthermometry, and isotopic (C-O-Sr) geochemistry on the burrow-associated carbonates (dolomite and calcite) of the Yingshan Formation of the Lower-Middle Ordovician in the Tarim Basin (NW China), in order to figure out the controls on the dolomitization of burrow infills and the effects on petroleum reservoir quality. The tempo-spatial distributional patterns of the burrow-associated carbonates within the sequence stratigraphic framework indicate that the development of different types of burrow-associated carbonates was dictated by the interplay of depositional environments and sea-level fluctuations of variable orders. The BADs were formed in a lagoonal setting during the lowstand of long-term sea level, whereas the burrow-associated calcites (BACs) were precipitated in a water circulation-improved lagoonal environment during the transgression of long-term sea level. The geochemical data reveal that the variably-evaporated (i.e., mesosaline to penesaline) and nearly normal seawaters were responsible for the development of BADs and BACs in the Yingshan Formation, respectively. In the anoxic near-surface to shallow burial settings, sulfate-reducing bacteria and a sufficient supply of dolomitizing fluids enriched in magnesium ions and their Mg^{2+} concentration may have played a significant part in the precipitation of BADs. Due to the burrowing process, the burrowed sediments became more permeable and served as conduits for the parental fluids responsible for the development of BADs, which have higher salinities and higher Mg^{2+} concentration than normal seawater. In such circumstances, burrow infills were favorably dolomitized. In contrast, the fluids with seawater-like Mg^{2+} concentration led to the formation of BACs. Under the conditions of a persistent supply of dolomitizing fluids, the dolomitization fronts may extend into matrix limestones and result in the creation of massive matrix dolomites. With the progressive burial, the overgrowth of BAD crystals was ceased by the emplacement of hydrocarbons from underlying source rocks of the Cambrian to Lower Ordovician. This led to that the better petrophysical properties (porosity and permeability) of BADs were retained and they can act as potential hydrocarbon reservoirs. The results could advance the understanding of the formation and reservoir implications of BADs in the geological records.

Keywords: dolomite genesis, ultra-deep dolomite reservoir, dolomitization model, Tarim Basin

Due to the good capacity of resistant to porosity-reducing effects by the compaction and pressure solution (Schmoker & Halley, 1982; Lucia, 2004), dolomite can preserve the pores during long-term burial. Dolostones can be high-quality oil and gas reservoir in ultra-deep (>6000m) strata (Lucia, 2004). So the formation of dolomite is of great significance to the preservation of the reservoirs (Rott & Qing,2013; Chen & Qian, 2017; Ye et al., 2019).

High quality reservoirs were well developed in the Lower Cambrian Xiaoerbrak Formation in Tazhong area of Tarim Basin, with average porosity of 9.01% (17 full diameter core samples). Core samples were collected from wells ZH1 and ZH2 in Tazhong area, petrographic observation and geochemical testing of 82 samples have been completed. Combined with the characteristics of in-situ trace elements, the main formation environment of dolomite and the dolomitization model of the Lower Cambrian in the Tazhong area is illustrated.

The research shows that the Lower Cambrian dolomite developed in the background of transgression during the sedimentary period of the Yurtus Formation and subsequent regression during the Xiaoerbrak period. The dolomite was formed in the tidal flat facies. The $\delta^{13}C$ of 82 samples have values of -3.11‰ – 0.48‰ (VPDB), with an average value of -1.15‰ (VPDB), the $\delta^{18}O$ values range from -9.32‰ to -5.39‰ (VPDB), with an average value of -6.99‰ (VPDB). These results are larger than those of limestone in the Lower Cambrian. Moreover, the rare earth elements (REEs) pattern of dolomite is similar to that of limestone. The in-situ trace element analysis of the pore lining cements and intergranular cements in the dolomite shows that the REEs patterns of the cements and the matrix are completely consistent. Ni/Co, V/(V+Ni) and Sr/Na ratios of dolomite indicate that dolomite was formed in a high-salinity and slightly reducing environment. A few strontium isotope values are close to the values of ancient continental aluminosilicate rocks. The carbon and oxygen isotope values and Z values of the Tazhong dolomite are positively correlated with the distance to the ancient continent. There are limestone intervals in the Wusonger Formation in Wells ZH1 and ZH2. All the evidences indicate that the dolomitization fluids derived from evaporating seawater. Seepage–reflux pattern is dominating fluxion mode of the dolomitization fluids during penecontemporaneous at the eogenetic to early mesogenetic stage. The formation of dolomite is related to the supply of evaporative fluid controlled by eustatic change. When sea level rises leading to insufficient supply of evaporative fluid, the limestone section is developed. While the periodic eustatic change and meteoric dissolution in the penecontemporaneous period, the cyclic dolomite reservoirs is formed. Therefore, the early-formed dolomites is crucial for the preservation of ultra-deep reservoirs.

Genetic types and distribution of lower Paleozoic dolomite in Bohai Oilfield

Yuan[1*]
1. , , Tianjin, , CHINA
E-mail: 693190097@qq.com

Keywords: Key words: lithofacies paleogeography , dolomite genetic differentiation marker , reservoir characteristics , dolomite distribution

Palaeozoic group is looking for bohai oilfield under the formation of large and medium gas fields, in view of the upper Paleozoic dolomite with high value exploration, but its genetic type and distribution of ambiguous exploration problems, the use of petrology, isotope and element geochemical method to carry out the lithofacies palaeogeography of the bohai sea lower palaeozoic era, the upper Paleozoic dolomite genesis identification mark, Research on genetic model, reservoir potential and distribution law and form four understandings:1) based on the outcrop of Cambrian and ordovician drilling fine contrast and sedimentary facies research, the bohai rim region in early Paleozoic of palaeogeographic pattern of the north-south high, intermediate low, are given priority to with water carbonate sedimentary, and sums up the early Paleozoic sedimentary characteristics and control factors of sedimentary evolution of the bohai sea and the surrounding lower palaeozoic era is established model, The lithofacies palaeogeography of bohai Sea and its surrounding area in four periods of early Paleozoic is described. 2) There are four kinds of dolomites in Bohai Sea: evaporative dolomite, reflux dolomite, mixed dolomite and burial dolomite. The differences of carbon and oxygen isotope characteristics, petrology, trace elements, diagenetic temperature, rare earth elements, paleo-oxygen facies, paleo-weathering and paleo-terrigenous dolomite were established. 3) To establish the genetic model of bohai dolomite and analyze its reservoir characteristics; The evaporative dolomite is mainly characterized by ultra-low porosity and density. The reservoir space of dolomite of osmotic backflow origin, mixed water origin and burial origin is characterized by pores, caves, structural fractures and related dissolution fractures, and the physical properties are mainly low porosity and low permeability. 4) the analysis summary different genesis of dolomite longitudinal and plane distribution of the bohai sea, evaporation causes dolomite development horizon confined to Cambrian zhangxia group - multifunction mountain, seepage reflux genesis of dolomite in the massive distribution, southern bohai sea is advantageous in seepage reflux formation dolomite development area, and has a decrease trend from the south to the north, Mixed water dolomite is developed in zhangxia Formation and Middle Ordovician along the karst slope of each paleo-uplift in The Bohai Sea, and buried dolomite is distributed in all layers, among which hydrothermal dolomite is mainly distributed along the fault zone.

Keywords: Longwangmiao Formation, dolomitization model, evaporation pump, seepage reflux, C-O-Sr isotopes, Sichuan Basin

The lower Cambrian Longwangmiao Formation (LWMF) dolostones are the most important producing strata in Sichuan Basin, SW China. The dolomitization model has been established for the LWMF dolostone in this paper through core description and outcrop investigation, cathodoluminescence, geochemical analysis such as major elements, trace elements, fluid inclusion and isotope of carbon, oxygen and strontium. The LWMF are mostly composed of dolostone, dolomitic limestone and calcareous dolostone, limestone in lithology. In Central Sichuan Basin (CSB), dolostones dominate while dolostones and partially dolomitized limestones can be found in Southern (SSB) and Eastern Sichuan Basin (ESB). In CSB, the δCe index of almost all of the samples takes on an obviously positive anomaly while the δEu index shows a negative anomaly (the δEu index of a few dolograinstones is positively abnormal). In ESB, the δCe index takes on an obviously positive anomaly while the δEu index shows a negative anomaly (the δEu index of a few samples from WT1 are positively abnormal). In SSB, δCe values of all the samples are positive abnormal and δEu index is positively abnormal. The MgO-CaO content of all the samples is positively correlated in CSB, but negatively related in ESB and SSB. In CSB, dolostones have the highest content of element Na (The average of element Na >350 ppm). the $\delta^{13}C$, $\delta^{18}O$ and $^{87}Sr/^{86}Sr$ values of dolostones generally greater than range of seawater. In fluid inclusion analysis, the homogenization temperatures and salinities indicate that the dolomitization fluids of the LWMF in CSB have low temperatures and high salinity, but the dolomitization fluids of the LWMF in SSB have high temperatures and high salinity. In SSB, dolostones have the lower content of element Na (The average of element Na >100 ppm), which is due to the leaching of atmospheric fresh water and the influence of hydrothermal fluid during the deposition period. The $\delta^{13}C$ and $\delta^{18}O$ values of samples in SSB are obviously positively correlated and the $^{87}Sr/^{86}Sr$ values of generally greater than range of seawater. In ESB, the $\delta^{13}C$ and $\delta^{18}O$ values of dolostones have the highest content of element Na (The average of element Na > 200 ppm). The $\delta^{13}C$ and $\delta^{18}O$ values of dolostones are more positive than those of seawater. The $^{87}Sr/^{86}Sr$ values of dolostones generally greater than range of seawater. We believe that the dolomitization model of the LWMF is an evaporation pump + seepage reflux model. During the sedimentary period of LWMF, the Sichuan Basin is a carbonate ramp with three-stage stepped deposits, which is high in the west and low in the east. The seawater gradually becomes open from west to East. The seawater is the most restricted in CSB, followed by the seawater in SSB, and the least limited ESB. The dolomitization also decreases with the gradual opening of the seawater. In CSB, The dolomitization fluid is palaeoseawater-oriented. In the SSB, the dolomite formed in seepage reflux, and is overlapped by hydrothermal fluid later and atmospheric fresh water. In the ESB, a seepage reflux mode of continueous seawater concentration.

Reservoir development characteristics and main controlling factors of Dengying Formation in Sichuan Basin

Huiyi Xiao[1,2], Xiongqi Pang[1,2*], Dinye Zheng[1,2], Caijun Li[1,2]
1. State Key Laboratory of Petroleum Resources and Prospecting, China University of Petroleum (Beijing), Beijing, CHINA
2. College of Geosciences, China University of Petroleum (Beijing), Beijing, CHINA
E-mail: pangxq@cup.edu.cn

Keywords: Sichuan Basin, Dengying Formation, Carbonate rock, Reservoir characteristics, Main control factors, Favorable development zone

Large packaged gas fields such as Weiyuan and Anyue have been found in the carbonate rocks of Dengying Formation in Sichuan Basin. However, there are some problems in the reservoir, such as strong heterogeneity, large changes in physical properties and various reservoir types, which makes oil and gas exploration and development more difficult. In order to further understand its oil and gas types and distribution law, the data of core description, logging interpretation, cast thin section, cathodoluminescence and high-pressure mercury injection are used to analyze the reservoir development characteristics and main controlling factors.

The reservoirs of Dengying Formation are stably distributed horizontally and developed in second member and fourth member longitudinally, with the characteristics of wide range and large cumulative thickness. Under the sedimentary background of shallow tidal flat, lagoon and mound beach, the reservoir of Dengying Formation mainly develops algal agglomerate dolomite, algal laminated dolomite, algal arenaceous dolomite, algal laminar dolomite and argillaceous dolomite, and different lithology shows specific development characteristics. The physical properties of Dengying Formation reservoir are characterized by strong compactness of ultra-low porosity and permeability, and locally high porosity and permeability. Among them, the porosity is distributed between 0.77% ~ 10.32%, with an average of 2.26%, and about 73% of the samples are concentrated between 1% ~ 3%. The permeability is between 0.0047 ~ 24.7md, with an average of 0.75md, and about 75% of the samples are less than 1md. A small number of rock sample data show the characteristics of low porosity and high permeability, reflecting the existence of fractures and micro fractures. The reservoir types of Dengying Formation vary widely. Intergranular solution pores, intragranular solution pores, mold pores and intergranular solution pores are developed in the micro, and karst caves, solution fractures and structural fractures exist in the macro. Combined with the lithology and physical properties of the reservoir, the reservoir space types are divided into 11 types of 6 styles in 3 categories.

The reservoir development of Dengying Formation is mainly controlled by two factors. (1) Favorable sedimentary facies. Mound and beach facies are favorable sedimentary facies of Dengying Formation with obvious facies control. High energy mound and beach facies rocks such as arenaceous dolomite, tufted dolomite and laminated dolomite have an average porosity of more than 3.5%. (2) Supergene karstification. Among the high-energy mound beach facies developed in the early stage, the physical properties are good. The reservoir can be used as the transmission conductor of karst water, dissolve and expand the early pores, and transform them into a karst superimposed and expanded pore system. On this basis, the favorable areas for reservoir development are predicted and divided into three favorable areas. (1) The most favorable area is the superposition area of karst platform or karst slope and Hill Beach complex. (2) The favorable development zones are karst platform, karst slope zone or Hill Beach complex area. (3) The more favorable development zone is karst highland or internal rift of Zitong-Junlian craton (limited lagoon sedimentary area).

Keywords: spatial evolution since reef formation,algal reef dolomite,tight dolomite,ankerite,primary dolomite,Transmission electron microscopy

The concentric circle model for the study of dolostone on isolated islands is a good example, which illustrates the process, results and mechanism of the interaction of dolomitization between water and rock along the flow path from the shelf edge to the center of the island.

In this paper, the characteristics, results and mechanisms of water-rock interaction of dolomitization during the early Neogene since the formation of the reef were studied by drilling through the exploration Wells of the Reef family of Xisha Islands to obtain the complete core. The occurrence, distribution and spatial evolution of algal reef dolomite, ankerite and tight dolomite since the formation of the reef were explained. A multi-mechanism isochronous genetic model for the formation of deep dolomite (≥1000m), middle deep dolomite (500-1000m) and shallow dolomite (≤ 500m) in different periods since reef formation has been established. It is pointed out that the formation of tight dolomite follows the filling failure mechanism and the dense accumulation mechanism of round particles with different diameters, which has significance for oil and gas exploration.

TEM has been used to study the crystal lattice constants, types and spatial point group characteristics of 1-5 nanoscale dolomites with the highest resolution to date. Dislocation, significant line defects and changes along the deep, middle and shallow layers have been revealed, and the dolomite atomic image model has been established.

It is pointed out that the original dolomite synthesized by the experimental synthesis technology is 3nm, which is similar to the original dolomite-ankerite found in the core of different layers in The Science exploration well. The original dolomite is clean, euhedral to semi-euhedral, and is enriched in pores, holes and fractures, and benefits from the promoting effect of microorganisms.

Keywords: Deep fluids, Hydrocarbon accumulations, Dolomite Reservoirs, Sichuan Basin

Deep fluid activity is closely related to carbonate reservoir transformation as well as oil and gas accumulation. The large-scale deep fluid activity caused by Emeishan Large Igneous Province (ELIP) brought a lot of deep material and energy to Sichuan Basin, changed the paleogeothermal and geochemical field of the region they flowed through, which had an important impact on the formation of Middle Permian dolomite reservoir in Western Sichuan. Through comprehensive analyses of petrographic, geochemical and fluid inclusion data from two drill core and three outcrop sections of the Middle Permian Formation in the western Sichuan Basin, the dolomitizing fluid, dolomite genesis and affect of deep fluid were discussed. The dolomite were divided into four types which are matrix dolomites (Md1, Md2 and Md3) and cement dolomites (Cd). Among them, the Md1 were formed in penecontemporaneous seawater by seepage reflux dolomitization, while Md2 were formed in heated Permian seawater through thermal convection. In the NW, the Md3 and Cd were formed by higher-temperature thermal convection without hydrothermal.In the SW, the lower $\delta^{13}C$ value and Sr contents, higher Mn contents and $^{87}Sr/^{86}Sr$ ratios, positive Eu anomalies as well as much higher Th and salinity values of inclusions shows that hydrothermal participated in the dolomitization, forming the Md3 and Cd through structure-hydrothermal dolomitization and the thermal convection of seawater mixed with hydrothermal. The deep fluid activities of ELIP provided both the material source (Mg^{2+}) for the dolomitization process and the migration motive power for the dolomitization fluid. From SW to NW, with the deep fluid activity decreasing, the abundance of Md3 and Cd which are closely related to the hydrothermal solution reduced.

Characteristics and genetic mechanism of porphyry dolomite in the Longwangmiao Formation in the central Sichuan area

1*

1. , , , , CHINA
E-mail: 2394697218@qq.com

Keywords: Longwangmiao Formation,Porphyry dolomite,reservoir characteristics,formation mechanism

The Lower Cambrian Longwangmiao Formation in the Moxi area of central Sichuan Basin is the largest single-packed marine carbonate gas layer discovered in China, The Longwangmiao Formation reservoirs have significant heterogeneity and mostly contain bitumen-infested dark patches .Based on the analysis methods of core observation, thin section identification, fluorescence reaction, cathodoluminescence and scanning electron microscope observation and geochemical characteristics, the research on the reservoir characteristics and genetic mechanism of the piebald dolomite in the Longwangmiao Formation in the central Sichuan area is carried out. The following research results are obtained(1) the porphyry dolomite in Central Sichuan are developed irregularly with black spots and white spots . Due to the strong heterogeneity of pores, the porphyry dolomite is filled with asphalt to form "dark patches", while the porosity with dense lithology or not filled with asphalt forms "white patches".(2)The solid bitumen in the Longwangmiao Formation reservoir in the central Sichuan area mainly comes from the Lower Cambrian source rock, and the oily bitumen mainly comes from the Lower Silurian Longmaxi Formation, and the genetic types of the bitumen are diverse. (3)The Longwangmiao Formation reservoirs in the Sichuan Basin are divided into porphyry-pore-type reservoir, porphyry-pores-vugs-type reservoirs, and porphyry-karst-type reservoirs in the study area according to the porphyry shape and void relationship. (4)The lithology and genesis of different types of "porphyry" reservoirs are also different.,the porphyry-karst-type reservoir is mainly formed by the epigenetic karstification of micrite (sand) dolomite; the porphyry-pores-vugs-type reservoir is due to the selective dissolution of granular dolomite; The porphyry-pore-type reservoir is due to the selective dissolution of micrite grain dolomite along biological burrows.

Genesis and distribution of thin dolostone in Early to Middle Permian Sichuan BasinChina

WENJIE YANG[1], XIUCHENG TAN[1*]
1. School of Geosciences and Technology, Southwest Petroleum University, Chengdu, Sichuan, CHINA
E-mail: tanxiucheng70@163.com

Keywords: Dolomite genesis,Distribution characteristics,Early-middle Permian,Sichuan basin

Most of the previous studies believed that the middle-lower Permian dolomite in Sichuan Basin was formed by tectonic hydrothermal action, and the distribution of dolomite was closely related to the distribution of basement faults. Through the analysis of petrological and geochemical characteristics of a series of outcrops and drilling cores, and according to the statistics of dolomite development in drilling, the results show that: (1) The thin-bedded dolomite can be divided into leopard porphyry grain dolomite and massive grain dolomite in macroscopic occurrence. The dolomite is mainly euhedral to semi-euhedral mesocrystalline dolomite. The original lithology is mainly sparry or micritic bioclastic grainstone, indicating that the dolomite is mainly developed in the grain beach facies. (2) The distribution range of carbon isotope of dolomite is similar to that of limestone and sedimentary seawater, and oxygen isotope is slightly higher than that of limestone, which may be due to the dolomite being subjected to high salinity dolomitization fluids. Strontium isotopes of limestone and dolomite are distributed in the Permian seawater range. The ree distribution curve of the macerals of the dolomite is "left inclined shape" with LREE deficit and HREE enrichment, which is the same as that of the seawater. Geochemical results show that the dolomite fluid is mainly Marine fluid with high salinity, not hydrothermal dolomitization. (3) The plane distribution of dolostone is characterized by continuous distribution around sedimentary landform highland, and the thickness of single layer is mostly in the range of 1~3m. Longitudinally, the dolomites are mainly distributed in the middle and upper part of the sedimentary cycle and are controlled by high frequency sequences. Combined with the geochemical characteristics and distribution characteristics of the dolomite, it is considered that the early-middle Permian dolomite in Sichuan Basin was formed by penecontemporaneous reflux infiltration dolomitization. Due to the high frequency variation of sea level, it is easy to form the leopard porphyritic dolomite with thin monolayer thickness and incomplete dolomitization.

Abstract: the characteristics of rare earth elements in dolomite, such as content, distribution mode and some important rare earth element parameters and their variation rules, are of great significance to study the genesis, provenance properties and paleoenvironment of dolomite, especially to establish genetic model. However, dolomite is easily affected by multi-stage diagenesis evolution in the formation process, so its geochemical characteristics are uncertain. It has only been more than ten years since the discovery of tight dolomite in well Xike 1. Predecessors have completed the research on petrology, Geochemistry (isotope tracing, etc.) and reservoir characteristics, but their rare earth element characteristics and micro regional petrological characteristics are the links less studied by predecessors. On this basis, the author takes the core of the first member of Sanya formation of well Xike 1 as the research object, and first distinguishes the surrounding rock and debris of tight dolomite, Through microscopic equipment, it is observed that the surrounding rock dolomite is in close contact, most of which are fine-grained particles, and the pores are small. The fine-grained dolomite includes automorphic, semi automorphic and heteromorphic, and a typical fog core bright edge structure is developed. At the same time, the rare earth element composition of surrounding rock is measured by laser in-situ denudation technology. The overall rare earth element distribution mode is in line with the rare earth distribution characteristics of normal marine carbonate rocks, which is manifested in LREE loss and CE negative anomaly. At the same time, the possible influence in the process of diagenesis is is discussed and analyzed by calculating the abnormal values of other specific elements.

Keywords: dedolomitization, tight dolomite, Well Xike 1, calcite rhombohedral pseudomorphic, speckled calcite

Dolomite is an important storage space for oil and gas including oil and gas in the South China Sea, and it is also a hot spot and frontier in basic research. This study focuses on the dedolomitization of tight dolomite in Well Xike 1. Contrary to dolomitization, dedolomitization represents the dissolution of dolomite and the formation of calcite, which can cause a series of changes in the original porosity, structure and mineral properties of dolomite. In this paper, using X-ray powder crystal diffraction, scanning electron microscopy and alizarin red staining analysis techniques, on the basis of the analysis of the lithological characteristics of the core, the phenomenon of dedolomitization was found by dyeing thin sections. The phenomenon of dedolomitization in the well section of this study is widespread, but the overall phenomenon is weak, and there is no obvious dedolomitization limestone layer. The overall performance is as follows:(1) Calcite completely replaces dolomite to form other shape granular; (2) calcite metasomatizes dolomite to form calcite rhombohedral pseudomorph; (3) Dolomite has speckled or plaque-like calcite; (4) Dolomite is selectively leached and dissolved; (5) Calcite fills dolomite dissolution pores; (6) Visible Dedolomitization of saddle-shaped dolomite. The dedolomitization of the first member of the Sanya Formation occurred in the environment of stagnant dedolomitization fluid and lower formation temperature, and the equal volume metasomatism of calcite to dolomite often occurred, so the effect on porosity and permeability was small.

Early dolomitization and subsequent recrystallization of Middle Ordovician carbonates in the Western flank of the Ordos Basin, Northern China: Implications for hydrocarbon exploration

Zhongtang Su[1*]
1. Institute of sedimentary Geology, Chengdu University of Technology, Chengdu, Sichuan, CHINA
E-mail: suzhongtang2012@cdut.cn

Keywords: early dolomitization,recrystallization, isotopic geochemistry,diagenesis,Ordos Basin

The pervasive dolostone from the Middle Ordovician Zhuozishan Formation in the Ordos Basin (Northern China) are considered as potential hydrocarbon reservoirs. Three types of matrix dolomites (Md) are recognized: 1) very fine to fine crystalline, nonplanar-a to planar-e dolomite (Md1); 2) fine to medium crystalline, nonplanar-a to planar-e dolomite (Md2); and 3) medium crystalline, planar-s to nonplanar-a dolomite (Md3). The initial dolomitization of Md1 and Md2 dolomites is inferred to have taken place in the presence of seepage reflux of slightly evaporated seawater in the near-surface to shallow burial settings, and insignificant recrystallization occurred in the process of being buried again, according to petrography, trace elements, and oxygen-carbon-strontium isotopic geochemistry. Coarser crystals with cloudy cores and clear rims consist of the Md3 dolomites, and the texture shows irregular contacts between planar-s and nonplanar-a crystal. Geochemical analysis reveals that the Md3 dolomites have a negative shift in $\delta^{18}O$ values with increasing Mn contents, and a negative $\delta^{18}O$ trend with depth in the same well, while the $\delta^{13}C$ does not tend to correlate with the oxygen isotopes. Additionally, the $^{87}Sr/^{86}Sr$ ratios of Md3 dolomites are relatively higher due to contribution of radiogenic ^{87}Sr. Petrological attribute and geochemical evidence suggest that the massive Md3 dolomites can be due to significant recrystallization of earlier formed dolomites during burial period. The unevenly distributed pores in Md3 dolomites suggest the heterogeneous structure of the precursor dolomites, which may be the Md2 dolomites. The residual particles of Md2 dolomites indicate the precursor limestones were deposited in a relatively high-energy part of the shoal. Hence, the wide distributed Md3 dolomites show salient facies-controlled characteristics, which suggests strategies for hydrocarbon exploration of potential heterogeneous dolomite reservoir.

Recrystallization of the Ediacaran cap dolomites from south China

Min Ren[1*]
1. Department of Geological Oceanography, Xiamen University, Xiamen, Fujian, CHINA
E-mail: mren@xmu.edu.cn

Keywords: Cap dolomite, Recrystallization, Ediacaran, Stoichiometry, Snowball earth

Using the globally distributed Ediacaran cap dolomites to understand the post-snowball earth after the Marinoan glaciation is hindered by potential alterations of the original environmental signals preserved in the rocks. The Ediacaran Doushantuo cap dolomites deposited on an open shelf in south China were studied and compared with the Cenozoic marine dolomites. The Doushantuo cap dolomites are (1) composed soley of LCD (low-calcium dolomite, %Ca < 55%); (2) near-stoichiometric (average %Ca = 50.8%); (3) characterized by high cation ordering (average cation ordering = 0.83); (4) featured by blocky nanotopography on the etched crystal surface which is typical for LCD; (5) dominated by nonplanar and planar-s fabrics; and (6) consisted of matrix dolomite crystal ~5–80 μm and void-filling crystals ~20–1000 μm in diameter. The above features differentiate the Doushantuo cap dolomites from many Cenozoic seawater dolomites such as the Miocene dolomites on the Cayman Islands, which are fabric-retentive with dolomites characterized by higher average %Ca and lower cation ordering, and comprise LCD and HCD (high calcium dolomite, %Ca >55%). Recrystallization that transformed the Doushantuo cap dolomites from metastable calcian dolomite to more ideal dolomite is pervasive and facies independent, during which the original geochemical signatures in the dolomites could have potentially been modified .

Evolution of Microbial Carbonate Platform in NW Tarim Block during the Late Ediacaran

yuanzheng Wang[1], Daizhao Chen[1*], Pan Tang[1]

1. Division of Cenozoic Geology and Environment, INSTITUTE OF GEOLOGY AND GEOPHYSICS, CHINESE ACADEMY OF SCIENCES, Beijing, CHINA

E-mail: dzh-chen@mail.iggcas.ac.cn

Keywords: Microbial carbonates, facies, sequence stratigraphy,platform evolution.

Microbial carbonates are widespread in the Ediacaran Qigebrak Formation in the north-west (NW) Tarim Block. Their potential for oil-gas reservation has been revealed by recent exploration. However, this potential was hindered by the controversial depositional evolution of the Qigebrak Formation. Here, we carried detailed studies on depositional facies and sequence stratigraphy on the microbial carbonates in the Qigebrak Formation. 18 types of facies, 8 types of depositional environments, and 3.5 T-R sequences were recognized. We identified the platform-margin stromatolite reefs in the Qigebrak Formation, and suggested two categories of carbonate platforms developed in this period, including the ramp in early stage and the rimmed shelf in the late stage. Evolution of the carbonate platform was controlled by the tectonic activities, which were possibly related to the Pan-African Orogeny.

Difference of hydrothermal reformation mechanism between matrix limestone and dolomite: a case study of Middle Permian and Upper Sinian in central Sichuan

As an important reservoir forming mechanism of carbonate reservoirs, hydrothermal alteration is a focus in the field of reservoir geology. Since the 1980s, petrological and geochemical evidences of hydrothermal alteration have been found in carbonate reservoirs of many petroliferous superimposed basins such as Western Canada Basin, Michigan Basin, Sichuan Basin and Tarim Basin in North America and West China. However, most studies only focus on the alteration results of matrix limestone by hydrothermal fluid, and propose specific alteration modes such as hydrothermal dolomitization, dissolution, recrystallization and filling. In recent years, some scholars have realized that there is a evidence system similar to matrix limestone in matrix dolomite, and proposed constructive alteration modes such as dissolution, recrystallization and hydraulic fracturing. However, in matrix limestone and matrix dolomite, hydrothermal alteration has formed different rock fabric types, with different geochemical enrichment and different alteration modes. Therefore, it is necessary to analyze the factors leading to the significant difference of hydrothermal alteration in different matric rocks. There are abundant hydrothermal fluid activities in Upper Sinian dolostone and Middle Permian limestone in Central Sichuan Basin, which provide excellent research objects for analyzing the genesis, stages, alteration modes and reservoir formation effect of hydrothermal fluid in different host rocks under the same geological background.

Based on core observation, thin section identification, cathodoluminescence, fluid inclusions, C, O, Sr isotopes and REE analysis, combined with geophysical data, the differences of hydrothermal alteration in matrix limestones and matrix dolomites are discussed in terms of rock fabric, geochemical characteristics, alteration mode and action sequence. Three types of hydrothermal rock fabrics are developed in the Middle Permian matrix limestones in the Central Sichuan basin, namely fine-meso-crystal hemihedral dolomite (RD2), saddle dolomite (SD) and other hydrothermal minerals (quartz and fluorite). Fine-mesocrystalline hemihedral dolomite (RD2) is the recrystallization product of low-temperature origin dolomite (RD1), resulting in slight loss of $\delta^{18}O$, significant enrichment of Mn-Fe and 87Sr/86Sr, positive Eu anomaly, forming temperature 133 °C on average. Fluorite, quartz, and sellar dolomite (SD) are directly crystallized from hydrothermal solution. The average temperature decreased gradually (146 °C, 132 °C, 126 °C, respectively), and the alteration sequence showed hydrothermal dissolution, quartz-fluorite filling, hydrothermal dolomitization and recrystallization, saddle dolomite filling. The same three types of hydrothermal rock fabrics are formed in the upper Sinian matrix dolomite. The fine- to medium- crystalline dolomite (FD) is the product of hydrothermal recrystallization of matrix micritic dolomite, resulting in slight negative anomaly of $\delta^{18}O$, significant enrichment of Mn-Fe and $^{87}Sr/^{86}Sr$, and positive Eu anomaly. The modified sequence is characterized by saddle dolomite and quartz filling-hydrothermal recrystallization. Deep basement faults and small fracture triggered by Xingkai and Emei movement comprise hydrothermal fluid migration conducting system, and the Middle Permian only affected by the second phase of taphrogenic activities. This study suggests that chemical composition and hydrothermal temperature of matrix rock are main factors controlling the difference of fabric and alteration sequence.

Decoding dolomites with curved crystal faces

Yifan Zhang[1], Mathias Mueller[1], Sumit Chakraborty[1], Christopher Beyer[1], Niels Jöns[1], René Hoffmann[1], Adrian Immenhauser[1,2*]

1. Faculty of Geosciences, ruhr-universität bochum, Bochum, Nordrhein-Westfalen, GERMANY
2. IEG, Fraunhofer Institution for Energy Infrastructures and Geothermal Systems, Bochum, Nordrhein-Westfalen , GERMANY
E-mail: Adrian.Immenhauser@rub.de

Keywords: dolomite, saddle dolomite, curved crystal, zonation

Dolomite, $CaMg(CO_3)_2$, is a common rock-forming mineral. It can form as a primary precipitate, a diagenetic replacement of aragonite, calcite, an earlier dolomite phase, or a direct pore-filling hydrothermal phase in a wide range of sedimentological, diagenetic, hydrothermal and metamorphic environments. Among the many subtypes of dolomite, one of the most spectacular forms is the saddle-shaped dolomite (saddle dolomite, baroque dolomite etc.). Saddle dolomites are characterized by curved (warped) crystal faces, curved cleavage, and sweeping extinction under cross-polarized light. It is commonly assumed that saddle dolomites indicate precipitation in deeper burial diagenetic environments and related elevated fluid temperatures of at least several tens of degrees Celsius. To the present day, however, the mechanistic origin of the warped crystal surfaces is still under debate, and the link between this unusual morphological feature and environmental conditions (fluid chemistry, temperature, etc.) is unclear. We selected four natural saddle dolomites (F9, L1.2, VS10_1, VS 10_6) from the Triassic Latemar buildup in the Dolomite Mountains of northern Italy with different curvature levels as test materials for the present study. Firstly, the surface curvature of the saddle dolomite crystals in each sample was quantitatively determined and statistically analyzed depending on the high-resolution scanning images of corresponding thin sections. The results reveal that the curvature level of four samples can be ordered as F9 ≈ L1.2 VS10_1 VS 10_6. EPMA analyses show that the four saddle dolomites are composed of $CaCO_3$, $MgCO_3$ and $FeCO_3$, with minor $MnCO_3$. $CaCO_3$ is the main component, ranging from 49.8 to 55.2 mol%, and $MgCO_3$ ranges from 42.7 to 50.4 mol%. The composition of the least curved sample, F9, is closest to the ideal stoichiometry of dolomite (Ca:Mg = 1:1). As the curvature increases, calcium in saddle dolomite becomes increasingly excessive in VS10_1 and VS 10_6. Surprisingly, L1.2 is the sample with the highest Ca-excess, attributed to secondary processes. Interestingly, the $FeCO_3$ content is positively correlated with the curvature level of saddle dolomites, i.e., the average Fe content is 0.38, 0.35, 0.79 and 0.91 mol% in F9, L1.2, VS10_1 and VS 10_6, respectively. In addition, element distribution maps show that Ca is nearly homogeneously distributed in all four samples, while Mg distribution maps displays small-scale changes, indicating a slight zonation. By contrast, the distribution of Fe shows strong zonation in saddle dolomites, especially in VS10_1 and VS 10_6. Zonation generally results from several pulses of dolomitizing fluid. We speculate that the dolomitizing fluid and environmental conditions associated with Fe enrichment are key to the formation of saddle dolomite. Alternatively, iron in the structure may be directly related to saddle dolomite's warped morphology. In addition to the data discussed here, we are presently performing dolomite precipitation experiments, aiming to reproduce dolomites with curved crystal surfaces.

Diagenetic alteration of early-formed dolostones by fault-controlled hydrothermal convection of entrapped seawater: the middle Permian Qixia Formation in central Sichuan Basin, SW China

Liyin Pan[1*]

1. Department of Marine Petroleum Geology, PetroChina Hangzhou Research Institute of Geology, Hangzhou, Zhejiang, CHINA
E-mail: plyin@126.com

Keywords: hydrothermal dolomitization, carbonate U-Pb geochronology, Emeishan Large Igneous Province, middle Permian, Sichuan Basin

This paper integrates petrography, carbon-, oxygen- and strontium-isotope geochemistry, and in-situ U-Pb geochronology on the middle Permian Qixia Formation dolostones in central Sichuan Basin, SW China, in order to get further insights into the conditions of their origin and diagenetic evolution. The Qixia formation dolostones in the study area, typically thin-bedded and alternating with limestones, consist of three dolomite phases, a replacive phase (Rd) and two void-filling phases, i.e., vug-filling coarse crystalline euhedral dolomites (Dc) and vug/fracture- filling saddle dolomites (SD). These dolomite phases show comparable carbon-, oxygen- and strontium- isotope compositions that could be easily interpreted to indicate similar diagenetic conditions, probably during a continuous dolomitization event. However, the obviously different U-Pb ages of these dolomite phases suggest that they were more likely precipitated in different episodes. The U-Pb ages of Rd and Dc, ~284 Ma to 272 Ma, roughly coinciding with the depositional age of Qixia Formation (284-273 Ma), imply a syn-depositional origin of these two phases, which, together with the stratabound occurrence of Rd and vug-filling Dc, and their affinity of carbon and strontium isotope compositions to those of the middle Permian seawater, suggest an reflux dolomitization event by penecontemporaneous seawater. In contrast, the saddle dolomite cements (SD) yield U-Pb ages ~10 Myrs younger than the Rd and Dc, which, in combination with the occurrence of SD in both dolostone and limestone intervals, indicate an alteration event of the early-formed replacive dolostones (Rd), probably by hydrothermal fluid flow. Furthermore, the precipitating timing of the vug/fracture-filling saddle dolomite cements is fairly close to the rifting phase associated with the Emeishan Large Igneous Province (ELIP) during the terminal middle Permian, which leads us to link the origin of these saddle dolomites to the influx of hot fluids along rift-related faults. Finally, a fault-controlled, hydrothermal alteration model of penecontemporaneous dolostones by ELIP-induced thermal convection of entrapped marine connate waters was proposed to elucidate the formation and evolution of these dolomites.

Keywords: primary dolomite, bead, arrow or blunt-toothed pierced structure, liquefaction, 2nd-member of Dengying formation,Northern Sichuan

The soft sediments deformation caused by gravity imbalance, slide, slump, liquefaction and earthquake has always been one of the focuses geo-hazards in sedimentary geology. The definitive criteria for identifying the triggers of its deposits are still under construction. This paper reports a new discovery of a special kind of dolomite vein in the Upper Sinian Dengying Formation in northern Sichuan. This "bead-, arrow- or blunt-tooth-shaped" rhombic micrite dolomite vein, pierces into microbial dolomite with development of the radial-ring inner with grape and belts-likely outer structure, accompanied by the phenomena of convolution, pinch and swell, micro-folds and upward branching shear fractures, breccia, pseudo-nodules and water escape and sediment-injection structures in situ. It's laterally continuous and vertically repeated, separated from un-deformed or without extreme features layers. This dolomite vein, characterized by the relative high value of $\delta^{13}C$ or the turning period from rise to fall of sea-level, were identified as liquefaction and fluidization related to be seismic shocks in the weak extensional tectonic environment. The Neoproterozoic aragonite-dolomite seas with a viscous soft sediment at bottom, high Mg / Ca ratio and pH value promote the growth of microbial mats and formation of proto-dolomite. There are at least two to four episodes of seismic shocks in an approximate 5.5 Ma for the deposition period of 2nd-member of Dengying formation. Moderate to weak earthquakes, successively induce the liquefaction flow, heating of pore fluid and cooling of pore fluid during upward piercing which further result in the direct precipitation of primary dolomite due to the supersaturation. This study provided a new novel explanation to the origin of Neoproterozoic primary dolomite.

Sedimentology and petrography of the limestones from a Neoarchaean dolomite-dominated platform: clues for understanding dolomitization in the Transvaal Supergroup, South Africa

Mmasetena Anna Molekwa[1], Zubair Jinnah[1*], Robert Bolhar[1]
1. School of geosciences, University of the Witwatersrand , Johannesburg, Gauteng, SOUTH AFRICA
E-mail: zubair.jinnah@wits.ac.za

Keywords: Limestone, dolomitization, carbonates, carbonate diagenesis, Lime Acres Member, Transvaal Supergroup

The Neoarchaean Lime Acres Member of the Campbell Group in the Griqualand West sub-basin, Transvaal Supergroup, represents one of the oldest, well-preserved carbonate platform successions in the stratigraphic record. The Lime Acres Member is the most limestone-rich unit in a dolomite-dominated carbonate succession and holds important clues as to when and how dolomitization occurred. Previous studies have not indicated whether the unit has been dolomitized or never underwent dolomitization. The Lime Acres Member strata consist of various carbonate lithofacies (mostly well-preserved stromatolitic limestones) interbedded with carbonaceous shale and chert. The carbonate lithofacies include stratiform, domal and columnar stromatolite limestones, massive micritic, laminated and fenestral limestones and, intraclast limestone breccia. Detailed study of the morphology and microstructures of these carbonate lithofacies and their relationship with surrounding sedimentary rocks are employed to reconstruct the depositional environments and deduce the diagenetic history of the Lime Acres Member carbonates.

Sedimentological and petrographic examination revealed a cyclic sedimentation shallowing-upward pattern, which reflects variations of the sea level during the deposition. The Lime Acres Member was likely deposited in a transgressive shallow marine environment. The presence of wavy and flaser lamination provides evidence for bi-directional currents. Pore-filling, vein-fills, fenestrae and stylolites provide evidence for early diagenetic processes. Organic matter locally occurs along the cortices of allochems and laminations.

Despite being a limestone-rich unit, dolomite is present but rare. SEM-EDS analysis using a Tescan-integrated-mineral-analyser (TIMA) documents that dolomite is restricted to stratiform and cross-cutting veins. The frequent occurrence of angular clast of the host rock (limestone) within the dolomite veins indicates that the veins were generated by hydraulic fracturing. Elemental and mineral phase maps show that most limestone layers consist of> 95% calcite, implying that the Lime Acres Member is devoid of significant dolomitisation.

Contribution of the allogenic sediments to the source-to-sink system in the sequence of rifting, insight from the case study in Qiongdongnan Basin

Chao FU[1,2], Shengli Li[2*], Shunli Li[2]
1. CNOOC Beijing institute, China National Offshore Oil Corporation, Beijing, CHINA
2. China University of Geosciences, Beijing, Energy School, Beijing, CHINA
E-mail: slli@cugb.edu.cn

Keywords: Breakup sequence, Source-to-sink system, Rfting stages,Detrital zircon U-Pb,

Continental margin rifting basins underwent a crust lithofacies breakup period and formed a distinct source-to-sink system. Mass sediments deposited in the proximal margin area have been accepted in many case studies worldwide. Unlike traditional continental margin rifting basins, the mass of allogenic sediments is migrated in the drainage basin in the North continental margin in the South China Sea (SCS) and rebuilt its stacking pattern. To clarify the allogenic sediments' contribution, we selected the Qiongdongnan Basin (QDNB) in the north margin of SCS to explore the various growth patterns during the breakup sequence. According to the 3D seismic profiles interpretation and core samples description, we recognized the sediments' stack pattern. Then, with the U-Pb age data and the heavy mineral assemblage, we identified allogenic sediments' provenance and recovered the source-to-sink system in QDNB. The results show that, during the Eocene to the early Oligocene, autogenic sediments are dominated at the sync-rifting stage, while during the transitional stage, allogenic from central Vietnam migrated to the eastern of the drainage basin and then to the post rifting stage during Miocene, it wholly mixed with the autogenic sediments from the proximal area. According to the calculated subsidence rate and their topography variety, we rebuilt the source-to-sink system accompanying the rifting process and divided them into three types: narrow-deep, wide-shallow, and wide-deep. The steep slope in the western W-QDNB, its prograding deltas are observed as more coarse-grained accumulated in the upper slope and the proximal outer continental margin area. The eastern W-QDNB mainly developed fine-grained sediments along the gentle slope. Combining the sedimentary process numerical simulation results, we get that the allogenic sediment injection makes the high-angle graben pattern make more sediments migrate from the proximal outer continental margin area to a distal area. With the statistical method, we highlight the vital role of local forcing factors in controlling the sediment distribution during the rifting stage. During the sync-rifting and transitional stages, we found that the terrane height in high-angle slope areas controlled by the accommodation space provided by the fault's displacements or the terrain height, and the allogenic sediments' injection would decline the terrane height's controlling factor to the source-to-sink system volume. As to the post-rifting stage, sediments supply shows high relevancy to the depositional volume, and accommodation space is the less one, while the injection of the allogenic sediments enhances the controlling factors of sediments supply.

Stabilization and destabilization of downstream alluvial channels in a non-deltaic transgressive system: A tank experiment

Tetsuji Muto[1*]

1. Department of Environmental Science, Nagasaki University, Nagasaki, JAPAN

E-mail: tmuto@nagasaki-u.ac.jp

Keywords: alluvial channel, autostratigraphy, length scale, non-deltaic, sea level rise, transgression

The autostratigraphy theory tells that the downstream alluvial plain with an area (A) exceedig a critical value (A_{crt}) can no longer maintain deltaic sedimentation during relative sea level rise, but is forced to retreat as a non-deltaic transgressive system where the A reduces asymptotically toward A_{crt}. The morphodynamics of alluvial channels evolving in such a system are investigated through a series of tank experiments, bringing the following notions. At early times of the transgression ($A >> A_{crt}$), the alluvial channels tend to be stabilized, but their mouth lobes tend to backstep in a linear trend. As the alluvial plain continues to contract ($A \rightarrow A_{crt}$), the channels' lateral mobility synchronously increases along with intensified lateral shifting of the mouth lobes, in correspondence with continuous increase in aggradation rate. Eventually the alluvial plain area reaches the critical value ($A \sim A_{crt}$). Given a hinterland slope being smaller than an imaginary foreset slope that locally the system might prograde with, the alluvial plain area no longer reduces, while the non-deltaic transgression is retained. During this particular A_{crt} stage, the alluvial channels are fully destabilized with incessant lateral migration and/or frequent avulsion to build autosteps. These experimental observations support the validity and significance of autostratigraphic scales of length (Λ_{3D}) and area ($\Lambda_{3D}^2 = A_{crt}$) as a fundamental control on the spatial growth of deltaic and non-deltaic systems under relative sea level rise. Stabilization and subsequent destabilization of alluvial channels recognized in a stratigraphic succession can thus be autogenic in some part, particularly when the alluvial plain progressively contracted toward A_{crt}. With an anticipated rate of anthropogenic sea level rise for next centuries, most of the existing alluvial-deltaic systems on marine coasts will have been in a state of over-expansion ($A >> A_{crt}$). These systems will inevitably become non-deltaic transgressive systems evolving in a way from a channel-stabilized stage to a channel-destabilized one.

Sedimentary model and controlling factors of Yuanzigou alluvial fan in Daihai Lake, Inner Mongolia

Feng Shuo[1], li shun li[1*]
1. School of Energy , China University of Geosciences (Beijing) , Beijing, CHINA
E-mail: lishunli@cugb.edu.cn

Keywords: Alluvial fan ,Formation process, Fluid type, Influencing factors ,Sedimentary model

Alluvial fan depositional systems are widely developed across the country, especially in the margins and interiors of major continental hydrocarbon-bearing sedimentary basins in my country. They are characterized by large scale, diverse systems, and well-configured source-reservoir-caprocks, and contain huge exploration potential. Therefore, in this study, the 300-m alluvial fan section exposed in Yuanzigou, Daihai Lake, Inner Mongolia, was used as an example to describe the field outcrop section and the exploration trench. According to the grain size and arrangement of the site, 7 lithofacies and 6 vertical assemblages are divided; the fluid types deposited in the Yuanzigou alluvial fan are divided into three types - clastic flow, torrent, and tractive flow. The main control fluid types of the stages are different, and the sedimentary evolution process is divided into three stages, which have a good corresponding relationship with the changes of the Daihai Lake climate. At the same time, AMS14C dating was used to identify the sedimentary interface, and the denudation of sediments and the difference in provenance supply caused by changes in slope, precipitation and temperature were analyzed. The sedimentary modes are: slope-driven detrital flow type, precipitation-slope co-driven torrent type, high temperature and high precipitation-driven tractive flow type

3. Department of Geological Sciences and Geological Engineering, Queen's University, Kingston, Ontario, CANADA
4. State Key Laboratory of Estuarine and Coastal Research, East China Normal University, Shanghai, CHINA

E-mail: xshan@fio.org.cn

Keywords: Changjiang coastal mud wedge, Min-Zhe Mud Belt, coastal mud, shallow-marine mud, Taiwan Strait, East China Sea

The coastal mud wedge is one of the most important settings where shallow-marine muddy deposits accumulate. However, until recently, there are very few detailed sedimentological studies on it. To investigate the sedimentary processes of one of the largest coastal mud wedges, the Changjiang Coastal Mud Wedge (CCMW), we used chirp shallow seismic stratigraphy and carbon dating of a sediment core from the northern end of Taiwan Strait to provide a regional stratigraphic framework. Sedimentological observations and organic geochemical analysis of the sediment core, combined with detailed comparison with the eustatic sea-level curve, permit estimation of the changing paleowater depths and sedimentary processes responsible for the coastal mud wedge. The clay mineralogy and U–Pb detrital zircon geochronology were analyzed to illustrate the provenance evolution.

Three regional unconformities were identified that probably correspond to the last three glacial maxima, MIS 2, MIS 6 and MIS 8. The MIS 6 and MIS 8 unconformities display pronounced incised valleys that were likely carved by the Minjiang River. The strata between the MIS 2 and MIS 6 unconformities (seismic unit 2) have 14C ages that indicate that the valley filling occurred during the long-term sea-level fall of MIS 3. The lower part of this valley fill is composed of bay-head delta plain to delta-front deposits, from base up. A provenance study of the lower fill reveals the predominance of the Minjiang sediments, with some Changjiang sediments, which confirms a deposit that accumulated in the Minjiang estuary, with some southward transport of Changjiang mud by the Zhe-Min Coastal Current. The middle valley fill contains shallow-marine mud that comprises significant amounts of Changjiang sediments. While the shoreline lay seaward of the core site (i.e., during initial filling of the valley), the main sediment supply was by the Minjiang, but after the shoreline moved landward of the core location (middle valley fill), the Minjiang contribution decreased (presumably because it was trapped in the contemporaneous estuary), and the contribution from the distant Changjiang became important/dominant. During the transgression of the shoreline, the Minjiang estuary was inundated and became a partially filled incised valley. The clay mineralogy of the upper valley fill (coastal mud) reveals the predominance of the Changjiang sediment, which suggests that the remainder of the valley was filled by the CCMW. This is also for the first time that the existence of the CCMW during MIS 3 is reported.

Integrated water-depth estimates, provenance and core observations reveal the presence of distinct shallow-water and deep-water facies within the CCMW. The shallow-water (<20 m water depth) facies contains fluid-mud layers, highlighting the role of waves and tides in resuspending previously deposited muds. The deep-water facies consist of muds that were influenced by ocean currents and are more intensely bioturbated and local rich in shells. The succession here is dominated by muddy deposits that initially look "simple", but upon closer examination have a very complex sediment provenance, and with many unconformities, due to sea-level fluctuations during MIS 3, in what might initially look like a continuous sedimentary succession.

Shoreline autoretreat in salt-bearing basins: Insights from numerical modelling

Wei Li[1,2], Junhui Wang[1,2*], Zhiyuan Ge[1,2]

1. State Key Laboratory of Petroleum Resources and Prospecting, China University of Petroleum (Beijing), Beijing, CHINA
2. College of Geosciences, China University of Petroleum (Beijing), Beijing, CHINA

E-mail: wangjunhui@cup.edu.cn

Keywords: shoreline autoretreat, salt tectonic, sea-level, numerical modelling, sedimentology

Shoreline autoretreat is an autogenic nonequilibrium response of deltaic systems to constant sea-level rise. The theory of this phenomenon has largely guided our understanding of the evolution of deltaic clinoforms. Until now, the shoreline autoretreat is only modelled in tectonic-quiescent settings where the basin has constant slopes. Here we extend the model to salt-bearing basins to investigate how the moving of underlying salt exerted by overlying sediment affects this process. We use finite element modelling to investigate three sediment filling and sea-level rise scenarios. In these 3 models, the sedimentary wedges have the same depositional slopes including the hinterland slope, the topset surface slope and the foreset slope. In Model 1, both rates of sediment supply and relative sea-level rise were constant. Model 2 had the same sea-level rate as Model 1 with a higher sediment supply. In Model 3, we forced an increasing rate of sea-level rise and the sediment supply kept up with the rise. In all of these models, the gravity force exerted by the overlying sediment drives the depositional wedge to extend seaward. The topset of these models inevitably modified the process of shoreline autoretreat compared to cases without the viscous salt. In Model 1, the shoreline cyclically changed its phase from progression to regression, indicating a periodic autoretreat. In Model 2, as the sediment supply increased, the length of the topset strata also increased and the shoreline continuously moved seaward without retreat. In Model 3, the sea-level rose with increasing sediment supply, which resulted in the chaotic lateral seaward movement of the shoreline and no obvious autoretreat processes occurred. Our study suggests that shoreline autoretreat is ineffective in salt-bearing basins due to the viscous salt layer which accelerates the progradation of sediments, elongates the delta topset, and slows down the height of relative sea-level rise.

Influence of laumonite cements in Shaximiao Formation of Middle Jurassic on reservoir development in central Sichuan Basin

Anqi Wang[1], Zuowei Hu[1*]
1. , , , , CHINA
E-mail: huzuowei@foxmail.com

Keywords: Laumonite, Shaximiao Formation, Central Sichuan Basin, Pore type, Reservoir development

Authors: Anqi Wang, Zuowei Hu, Yun Li, Lin Zheng

Laumonite cement is a typical authigenic mineral in sandstone reservoirs, but its influence on sandstone reservoirs remains controversial. Shaximiao Formation of Middle Jurassic in Central Sichuan Basin is one of the hot strata for tight oil and gas exploration and development in China (Yang Yueming et al., 2016), and the secondary dissolved pores of laumontite have been considered to be the most important reservoir space type (Lu Wenzhong et al., 2004; Yang Xiaoping et al., 2005). In this paper, the middle Jurassic Shaximiao Formation in central Sichuan Basin is taken as the research area, and the research is carried out systematically from four aspects : reservoir pore types, occurrence state of laumontite, formation time of laumontite, and relationship between laumontite and reservoir evolution. The results show that the pore types are mainly primary intergranular pores, and few secondary dissolved pores in laumontite. Laumontite cements often exist in sandstone reservoirs in two forms: one is filled in intergranular pores in the form of continuous crystals, and the other is star-like or spot-like when the content of laumontite is relatively low, which exists in the form of metasomatic plagioclase and is often distributed along the cleavage fracture or bicrystal grain of plagioclase. Laumontite is often developed outside the secondary enlargement edge of quartz, and chlorite film is developed outside the quartz particles. It is judged that the formation time of laumontite is later than that of authigenic quartz and authigenic chlorite. Laumontite has no direct relationship with early-stage crystalline calcite, but associated with late-stage crystalline calcite. The content of laumontite has a negative correlation with the porosity. The higher the content of laumontite is, the lower the porosity is, indicating that laumontite hinders the development of pores to a certain extent and has a certain destructive effect on reservoir porosity. The whole Shaximiao Formation is buried shallowly (about 2600 meters). It is estimated that the formation temperature of laumontite should be higher than 80 °C. The laumontite may be the product of A-B stage in the middle diagenetic stage. Under the microscope, plagioclase dissolution and metasomatism are found, and a large amount of Ca^{2+}, Na^{+}, K^{+} can be precipitated. The plagioclase dissolution and metasomatism residual is mainly albite. Due to the special molecular structure of zeolite, ions with positive charge (such as Na^{+}, Ca^{2+} and other alkali metals or alkaline earth metal ions) are needed to neutralize in the formation process. The middle diagenetic stage A is alkaline pore water environment, and abundant plagioclase in stratum is more favorable for the formation of laumontite, so it is speculated that the formation of laumontite is mainly caused by albitization of plagioclase. The diagenesis intensity of Shaximiao Formation sandstone is weak, so the primary intergranular pore is the main pore type in the reservoir, not the secondary dissolved pore of laumontite. To sum up, the emergence of zeolite in a certain extent will bring destructive effects on reservoir development.

Characteristics and Main Controlling Factors of the Paleogene Sedimentary Sequence in Maxian District, Qaidam Basin

Fan Yan[1], Xiang Cai Fu[1*]
1. College of Geosciences, China University of Petroleum, Beijing, CHINA
E-mail: xcf@cup.edu.cn

Keywords: sedimentary sequence,tectonic subsidence,the Paleogene,Maxian district,Qaidam Basin

The Maxian district is located in front of the Qilian Mountains thrust belt in the northern margin of the Qaidam Basin. Through core description, logging and seismic data, we identified the sequence interface of the Paleogene in the Maxian district, and definituded the sedimentary filling pattern by combining with seismic facies. The results showed that two first-order, one second-order and one third-order sequence interface were developed in the Paleogene of the Maxian district, and alluvial fan braided river delta sedimentary system was formed. Controlled by the Xiannan fault and the Mabei fault, barrier island was generated in the Paleogene of the Maxian district. Under the tectonic framework, the sedimentary filling pattern of a strike-slip pull-apart basin was developed, with the characteristics of north-south zoning and east-west block. Factors controlling the sedimentary sequence of the Paleogene in the Maxian district include tectonic subsidence, supply of sediments and lake level fluctuation. Firstly, in evolution of the sequence of the Paleogene, the Indian plate subducted and collided with the Eurasian plates. Meanwhile, the Qilian Mountains, situated in the northeast of the Maxian district, uplifted rapidly at a rate of 60m/Ma to 100m/Ma. The uplift of the Qilian Mountains provided clastic matter for the Maxian district situated in the expot of provenance system named Yuqia. In addition, the uplift of the Qilian Mountains contributed to quick subsidence of the piedmont depression belt. The subsidence rate surpassed 300m/Ma in the late Paleogene, which was more than twice of the early Paleogene. Because the subsidence rate of the basin exceeded the falling rate of lake level, the lake level rised continuously. The rasing lake level and provenance system collectively worked together to control the formation of progressive and regressive sequence of the basin. Finally, as a result of oblique strike-slip pull-apart accompanying the uplift of the Qilian Mountains, main boundary faults in the Maxian district were generated. These boundary faults together with Xiannan fault in south and Xianbei fault in north of the Maxian district constituted tectonic framework of barrier island, and controlled the sedimentary filling pattern.

Anatomy of a third-order transgressive–regressive sequence along the western coast of the late Pennsylvanian North China epeiric sea: Linking hydrodynamics to architectural development

Jincheng Liu[1*], Jingqiang Tan[1]
1. School of Geosciences and Info-physics, Central South University, Changsha, Hunan, CHINA
E-mail: liujincheng@csu.edu.cn

Keywords: Third-order transgressive–regressive sequence, architectural development, late Pennsylvanian, epeiric sea, shoreline morpho-hydrodynamic evolution

The Ximing Sandstone–to–No. 8 Coal succession of the Taiyuan Formation in the Linxing gas field records complex internal architecture of a transgressive–regressive sequence (i.e. T–R Sequence S8) developed along the western coast of North China epeiric sea during the late Pennsylvanian nonglacial period of the Late Paleozoic Ice Age (Liu et al., 2020). Based on facies analysis, sequence stratigraphic analysis, and hierarchical architectural classification (Vakarelov & Ainsworth, 2013) of seismic, outcrop, core, and well log data, T–R Sequence S8 was first subdivided into transgressive and regressive element complex assemblage sets (TECAS8, RECAS8) by a maximum flooding surface (MFS8) that is embedded within a carbonate- and/or shale-rich condensed section and up-dip within a coal seam, and is locally truncated and replaced by a regressive surface of marine erosion (RSME6). Within the framework of TECAS8, RECAS8 and their bounding surfaces, fourteen types of element complexes (EC) associated with hydrodynamic process dominance (Ainsworth et al., 2011; Rossi et al., 2017) were differentiated on individual cored and/or wireline-logged wells, which quantitatively or qualitatively characterizes the relative influences of wave, tide and fluvial processes on the development of channel, onshore, mouth bar, tidal flat, funnel basin, transgressive lagoon, transgressive lag, barrier, offshore transition, beach, and lagoon element complexes. These element complexes were grouped into five distinct element complex sets (ECS) and four element complex assemblages (ECA) on interwell-scale or field-wide, core and well log-based cross-sections, reflecting a progressive change from a tide-dominated, wave-influenced and fluvial-affected (Twf) incised-valley estuary–barrier system (ECA-A) through a Twf-transgressive coastal plain–lagoon–barrier system (ECA-B) to a wave-dominated, tide-influenced and fluvial-affected (Wtf) transgressive coastal plain–tidal shoreface–inner shelf system (ECA-C), and finally to a Wtf-regressive coastal plain–lagoon–beach system (ECA-D). The high-amplitude third-order sea-level change coupled with the high-gradient coastal profile (i.e. coastal gradient > gradient of shoreline trajectory; Catuneanu & Zecchin, 2016) is the dominant control on the stratal stacking patterns. The channel migration, peat compaction, shoreline auto-advance (Guerit et al., 2021) and auto-retreat, and bedrock inheritance modified the depositional response to third-order relative sea-level change through time. This study contributes to a better understanding and prediction of near-provenance epeiric shoreline morpho-hydrodynamic evolution in response to third-order relative sea-level change (Yoshida et al., 2007).

Analysis of Sedimentary Microfacies of the thick sandstone on the Oligocene Huagang Formation in the Central Part of the Xihu SagEast Sea BasinChina

yixiu zhu[1*], zezhou li[1], rongkun xiong[1], zhenyu liu[1]
1. College of Geoscience, China University of Petroleum (Beijing),, Beijing , CHINA
E-mail: zhuyixiu@cup.edu.cn

Keywords: braided delta, sedimentary microfacies, the upper of Huagang Formation, huge thick sand bodies, Xihu Sag, East China Sea basin

The upper member of Huagang Formation in the Central Reversal belt's central aera of the Xihu sag in the East China Sea basin developed thick clastic sand bodies, the theory that it formed in rivers, foreshores, deltas, river-delta superposition, etc. is constantly updated, there still exists great dispute over its sedimentary microfacies and origin. The research comprehensively used the cores and logging data of the three wells in the study area, as well as a series of laboratory analysis, and with the three-dimensional seismic profiles formed by the three wells, studied the core facies markers and logging facies characteristics of the upper Huagang Formation, especially the 3rd member of the Huagang Formation in the three wells. The core facies, single-well facies and profile facies of three wells are established, at the same time, the research results of regional sedimentary evolution and sedimentary environment characteristics are combined to analyze the microfacies types, sedimentary environment and facies distribution of the sandstone in the upper member of the Huagang Formation in the study area. The results show that the upper member of the Huagang Formation in the study area mainly develops the braided river delta-front subfacies, the 3rd member of Huagang Formation mainly develops the braided river delta-front underwater distributary channels microfacies, while the 2nd and 1st member of Huagang Formation develop the braided river delta front underwater distributary channels and interdistributary microfacies, and their interdistributary microfacies relatively more developed. It's not developmental of facies markers indicating marine facies and transgression in the upper member of the Huagang Formation. Vertically, multi-stage underwater distributary channel sand bodies superimpose and featuring large thickness, the lower part of the upper member of the Huagang Formation has more developed sand bodies and appears "sand-covered mud", while the upper sand layer is relatively thin, showing "mud-covered sand", sandstone has great horizontal extension. Laterally, the underwater distributary channels are characterized by tree-like bifurcation and continuous distribution from northeast to southwest, with its provenance in the northeast. It is believed that a lacustrine-delta sedimentary system of continental setting exists in the study area and is typical traction current deposits without any transgression sequence, but there are thin interlayers of sandy debris flow locally, and the whole is caused by the deposition of high-energy flowing water.

Sedimentary filling evolution controlled by basin-mountain coupling: A case study of the Xujiahe Formation in the Northeast Sichuan Basin

Shuai Hou[1*]
1. School of Geosciences, China University of Petroleum, Qingdao, Shandong, CHINA
E-mail: 2498152208@qq.com

Keywords: Braided delta, provenance direction, sedimentary microfacies, basin-mountain coupling, Xujiahe Formation

It is of great significance to clarify provenance direction for sedimentary filling evolution in the study area. The lithology and rock composition of the Xujiahe Formation in the northeast sichuan basin differ significantly in different depositional periods. The provenance of the xujiahe Formation in different depositional periods is determined by heavy mineral analysis, stratigraphic thickness variation and rock mineral genesis analysis. Braided delta deposits are mainly developed in the study area , the sedimentary facies and lithofacies characteristics of Xujiahe Formation in northeast Sichuan basin are studied based on logging, core, outcrop and geological data. For sedimentary analysis, core and outcrop observation is the most direct and effective method, and the response relationship between logging and lithology can help us predict sedimentary facies. In addition, the introduction of the outcrop improves the forecasting accuracy and continuity, this study analyzes the multiphase superimposed sedimentary sand body and identify which due to factors such as water effect strength formed by various sedimentary structure, sedimentary sequence structure characteristic is the main research area. These results provide evidence for the development of multiphase channel deposits in the study area under the influence of provenance changes and tectonic evolution. A new method of comprehensively analyzing sedimentary filling evolution from outcrop - core - logging data is established. In addition, the intervention of the above methods provides a feasible method combining logging and core for the identification of sedimentary microfacies in Xujiahe Formation, the establishment and restoration of upstream sedimentary model and the verification of basin-mountain coupling mechanism of delta sedimentary facies. The results showed that under the influence of activity surrounding orogenic belts, the source can be divided into three directions, respectively from the Longmen mountains, MiCangShan and Dabashan mountain, but in different sedimentary period, the direction of provenance and significant differences source input, in addition content source input material and can let a space rate of change was the key to analysis of sedimentary evolution. Based on the above analysis results, the sedimentary facies response characteristics and logging curves of the study area are established, and the sedimentary filling processes in different sedimentary periods under the control of tectonism are recovered. The results show that the sedimentary filling evolution is controlled by the coupling of the basin tectonic evolution and the activity of the surrounding orogenic belt, and they interact to form the palaeogeomorphic pattern.

Depositional architecture and process of lacustrine delta-sublacustrine controlled by high-resolution sequence stratigraphic frameworkA case study of the second Member of Dongying formation in the Nanpu sag of the Bohai Bay Basin, eastern China

pengyu Wang[1], benzhong xian[1], rongheng tian[1*]
1. College of Geosciences, China University of Petroleum, Beijing, CHINA
E-mail: tianrh1996@126.com

Keywords: Faulted lacustrine basin, delta, sublacustrine fan, sandy debris, turbidite

The deltas and sublacustrine fans in continental faulted basins are the key targets of oil and gas exploration and have good oil and gas prospects, but their sedimentary patterns and distribution characteristics are complicated, posing challenges to oil and gas exploration and development. In this paper, the delta-sublacustrine fan depositional model and its main controlling factors are studied in combination with 3D seismic data, core data and well logging data of the second member of the Dongying Formation in No.4 structure in the Nanpu sag. Based on high-precision seismic interpretation and single-well logging response feature interpretation, it was identified that the depositional period of the second member of the East was divided into 1 third-order sequence, 3 system tracts, and 9 fourth-order sequences. Consequently, the depositional characteristics and depositional model of a delta-sublacustrine fan of fourth-order sequence are investigated and established based on core observation, seismic reflection and well log response. Results show that during the sedimentary period of the second Member of the Dongying Formation, the tectonic activity was weakened, the paleogeomorphology, lake level fluctuation and paleoclimate became the main controlling factors of the delta-sublacustrine fan sedimentary model.Meanwhile, the paleogeomorphology mainly controlled the provenance direction of the second Member of the Dongying Formation and formed four channels that provided favorable migration channels for the development of the delta.Furthermore, the delta-sublacustrine fan depositional scale and sedimentary model was controlled by lake level fluctuation and climate change. The study also shows that there was a dry-wet climate transition during the depositional period of the second member of the Dongying Formation. Firstly, during the period of the highstand tract system, the climate was dry, the lake level dropped rapidly, the provenance supply was sufficient, and a large number of terrigenous detritus entered the lake basin.In this period, the delta was mainly prograded along the provenance direction, and the distributary channel was dendritic with weak bifurcation ability. While the sublacustrine fan has higher sand content and stronger erosion energy, and the sedimentary type is mainly channel-fill sandy debrites and sand-rich lobe deposits. Secondly, during the deposition period of the lowstand region, the climate was humid, the lake level rise slowly, the sediment supply gradually decreased, the flow increased, the terrigenous detritus changed from coarse sandstone to fine sandstone, and the deltaic channel bifurcation ability increased, forming a network distributary channel system. Meanwhile, the sublacustrine fan has stronger erosion ability and higher mud content. Therefore, the main depositional elements are channel-fill turbidites and mud-rich lobe deposits. Thirdly, during the period of the transgressive tract system, the lake level rise rapidly, and although the climate was humid, the provenance supply was further increased. Under such circumstance, the network distributary channels were the main depositional element of the delta, and it was difficult to form large-scale sublacustrine fan deposits at the far end of the delta. In general, the established delta-sublacustrine fan depositional model in this study will help provide guidance for oil and gas exploration and development.

Characteristics and Influence of coarse particle Sedimentation in terrestrial facies Source-Sink System3D tank experiments

SIYUAN WEI[1*]
1. College of Energy Resources, China University of Geosciences,Beijing, Beijing, CHINA
E-mail: 201771283@yangtzeu.edu.cn

Keywords: coarse particle,3D tank experiments, sedimentary process

Coarse particles refer to particles that are not easily transported after being deposited under the action of external forces such as hydrodynamics due to their own conditions such as volume and gravity. In the simulation experiments, we found that in the study of a complete terrestrial facies source-sink system (including sedimentary facies such as alluvial fans, rivers, deltas, etc.), the distribution position and stacking style of coarse particles affected the sedimentary process and sand bodies of the sedimentary facies belt. form, which in turn affects the entire associated source-sink system.

In alluvial fans, the location of coarse particle is mainly affected by tectonic movements and topographic conditions. Affected by faults, particle transport is hindered. At this time, coarse particles often accumulate near faults to form water-dividing shoals, and reverse sand-gravel bars with coarse particles are developed near bulges or folds.

In fluvial fan, the development location of coarse particle is mainly affected by factors such as river type, hydrodynamic conditions and migration frequency. During the development of a single channel, the coarse particles were mainly concentrated on the head of the tongue-shaped sand dunes and the edge of the channel, and a small amount appeared in natural dikes carried by floods. The coarse particle of braided river are mainly concentrated near the distributary shoal of the central bank. The reduction of the flow velocity caused by the division of the river promotes the unloading of the coarse particle here. The increment of coarse particles is positively correlated with the longitudinal extension of the shoal. Coarse particles in meandering rivers are mainly concentrated on the convex bank, while stable meandering rivers will unload a small amount of coarse particles at the edge of the channel.

In the delta, the development location of coarse particles is mainly affected by factors such as channel hydrodynamics, topographical conditions, and wave action near the lake shoreline. During the flood period, a large number of coarse particles were transported by the surface of the sand body.

Remote sensing analysis methods and application of modern source-to-sink systems

Zhou Hongying[1*], Yuan Xuanjun[1], Xing Xuewen[1], Zhang Zhijie[1], Wang Guihong[1], Ma Zhiguo[1], Wan Li[1], Zhou Chuanmin[1]

Keywords: source-to-sink system, modern sediment, coarse-grained fan, northwest Junggar basin

The study of source-to-sink systems is an important topic of great concern in the field of earth science in the world today. The division of source-to-sink system units are the basis for the quantitative research, and fine anatomy of source-to-sink systems; however, reports of the division of source-to-sink systems, and their characteristic analysis at home and abroad is relatively rare. Preferably, it is more focused on the coupling of source-to-sink systems, the prediction of sedimentary pattern scales, and the analysis of its control factors. In this paper, a quantitative remote sensing analysis method of modern sedimentary source-to-sink system based on DEM (Digital Elevation Model) is proposed. The remote sensing, digital elevation information and spectral information are fully used to introduce remote sensing terrain analysis technology into the field of modern sedimentology, which is used to divide the spatial distribution of source-to-sink system elements and quantify the element characteristics of source-to-sink system. The modern coarse-grained alluvial fan at the northwest edge of Junggar basin was selected to carry out an example dissection. The boundary of the source area of the Liushugou fan, the sediment transport channel, and the sediment aggregation area of the Liushugou waterway was accurately divided. In addition, the lithogic geomorphological parameters of the channel area and the morphological parameters of the channel area, and the sediment distribution parameters of the sink area were quantitatively depicted. The remote sensing analysis technology of modern source-to-sink system effectively makes up for the defect that other source-to-sink analysis methods cannot quantitatively extract sedimentary elements, and expands the traditional source-to-sink sedimentation analysis method from qualitative to quantitative, making it a new technical means for the analysis of modern sedimentary source-to-sink system, which has important reference value for the quantitative research and fine anatomy of source-to-sink system, and provides a basis for the analysis of the sedimentation process of source-to-sink system.

Fossilized Autogenic Responses of Grain-Size Transition to Sediment Supply and Water Discharge: Alluvial Fan Experiments

Haein Shin[1], Wonsuck Kim[1*], HyoJae Lee[1], Chris Paola[2]
1. Earth System Sciences, Yonsei University, Seoul, KOREA, SOUTH
2. Earth and Environmental Sciences, University of Minnesota, Minneapolis, Minnesota, UNITED STATES
E-mail: delta@yonsei.ac.kr

Keywords: Autogenic process, grain-size transition, upstream boundary condition

Autogenic processes can produce large-scale, organized stratigraphic signatures that manifest morphodynamic changes associated with upstream boundary conditions. However, the connection between upstream boundary conditions and their depositional patterns built by autogenic processes has not been thoroughly investigated. Here, the combination of theory, experiment, and field application explores the possibilities of short-term autogenic change of lithofacies as a stratigraphic indicator of upstream boundary conditions. A series of six experiments was conducted to test the effects of sediment supply and water discharge rates on autogenic advance and retreat of the lithofacies boundary (grain-size transition) in a bimodal alluvial fan. For each experiment, time-lapse images and laser topographic scans of the fan surface and sliced cross sections of the final deposits in radial coordinates were collected to quantify characteristic timescales of the autogenic processes. The timescales captured in the time-series data for fan-margin migration and surface wet-fraction change, and the grain-size transition (GST) trajectory shown in the final deposit as a zigzag pattern generally shorten as sediment supply rate increases and water discharge rate decreases. Increasing the sediment supply accelerates the filling of the fluvial sediment buffer and takes a short duration of the fluvial sediment storage and release cycle—producing high frequency and high magnitude of zigzagness in the GST trajectory. Increasing the water discharge tends to widen channels and takes a long duration of the fluvial sediment storage and release cycle—constructing low frequency and low magnitude of zigzagness in the GST trajectory. Furthermore, the relationship between upstream boundary conditions and the patterns of GST trajectory prove the possibility of autogenic stratigraphic signals as a tool to infer the boundary conditions.

The intrinsic curvature of non-deltaic transgressive shelf profiles: The autostratigraphic rationale

Junhui Wang[1*], Tetsuji Muto[2]
1. College of Geosciences, China University of Petroleum (Beijing), Beijing, CHINA
2. Department of Environmental Science, Nagasaki University, Nagasaki, JAPAN
E-mail: wangjunhui@cup.edu.cn

Keywords: Autostratigraphy, non-deltaic transgression, physical and numerical simulation, shelf profile

The shelf, a key element of the source-to-sink sediment routing system, exhibits generally a landward steepening profile. Existing models ascribe this curvature to reduced impact of sea level rise (i.e. increase in sediment supply and/or deceleration of sea level rise), or redistribution of sediment by marine processes to build an equilibrium shelf surface. Here we present a totally different rationale derived from the autostratigraphy theory, which suggests that during constant rise of relative sea level, (1) the downstream alluvial river has the limit in length beyond which it cannot sustain deltaic sedimentation, and (2) the "over-extended" river inevitably shrinks in a non-deltaic transgressive regime whereby the local shelf surface immediately basinward of the shoreline steepens landward. With this background, our two-dimensional geometrical modeling leads to the finding of a simple governing equation that can be described with normalized alluvial length and alluvial slope, and can account for the intrinsic curvature of the shelf profile. The validity of this model and related notions is supported by flume experiments and applications to modern systems, providing a baseline for understanding the origin of the curvature of natural transgressive shelf profiles.

Keywords: sequence stratigraphy,the sedimentary model of progradation complex of shallow braided delta,secondary distribution,high-quality reservoirs

Yanchang Formation is rich in oil resources in Ordos Basin. In recent years, with the popularization of 3D seismic, many progradation complex reflections can be seen in the seismic profile of the middle and lower members of Yanchang formation. Compared with the traditional lithologic strata, seismic strata has obvious layer crossing phenomenon. In order to explain the phenomenon and improve the exploration benefit, the paper studies Chang 6 progradation complex based on the principle of sequence stratigraphy and establishs corresponding filling pattern and clarifies the law of oil enrichment.Through logging-seismic comparison, three sets of "sand-mud combination" marker layers in the progradation complex are established for the very first time, and a reliable sequence-stratigraphic division and comparison framework is established. In this paper, the sedimentary model of progradation complex of shallow braided delta is established (which is different from the blanket type and the Gilbert type). This paper believes that there is a secondary distribution of sedimentary bodies and sedimentary facies. The sedimentary genetic types of progradation complex sand body are mainly multi-stage mouth bar, single-stage mouth bar, river bar superposition, short distance slumping, distal sand bar and turbidite fan. There are two combinations of plane facies belt distribution: one is multi-stage mouth bar - single-stage mouth bar - river + mouth bar - slumping body; The other is multi-stage mouth bar - single-stage mouth bar - river + mouth bar. The reservoir is evaluated according to the porosity, permeability, oil-water content and oil test results of logging interpretation. The result is that the river-bar combination reservoir in Chang 6 is the best, followed by the mouth bar and semi-deep lake slumping reservoir, however, turbidite fan and short-distance slumping reservoirs are average. Relatively high-quality reservoirs (river-bar superimposed type) developed at the top of Chang 6_3^1, Chang 6_2^1, and Chang 6_1^1, and gradually migrated eastward with the progradation complex.This study provides a new idea for the study of sequence stratigraphy of the Triassic Yanchang Formation in Ordos Basin, meanwhile, provides a typical example for re-characterizing the distribution of sand body, and also plays an important guiding role in oil and gas exploration and development. The study enriches the theory of stratigraphic sequence stratigraphy in continental basins in China, and has important reference significance for seismic sedimentary research in other similar domestic and abroad basins.

Characteristics and distribution of sedimentary facies of xu4 and Xu6 members of Lower Triassic in Wubaochang-Huanglongchang area

LAN HUANG[1*]

1. School of Geoscience and Technology, Southwest Petroleum University, chengdu, sichuan province, CHINA
E-mail: 798596950hl@gmail.com

Keywords: xujiahe formation,sedimentary facies,wubaochang-huanglongchang area in northeastern

Taking xujiahe Formation in Wubaochang-Huanglongchang area as the research object, based on various drilling data and modern sedimentology theory, the sedimentary facies types and their distribution, evolution and facies models in this area are further studied to provide a basis for the search of favorable exploration zones.

According to the classification and analysis of sedimentological, paleontological and logging facies, the fourth and sixth member of Xujiahejie Formation in the study area mainly developed differentiated river delta sedimentary facies. The provenance of this period mainly originated from the northeast daba Mountain, and the subfacies can be divided into the Banbian River delta plain and banbian River delta front according to the thrust direction of the sediment source. Microfacies include distributary channel, marsh and interdistributary bay.

According to the analysis results, the sedimentary facies plane distribution of xu4 - Xu6 member is drawn. The results show that: 1. The lake basin shrank and the river energy increased during the sedimentation of the fourth Member of Xudian Formation. The delta plain expands to south west and develops flood plain subfacies. Distributary channel sandbodies were generally developed in the study area during this period, and their quantity and thickness increased greatly, and fluvial sedimentation became stronger. During the sedimentary period of xu5 Member, the lake basin expanded and the delta plain contracted towards the provenance direction. The boundary between delta plain and delta front is roughly located near Huanglong 4 and 5 Wells. Floodplains developed in the study area during this period. The sand body is mainly channel sand body and distributary channel sand body. The quantity and thickness of distributary channel sand body decrease, and fluvial sedimentation becomes weaker. During the deposition of xu6 Member, the lake basin shrank, the delta plain advanced to the southwest direction, and the river energy increased. Distributary channel sandbodies were generally developed in the study area during this period. The sand body mainly consists of channel sand body and distributary channel sand body, the number and thickness of channel sand body increase greatly, and the fluvial sedimentation becomes stronger.

Sedimentary characteristics and development model of sublacustrine fan in the third member of Paleogene Dongying Formation in Liaozhong Sag

Zhengwu Ma[1*]
1. Bohai Petroleum Research Institute, Tianjin Branch of CNOOC Limited, Tianjin, CHINA
E-mail: 369574093@qq.com

Keywords: sedimentary characteristics,development models,sublacustrine fan,Dongying Formation,Liaozhong Sag

Based on the observation, description and analysis of cores, combined with the analysis of petrology, logging response and seismic response, it is concluded that sublacustrine fan deposits were developed in the third member of Paleogene Dongying Formation in liaozhong Sag, and the sedimentary structure types are rich and the characteristics are obvious. Sublacustrine fan sedimentary in compositional maturity of medium and high textural maturity of sandy conglomerate, sandstone is given priority to, can identify horizontal bedding, mudstone tear, slump deformation structure, surface of discontinuity, bedding and other sedimentary structure, show the typical characteristics of the underwater gravity flow deposits, and has obvious slump, secondary handling characteristics, Natural gamma ray and electrical resistivity curve of the micro gear box, a bell and finger and their combination is given priority to, the more performance for the low frequency seismic reflection features, in - good continuity, high amplitude, as a whole has a certain strong reflection configuration, and the lacustrine facies mudstone weak amplitude blank reflection exists obvious difference, from the middle to thinning until pinchout on both sides. Based on the above analysis, the sublacustrine fan in the study area can be divided into three sedimentary subfacies including inner fan, middle fan and outer fan, and several microfacies including main channel and braided channel. The inner fan subfacies is mainly developed at the root of the sublacustrine fan, which is mainly deposited by gravity clastic flow. At the bottom, scour surface, parallel bedding and slump deformation structure are developed. The debris of mudstone can be seen. The middle fan subfacies vertically presents a positive cycle consisting of multiple periods of positive rhythm superposition, which is coarse-grained, reflecting the characteristics of gravity flow deposition. There is a scour surface between the bottom of the cycle and the underlying mudstone, and cross-bedding and mudstone tearing debris can be seen locally. Horizontal bedding and deformation bedding are developed in the outer fan subfacies. A longitudinally incomplete bauma sequence is BCD or CDE. The sedimentary characteristics of sublacustrine fan are controlled by provenance supply, paleogeomorphology and distribution of slope break zone, and the distant delta is the prerequisite for sublacustrine fan development. The paleogeomorphology provided accommodation space and controlled the location and scale of sublacustrine fan. The slop-break zone controls the deposition rate of sediments and the regulation and redistribution of sublacustrine fans.

Lithofacies types and characteristics of typical channel sandbodies in Jinqiu Gas Field, Sichuan Basin

Can Ling[1], mei yan Fu[1*], guang hui Duan[1]
1. School of Energy, Chengdu University of Technology, Chengdu, Sichuan, CHINA
E-mail: fumeiyan08@cdut.cn

Keywords: Sichuan Basin,Jinqiu gas field, Shaximiao Formation,Single sand body,Lithofacies

Tight sandstones from the Jurassic Shaximiao Formation in the Jinqiu Gas Field of Sichuan Basin are rich in natural gas and distributed along channels. The complex internal structure and strong heterogeneity of the channel single sand bodies of the Shaximiao Formation in the study area restrict the production and gas development. This study aims to reveal the lithofacies types and characteristics of channel single sandbodies of the J2S2 member of the Jurassic Shaximiao Formation. Based on the drilling cores, well logging, analysis and testing, nine types of lithofacies are divided, using the bedding, grain size and composition characteristics. The lithofacies types include massive medium-grained sandstones, massive fine-grained sandstones, large cross-bedding medium-grained sandstones, small cross-bedding fine-grained sandstones, parallel bedding medium-grained sandstones, parallel bedding fine-grained sandstones, horizontal bedding argillaceous siltstones, massive mudstones, horizontal bedding mudstones. The vertical assemblage types of lithofacies in the single sand bodies include massive + cross-bedding lithofacies assemblage, cross-bedding + parallel-bedding + horizontal-bedding lithofacies assemblage, cross-bedding + parallel-bedding lithofacies assemblage. Based on the differences of physical properties and logging response characteristics of lithofacies types, the lithofacies assemblages of channel single sandbodies in the study area are divided into three categories, e.g. class I-homogeneous, class II- weakly heterogeneous and class III-strongly heterogeneous. Among them, the physical properties of sand bodies with classI-homogeneous are best. According to the logging values of three types of lithofacies assemblages, the logging identification standards of various lithofacies assemblages are established. This study provides a geological basis for the prediction of high quality reservoir of the Shaximiao Formation in the Jinqiu Gas Field, and improves the development of the tight gas from the Jurassic Shaximiao Formation.

E-mail: sabin.rotaru@geoecomar.ro

Keywords: delta lobe, river engineering, sedimentation rate, depocenter

The majority of world river deltas are at present intensely affected by anthropogenic activities. One of the most damaging effects is the reduction of sediment supply due to damming in the river catchment and channelization inside the delta plain, which causes coastal erosion and thus ultimately endangering settlements on the delta plain. For this study we look at how Danube delta front responds to change from a natural to an anthropogenic regime by investigating the sedimentation rates reflected in bathymetric changes.

We analyzed decadal bathymetric changes for six time intervals spanning the last approximately 150 years (between 1865 and present). For each interval a sediment thickness map was made. Before 1900, the Danube delta front records a net positive sediment budget outlined by a rapid shoreline progradation (> 50 m/year) of the Chilia (northern) lobe and a high deposition rate (0.8 m/year in the deepest part) in front of the Sfantu Gheorghe (southern) lobe. After 1900, the natural regime of the delta was increasingly affected by anthropogenic influence on the Danube river catchment and changed delta sedimentation patterns. Consequently, Chilia lobe faced a gradual decrease in shoreline progradation rates reaching 20 m/year in the 1920s and erosion on the coast exposed to dominant waves, starting with the 1940s. The engineering works which started in the 1860s at the Sulina mouth extended the channel mouth jetties transforming the Sulina distributary in a shipping channel. The jetties extension enhanced erosion in the downdrift part of Sulina mouth due to local wave diffraction. Furthermore the Sulina jetties blocked the southward longshore sediment transport which deprived the southern Sf. Gheorghe lobe of the sediment supply generated by the Chilia mouths. This effect, together with the constantly decreasing overall river sediment input and increased storminess on the deltaic coast led to intensification of wave processes reworking Sfantu Gheorghe river mouth sediments and fast migration (0.2 km/year) of the depocenter toward the southern tip of its barrier island Sacalin. Sediment transported to the Danube delta decreased significantly after the 1940s when areas affected by coastal erosion expanded. Construction of river dams and embankments depleted the delta front of sediments while the intensification of delta plain channelization reduced the main distributaries water discharge. The effects of this human intervention is also reflected in the shrinkage of sediment depocenters identified on bathymetric maps and their migration towards south. Chilia and Sfantu Gheorghe depocenters record low rates of accumulation (0.15 to 0.3 m/year) and migrate southward with rates of 0.1 km/year suggesting stronger wave processes dominance over the river influence which previously controlled depocenter formation.

Sedimentary characteristics of shallow-water Delta in chang 8 member of Yanchang Formation of the Upper Triassic in Yanchi area, Ordos Basin

Ting Shu[1*], Guofeng Cheng[2], Hua Chen[2], Guizhen Liu[1]
1. College of Earth Sciences and Engineering, XI'an Shiyou University, Xi'an City, Shaanxi Province, CHINA
2. Changqing Oilfield Branch of PetroChina, No.5 Oil Production Plant, Xi'an City, Shaanxi Province, CHINA
E-mail: 1095321082@qq.com

Keywords: shallow-water delta, sedimentary characteristic, Yanchi area,Ordos Basin

The shallow-water delta in lacustrine has become the focus of sedimentological research and oil and gas exploration. The rich oil and gas resources have been found in shallow-water deltaic sandstone reservoirs in lacustrine. Shallow-water deltas are one type of deltas developed in lacustrine with shallow water and relatively tectonically stable tableland, gentle topography and slow overall subsidence, featuring stable sedimentary thickness, continuous sedimentary sequence and large scale development of delta front facies belts.

Chang 8 member of Yanchang Formation is a typical deltaic delta front facies sedimentation in the Yanchi area of Ordos Basin. Core observation shows that coal lines, leaves and roots of plant, wormholes, sedimentary structures and other shallow water environmental markers are widely developed, and a large number of small cross-stratification, trough cross bedding stratification, wavy cross-stratification and depressional cross-stratification are developed, and the sedimentary sequence shows normal rhythmic characteristics. The sedimentary microfacies mainly including the underwater distributary channelthe underwater natural levee and the interdistributary microfacies, and its underwater distributary channel have characteristics of meandering river with low sinuosity. Under the control of the basin depression background, the sedimentation and sandbodies distribution of shallow-water delta are influenced by the raise and fall of the lake level, climate and supply of sources, which are as follows: In the periods of high water levels, the shoreline of the lake is rapidly moved towards the sources area and strip-shaped or birdfoot shaped subaqueous distributary channel sandbodies developed. In the periods of low water levels, the delta plain is mainly developed. The sandbodies is distributed in a strip-like form.

Sedimentary facies and sedimentary model for the Chang-6 oil measuresof the Triassic Yanchang Formation in the Qilicun Oil FieldOrdos Basin

yiyang chen[1*]
1. , , , , CHINA
E-mail: 302600815@qq.com

Keywords: Ordos Basin,shallow-water delta,sedimentary facies,Yanchang Formation,Qilicun Oil Field

Sedimentary facies and sedimentary model are constructed according to well logs and section examinationof the Chang-6 oil measures of the Triassic Yanchang Formation in the Qilicun Oil FieldOrdos BasinThe study shows that the target layer in the study area develops delta front subfacies deposition, and it does not have the three-layer structure of topsets, foresets and bottom sets of the Gilbert-type delta model.From the perspective of sedimentary structure, the delta has thin monomer and is widely distributed with the characteristics of “blanket” sedimentary structure and the dominant development of sand body of underwater distributary river course.The development of sedimentary microfacies takes the sand body of distributary river course as the skeleton, the mouth bar is generally not developed, and the distributary river course is subject to different degrees of sheeting transformation.On the one hand, when the river channel expands rapidly after entering the lake, it forms a plane flow to the center of the lake basin, and the sediment in the early stage is scoured and reformed after the river channel expands in the later stage.On the other hand, the transformation of lake water waves makes it difficult to preserve the estuary dam sediments formed at the estuary.Sedimentary microfacies consists of the subaqueous distributary channel and interdistributary bay microfacies in the delta front subfaciesThe controlling factors include tectonic evolutionclimateslake-level changes and sediment supply systemsDuring the deposition of the Chang-6 oil measures of the Triassic Yanchang Formationthe broad channels facilitated the wide spreading of water-carried fine-grained sediments and progradation toward the center of the basinand resulted in the formation of the“blanket”structure composed of the sandstone-mudstone couplets in the subaqueous distributary channel faciesGenerally, it is an interbedding development of sandbody and mudstone of underwater distributary river course.

Does the effect of sediment retention and bottomset accumulation lead the linearly prograding deltaic shoreline?

Minsik Kim[1], Wonsuck Kim[1*]
1. Earth System Sciences, Yonsei University, South Korea, Seoul, KOREA, SOUTH
E-mail: delta@yonsei.ac.kr

Keywords: shoreline progradation, retention rate, delta

Deltas are formed at the mouth of rivers as rivers lose their confinement and develop alluvium. Traditionally, the A/S (accommodation/sediment supply) ratio is considered for a main control on the shoreline migration. A delta progrades basinward (shoreline regression) when the S is greater than the A. The progradation rate decreases as the delta expands because the subaerial delta surface increases. However, interestingly, the Lafourche Delta is known to prograde at a steady rate even with the expanding delta surface and compaction hindering the progradation. Previous studies presented several hypotheses to explain this deviation. In this study, we investigate the effect of 1) bottomset aggradation and 2) retention rate increase on maintaining shoreline progradation rate. We integrated bottomset and compaction module into the delta building model to test these two hypotheses in the Lafourche Delta. The modeling results demonstrate that when the bottomset aggradation increases, the shoreline progradation tends to be linear, yet it is insufficient to explain the constant shoreline progradation rate of Lafourche Delta. On the other hand, the increased retention rate resulted in an almost constant progradation rate

The problems and solutions of the Sr/Ba ratio for salinity recovery of terrigenous clastic sediments

Aihua Wang[1*], JianKun Liu[1], Hualing Li[1], Naicen Xu [1], Fei Zhang [1]
1. Sedimentary Geochemistry, Nanjing Center of Geological Survey,GCS, Nanjing, Jiangsu, CHINA
E-mail: njywa@qq.com

Keywords: salinity recovery ,the Sr/Ba ratio , selective extraction, Distinguishing of the marine and terrestrial sedimentary environment, terrigenous clastic sediments

The salinity recovery of sedimentary environmen during the deposition of terrigenous clastic sediments is one of the main contents of sedimentology. The Sr/Ba ratio is one of the commonly used proxy for the salinity recovery of terrigenous clastic sediments. It is generally believed that the Sr/Ba ratio of marine sediments is greater than 1.0 and the Sr/Ba ratio of terrigenous sediments is less than 1.0, but the effect of practical application is often not satisfactory. The existing data show that most of the terrigenous clastic loose sediments (or terrigenous clastic sedimentary rocks), whether salty water or fresh water, generally have a total Sr content of 100 ~ 300 mg/kg and a total Ba content of 300 ~ 700 mg/kg, Therefore, under normal circumstances, their Sr/Ba ratio is generally less than 1.0. So, Is the Sr/Ba ratio not suitable for distinguishing the terrestrial and marine sedimentary environment?

The results of strontium and barium by Sequential extraction analysis from natural sediments of different salinity series in the modern Yangtze River Delta show that about 62% of the total strontium and 93% of the total barium in terrigenous clastic sediments exist in clastic silicate minerals. Their content has nothing to do with salinity, but only with hydrodynamic force and mineral composition of clastic sediments. This explains why the Sr/Ba ratio of most terrigenous clastic sediments (rocks) are less than 1.0 whether deposited in fresh water environment or salt water environment.

The results by sequential extraction analysis also showed that the content of exchangeable and carbonate-bound Sr and Ba were mainly related to the changes of salinity environment, and other Occurrence mode of Sr and Ba had no good correlation with salinity. Therefore, we can distinguish the marine and terrestrial sedimentary environment of terrigenous clastic sediments by selectively extracted Sr/Ba ratio of exchangeable & carbonate-bound Sr and Ba.The Sr/Ba ratio extracted by 1M NH4Ac and 10% HAc from the clastic sediments of the modern Yangtze River Delta shows that if the Sr/Ba ratio is less than 1.0, it indicates that the sediments are deposited in the river or upper delta plain environment of fresh water; If the Sr/Ba ratio is between 1~5, it will be deposited in the delta front environment of brackish water; if the Sr/Ba ratio is between 5~8, it will be deposited in the prodelta environment of salt water; if the Sr/Ba ratio is greater than 8, it will be deposited in the normal seawater environment. Obviously, analysis method by selective extraction is the only way to solve the poor application effect of trace element sedimentary geochemistry.

A review of the mismatch in grain size between modern and ancient tide-dominated deltas: does the rock record need to be reinterpreted?

Marcello Gugliotta[1*]
1. Faculty of Geosciences, University of Bremen, Bremen, GERMANY
E-mail: m.gugliotta.geo@gmail.com

Keywords: tide-dominated delta, grain size, ancient units, modern systems

Modern tide-dominated and mixed-energy tide-dominated deltas are heterolithic and relatively fine grained, yet units considered to be their ancient counterparts are sandstone prone and coarser grained. This study reviews and provides semi-quantitative data from 13 modern tide-dominated deltas and 31 interpreted ancient counterparts, highlighting the mismatch in grain size and additional incongruities.

The studies of modern and ancient systems are potentially complementary as they provide different insights on the depositional system (e.g., short term processes vs. long-term evolution); however, it is not rare that models based entirely on interpretations (or also modeling simulations) would contrast with well-known and measured dynamics from modern systems where certainties are obviously much greater. Although other reasons (e.g., preservation) might exist, comprehensive and supported explanations for these mismatches are rarely provided, and a misinterpretation of the ancient remains the most reasonable justification.

This review study questions nearly four decades of research on ancient (mixed-energy) tide-dominated deltas and suggests that a change in direction for interpreting ancient coastal to shallow-marine successions is urgently required. The knowledge gap between modern and ancient systems is likely destined to remain wide if geoscientists will persist underestimating the knowledge gained from modern systems when interpreting the rock record

Driving the salt or carried by the salt: a sedimentary wedge on a moving salt canopy

Yilin Fan[1,2], Zhiyuan Ge[1,2*]

1. State Key Laboratory of Petroleum Resources and Prospecting, China University of Petroleum (Beijing), Beijing, CHINA
2. College of Geosciences, China University of Petroleum (Beijing), Beijing, CHINA

E-mail: gezhiyuan@cup.edu.cn

Keywords: salt canopy ,extrusion rate ,sedimentary wedge,numerical simulation

Salt canopies are thick allochthonous salt presented in the deepwater area of salt-bearing passive margins. In the salt canopy region, two dominant mechanisms driving salt tectonic deformation are the contraction controlled by the gravity failure of the margin and the sedimentary loading associated with deepwater sedimentation. However, how the sedimentary loading interacts with the contraction is not well understood. We use numerical simulation to systematically investigate the interaction between deepwater sedimentation and an advancing salt canopy by varying the extrusion rate of salt and sedimentation patterns. The results show that the extrusion rate of the salt canopy has a first order control on the deformation pattern of the supra-salt sediment wedges. Increasing the extrusion rate directly increases the length of the deformation belt and allows the development of more contractional structures. In contrast, the sedimentary wedge can only dominate the deformation style when the extrusion rate is very slow. This study suggests that, the relative contribution between salt extrusion and sediment-differential loading in a salt canopy is closely linked to the extrusion rate of the system. Consequently, various styles of sediment-salt interaction may exist depending on the speed and nature of canopy advancement.

Alluvial fan evolution in response to glacial-interglacial climate cycles: A case study from Daihai Lake Basin, North China

Shuangqi Feng[1,2*], Chengpeng Tan[3], Hancheng Ji[1,2], Yanqing Shi[1,2]

1. College of Geosciences, China University of Petroleum (Beijing), Beijing, CHINA
2. State Key Laboratory of Petroleum Resources and Prospecting, China University of Petroleum (Beijing), Beijing, CHINA
3. Key Laboratory of Cenozoic Geology and Environment, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, CHINA

E-mail: feng868919@163.com

Keywords: Alluvial fan, debris flows processes, sheetflood processes, East Asian summer monsoon, colluvial slope failures

Understanding climate changes and resulting catchment-alluvial fans dynamics is helpful to reveal paleoclimate system by means of terrestrial archives, especially for during the interglacial-glacial cycles. However, it is debatable whether the alluvial fan deposits are capable of recording the orbital-scale climate fluctuations because the response time (10^6yr) of terrestrial landscapes for the climate changes are far longer than the cyclicality (~10^4-10^5yr) of high-frequency Milankovitch-period oscillations. Based on the detailed field survey, the sedimentary facies and the sedimentary processes of the late Quaternary Bantanzi (BTZ) fan in the Daihai Lake basin within the northern margin of the East Asian summer monsoon (EASM) is investigated. Meanwhile, a reliable interglacial-glacial chronology framework can be constructed utilizing the interfingering and interstratified relationship between fan deposits and loess-paleosol sequences and other chronological evidences. We find that the BTZ fan is constituted by the last interglacial debris-flow-dominated unit (DFU) and overlying the last glacial sheetflood-dominated unit (SFU). In consideration of the tectonically quiescent setting, the abrupt transition from debris-flow to sheetflood sedimentary processes over the last interglacial-glacial cycle is ascribed to the orbital-scale climate oscillations, which determine the enormous differences in precipitation and sediment supply within BTZ drainage basins. Compared with glacial periods, stronger extreme rainfall and more precipitation totals may surpass the threshold of catchment colluvial slopes failures to trigger widespread debris-flow processes due to the combination of global warming and northward migrating of the EASM rainfall belt during the interglacial. The study confirms the coupling response between the alluvial fan deposits and Milankovitch climate variations.

Deep-water sedimentary systems on the tectonically active Antarctic margin

Shan Liu[1*], Haiteng Zhuo[1], Kunwen Luo[1], Ming Su[1]
1. School of Marine Science, Sun Yat-sen University, Zhuhai, Guangdong, CHINA
E-mail: liush296@mail.sysu.edu.cn

Keywords: submarine canyons, plastered contourite drifts, the active high-latitude continental margin, the Antarctic Peninsula

The active continental margins are sites of tectonics and complex sedimentary processes (Fisher, 1974; Miller and Kuehl, 2010; Harris et al., 2014). Tectono-sedimentary interactions occur through geological time and determine the modern morphology of the margin (Ranero and Sallarès, 2004; Gamberi et al., 2015; Bailey et al., 2020). Such interactions, however, are poorly documented in high-latitude regions. This study focuses on the deep-water sedimentary systems on the South Shetland margin, the only remaining active continental margin in Antarctica. Analysis of bathymetric and seismic datasets allows the recognition of numerous gullies, 20 canyons, and a plastered contourite drift. Mineral contents and grain size derived from the gravity core indicate the main sediment input from the South Shetland Islands. Sediment transport is dominated by turbidity currents, while weak bottom currents further rework the sediments on flat terrace and the lower continental slope. Although the evolution stages of canyons and gullies can hardly be determined because of the lack of chronographic control, incision-infill features in seismic unit 1 and 2 shows the long-term influence of turbidity currents. Sedimentary features on the South Shetland margin are profoundly controlled by tectonic-resulted slope morphology and marginal compression. Gullies only shown on steep (slope>7°) and rugged slopes where tectonic compression is significant. The thalweg profiles and sinuosity of canyons are controlled by variations in the slope gradient. The plastered contourite drift is restricted to the fault-generated terrace. Frequently occurred earthquakes and the convex geometry of the drift influence the slope instability and might trigger the sliding. Two types of deep-water sedimentary models are suggested for the Antarctic continental margin. Type I is the most common hybrid turbidite-contourite depositional system. Type II represents separated systems of canyons and contourite drifts. The former is generated on the gentle slope (slope<2°), while the latter occurs on steep ones (slope>9°). Sedimentary features on the South Shetland margin and similar island arc systems have no latitudinal variations and are comparable in size. Tectonics exert a first-order control on the sedimentary systems. The results provide a deeper understanding of tectono-sedimentary interactions on the active continental margins.

Architectural characteristics, evolutionary stages, and sedimentary models of clastic beach bars

Xin Li[1*], Longwei Qiu[1], Jian Fu[1]
1. School of Geosciences, China University of Petroleum-Huadong, Qingdao, Shandong Province, CHINA
E-mail: lixin15619940816@163.com

Keywords: architectural units, sedimentary models, evolutionary stages, beach bars, machine recognitionShandong Penisula

Beach bars are important reservoirs and have good exploration potential in several petroliferous basins globally. However, most of the models used for understanding the architecture of beach bars are macro-patterns of source-to-sink. They have imprisoned the further development of this territory, and we need new attempts to break through the current bottlenecks.

Our study areas were the Binhai Park of Rongcheng, Moon Bay and the Fenghe Estuary of Qingdao. These places are all distributed along the coast of the Shandong Peninsula in China. We also analyzed a beach bar of the fourth member in the Shahejie Formation of the Paleogene deposits found in Dongying Sag (Bohai Bay basin). We studied hydrodynamic zoning and the sedimentary environment and established fine-scale architectural units using field surveys, fine-scale scanning with unmanned aerial vehicles (UAVs), cores, grain size analysis, X-ray diffraction analysis, X-ray fluorescence analysis and conventional and image logging. Automatic identification of beach bar architectural units was conducted through principal component analysis and Bayesian discrimination.

The results indicated that the beach bars could be divided into shore beaches, submerged shoals and bars, based on different lithological and sedimentary characteristics. The architectural units of beach bars were divided into five subtypes, corresponding to four evolutionary stages based on hydrodynamic traits and the sedimentary environment. The evolutionary stages include the weak wave action stage, turbulent current - swash backwash stage, aeolian stage and swamping stage. Additionally, a discrimination standard was established based on principal component analysis and Bayesian discrimination while using fine-scale recognition to verify the units. The coincidence between manual recognition and machine recognition results was 94.8%. The discrepancy among the evolutionary stages of beach bars was compared based on the characteristics of architectural units, and the different sedimentary models for shore beach, submerged shoal and bar were established.

We hope that our methodology and models will help address the limitations in previous studies on beach bar reservoirs and will help promote improvements in the related theories and optimization of their exploration and development. Meanwhile, based on the research mentioned above, the finer description and dynamic simulation of beach bars can be continued in further studies.

Quantitatively distinguishing the factors driving sediment flux variations in the Daling River Basin, North China

Shuang Sun[1*]
1. School of Ocean Science, China University of Geosciences in Beijing, Beijing, CHINA
E-mail: sunshuang1227@outlook.com

Keywords: Small mountainous river, Vegetation coverage, Extreme climate, pollen, OSL

Understanding the riverine sediment load regime is crucial to sustainably managing fluvial-deltaic ecosystem restoration. However, in studies on global river sediment transport characteristics, small mountainous rivers (SMRs), transporting 45% of the global sediment flux into the sea, have been largely ignored. Furthermore, SMRs have hydrologic characteristics of instantaneous enormous fluxes under extreme climate, but the research on their driving factors affecting sediment transport is insufficient, not only the modern, but also the late Holocene time scales. Partial derivation method and multiple double mass curves were applied to a small mountainous river in North China, the Daling River to study how the three most variable factors—precipitation, vegetation coverage, and reservoirs—have quantitatively controlled sediment flux in the basin and its subregions in the last 50 years. The OSL (Optically Stimulated Luminescence) and 14C dating method were both used to establish the age framework, additionly, pollen and phytolith proxies were used to reconstruct paleoclimate via WA-PLS model, including the precipitation, temperature, and vegetation coverage of Daling River Basin in the Late Holocene. From 1961–1979 to 1980–2015, the 78.55% reduction in sediment flux was due primarily to restored vegetation coverage (50.42%-61.11%), followed by reservoirs (18.13–44.09%) and precipitation (5.49–22.34%) in the Daling River Basin (DRB) and its subregions. The restored vegetation in the DRB has intercepted a large amount of sediment, reducing the sediment flux transported to the reservoirs. Besides, the Daling River releases enormous amounts of sediment during heavy rainfalls. However, increasing vegetation coverage in recent years has changed the transport characteristics of sediment into temperate changes in runoff and sediment flux under extreme climatic conditions; thus this river provides a useful example of studying the characteristics of sediment transport controlled by nature and human activities against extreme climate conditions. In the DRB, topography, lithology, and vegetation density are the motivators for the differences in sediment flux and its change rates, from upstream to downstream. While in the Late Holocene, sedimentary rates in the Daling River estuary increased abruptly from 0.14 cm/a (~2-3ka) to 0.87 cm/a (~1-2ka), then decreased to 0.32 cm/a (~1ka), meanwhile, average vegetation coverage (NDVI: normalized difference vegetation index) decreased from 0.72 to 0.69, again reduced to 0.66. Annual mean precipitation and temperature were 615.12 mm and 13.23℃; 615.79 mm and 10.52℃; 640.13 mm and 14.06℃ in the three periods. From 2-3ka to 1-2ka, the lower temperature has promoted vegetation decline, besides, the slight increase of precipitation has sped up the water and soil loss. However, since 1 ka, higher amplitude precipitation and lower vegetation density, coupling with bulk sediment accumulation, caused the river channel to transform from southwest to northwest, therefore, the sedimentary rates decreased in the southwest of the Daling River estuary. These findings emphasize the crucial role of vegetation in driving sediment transport from source to sink in temperate SMRs.

Provenance and Tectonic Setting of Sandstones from the Late Paleozoic Shihezi Formation, East Central of Ordos Basin, China

YanPing MA[1*]
1. School of Earth Sciences and Engineering , Xi'an Shiyou University , Xi'an, Shaanxi, CHINA
E-mail: bye9@sohu.com

Keywords: eastern central of Ordos basin,Shihezi Formation, provenance, tectonic setting

Petrography, major, trace, and rare earth element compositions of sandstones from the Late Paleozoic Shihezi Formation, East central of Ordos basin, in China, have been investigated to determine their provenances and tectonic settings. Petrologic studies demonstrate that all sandstone samples from Shihezi Formation are highly enriched in quartz (Q) but poor in lithic fragments and feldspar (F). The sandstone samples consist mainly of lithic quartz sandstone and litharenite with abundant metamorphic and volcanic fragments. On Q-F-L plots sandstones fall into the field of recycled-orogenic source. Chondrite-normalized Rare earth element (REE) patterns of Shihezi Formation samples with LREE enrichment, flat HREE, and negative Eu anomaly are attributed to felsic source-rock characteristics for Shihezi Formation sandstones. REE patterns of samples from study area are very similar to those of Archeozoic and Proterozoic metamorphotic rocks, such as granitic gneiss, monzonitic gneiss, diorite gneiss, biotite plagioclase gneiss, biotitequartz schist, granulite, mixed granite, etc, from Daqing Mountain, Wula Mountain, and Yin Mountain. Major element geochemistry of samples demonstrates that the most were derived from an active continental margin and passive continental margin, but some from an island arc of passive continental margin. Trace element geochemistry favors a continental-arc provenance mostly from felsic rocks. The major, trace element geochemistry of samples indicate that the source area have experienced complex tectonic settings, which related to combinating tectonic settings with active continental margin, passive continental margin, and continental arc, which correspond to the tectonic setting of northern source area. At the northern edge of the basin, the north margin of Ordos plate collision with Yin Mountain during 1.8~2.0Ga, which result in the collision belt towards continent, the tectonic setting have both active continental margin, passive continental margin, and continental arc. This deduction demonstrates that the uplift of the northern sourc area during late Paleozoic was the major source of Shihezi Formation clastic debris in the East central of Ordos basin.

Textures, provenances, and transport patterns of sediment on the inner shelf of the East China Sea

Jingyi Cong[1], Yong Zhang[1*], Gang Hu[1]
1. Department of Marine Fundamental Geology, Qingdao Institution of Marine Geology, Qingdao , Shangdong , CHINA
E-mail: qimgzy@163.com

Keywords: Provenance, Surface sediments, East China Sea, Yangtze river, Zhejiang-Fujian small rivers

Although many studies have been carried out on the mud wedge in the inner shelf of the East China Sea (ECS), the sediment sources and seismic textures of the mud wedge are still unclear and remain controversial. Therefore, this study utilizes grain size and clay mineral analyses of surficial sediment samples and high-resolution subbottom seismic profile interpretation to identify the provenance and texture of these mud wedge sediments. The results show that sediment sources on the inner shelf of the East China Sea are mixed by the Yangtze River, small mountainous rivers along the Zhejiang-Fujian, and western Taiwan coasts. The sediments derived from the Ou and Min rivers are mainly concentrated in the shallowest shelf area within a water depth of 20 m which is located north of the Min River Estuary. Their contribution to the estuaries and coastal areas reflects the different sediment transport patterns of the two small mountainous rivers. The thickness of the Holocene mud wedge between Hangzhou Bay and Taizhou Bay is greater than 20 m at a water depth of approximately 10 m. The cause of this phenomenon is possibly related to the presence of the Zhoushan Islands, which are distributed along the Zhejiang coast and appear to effectively trap sediments from the Yangtze River, facilitating sediment accumulation. The findings of this study will help improve our understanding of the sediment transport and deposition mechanism of deposition on the inner shelf of the East China Sea.

Sequence stratigraphic and geochemical records of paleo-sea-level changes in the Upper Carboniferous mixed clastic-carbonate successions in the eastern Qaidam Basin, China

Xiaojie Wei[1], Junjie Hu[1*], Zongxing Li[1], Yinsheng Ma[1], Xinxin Fang[1], Hui Shi[1], Bo Peng[1], Yuanyuan Yang[1]

E-mail: 40429468@qq.com

Keywords: eastern Qaidam Basin, Upper Carboniferous strata, mixed clastic-carbonate succession, sequence stratigraphic and geochemical characteristics, paleo-sea-level changes

The Upper Carboniferous strata in the eastern Qaidam Basin, China, constituted by several hundreds of meters thick mixed clastic-carbonate successions provides an excellent geological record of paleoenvironmental and paleo-sea-level changes during the Late Carboniferous icehouse period. Based on detailed outcrop observation and interpretation, five facies assemblages (fluvial channel, tide-dominated estuary, wave-dominated shoreface, tide-influenced delta, and carbonate-dominated marine offshore) are identified in cyclical stacking patterns. Correspondingly, four 3rd-order sequences were recognized and each 3rd-order sequence is composed by lowstand, transgressive and highstand system tracts. The lowstand system tract is generally dominated by fluvial channels as a result of river rejuvenation when sea-level falls. The transgressive system tract is characterized by tide-dominated estuary and retrogradational carbonated-dominated marine deposits formed during sea-level rise. The highstand system tract is dominated by aggradational marine and wave-dominated shoreface or tide-influenced delta deposits caused by sea-level fall and an increased debris supply. Sequence stratigraphy evolution and geochemical records from carbon and oxygen isotopes and trace elements suggest that four significant high-amplitude sea-level fluctuation events took place, and an overall long-term sea-level rise, which were primarily driven by Gondwana glacio eustasy. Assessing the result of the glacio-eustasy driven sea-level changes history in the eastern Qaidam Basin is useful in predicting the distribution and evolution of mixed cyclic successions in and around the Tibetan Plateau.

When and how are progradational coastlines actually prograding?

E-mail: valentin.zuchuat@emr.rwth-aachen.de

Keywords: Coastal dynamics, erosion, progradation, distributary fluvial system, Queensland, Digital Earth Australia Coastlines

The long-term development of ancient and modern coastal distributary fluvial systems (DFS) during periods of relative sea-level highstand or fall has often been associated with an overall progradational shoreline. However, the study of modern marginal-marine systems has demonstrated that the spatial and temporal distribution of sediment supply and the combination of depositional processes at the shoreline play an important role in the along-strike coastal dynamics of DFSs. In this context, can we assess when and how much of the coastline is actually prograding at a given time? To address this question, the yearly movements of a 654.63 km segment of the Queensland coastline along the Gulf of Carpentaria were calculated using the Digital Earth Australia Coastlines data between 1988 and 2019, which includes geographical information of the coastline position every 30 m along it.

Preliminary results of this study show that, over 31 years, only 46.86% of the coastline had a net progradation, whereas 53.14% of the coastline was eroded. On the other hand, 50.60% of the studied coastline is characterised by a positive average yearly rate of coastal progradation, which only occasionally exceeds 2 m/year (average yearly erosion rates follow similar trends). The difference between the 1988-2019 net coastal behaviour and the average yearly rates of coastal progradation/erosion indicates that parts of the system are more impacted by out-of-the-ordinary events than others, where ordinary environmental conditions seem to be able to overprint such events. Finally, even if the spatial distribution of coastal erosion VS coastal progradation between 1988-2019 is very discontinuous along the studied coastline, data suggest that the yearly coastal behaviour is overall homogeneous and cyclical, with most of the coastline experiencing alternately erosion or progradation at a yearly to 5-years scale. Although still unresolved, the exact nature of these cycles could potentially be explained with events such as El Niño/La Niña, or variations in tropical-cyclone frequency.

Along-strike variations in coastal behaviour occurring at short spatial and temporal scales, like the ones documented in this study, would surely influence the development, preservation, and trajectory of facies belts and associated key sequence-stratigraphic surfaces in marginal-marine settings. These variations would notably include: what processes are involved in the genesis of such surfaces, their timing, extent, and degree of amalgamation, even if the overall and long-term behaviour of the DFS seems to have generated a uniform coastal progradation. The implementation of short-term coastal dynamics in longer-term basin-development models of modern and ancient marginal-marine systems could refine their predictive power, but the increased uncertainty might limit their spatial and temporal relevance.

E-mail: yin.lu@uibk.ac.at

Keywords: Sediment density flows, Geological record, Flood plume, Turbidites, Sediment transport processes

In lakes and oceans, links between modern sediment density flow processes and deposits preserved in long-term geological records are poorly understood. Consequently, it is unclear whether, and if so how, long-term climate changes affect the magnitude/frequency of sediment density flows. One approach to answering this question is to analyze a comprehensive geological record that comprises deposits that can be reliably linked to modern sediment flow processes. To address this question, we investigated the unique ICDP Core 5017-1 from the Dead Sea (the largest and deepest hypersaline lake on the Earth) depocenter covering MIS 7-1.

We report a large dataset of sediment flow deposits (N >5,000) from the ICDP Core 5017-1. Based on an understanding of modern sediment density flow processes in the lake, we link homogeneous muds in the core to overflows (surface flood plumes, $\rho_{flow}<\rho_{water}$), and link graded turbidites and debrites to underflows ($\rho_{flow}>\rho_{water}$). Our dataset reveals (1) overflows are more prominent during interglacials, while underflows are more prominent during glacials; (2) orbital-scale climate changes affected the flow magnitude/frequency via changing salinity and density profile of lake brine, lake-level, and source materials; (3) regarding the generating of turbidity currents, the hyperpycnal plunging mechanism is more dominant during glacials, while the plume settling mechanism is more dominant during interglacials.

The current research bridges the gap between our understanding of modern sediment density flow processes and deposits preserved in a long-term geological record in the Dead Sea, a tectonically active subaqueous environment. It has wider implications for turbidite paleoseismology and implies that to develop prehistoric turbidites as a reliable paleoearthquake indicator, comprehensive modern sediment flow monitoring is essential. It also has wider implications for paleoclimate research in a tectonically active subaqueous environment. A sedimentary archive is filtered to remove significant instantaneous event deposits such as turbidites and debrites could help paleoclimatologists to better reconstruct paleoclimate change.

Nature's laboratory of sedimentology: Zealandia as a host region of the ISC 2026

Karoly Nemeth[1,2*], Mark Lawrence[3]

1. School of Agriculture and Environment, Massey University, Palmerston North, Manawatu, NEW ZEALAND
2. Lithosphere Physics Group, Institute of Earth Physics and Space Science, Sopron, Hungary, HUNGARY
3. Earth Resources and Materials, GNS Science I Te Pū Ao, Lower Hutt, New Zealand, NEW ZEALAND

E-mail: k.nemeth@massey.ac.nz

Keywords: source-to-sink, plate margin, volcaniclastic, uplift, erosion

Zealandia is a small, 4.9 Mkm2 region of continental crust in the South Pacific that was once part of Gondwana. As a result of widespread Late Cretaceous crustal thinning, preceding supercontinent breakup, most of Zealandia became submerged. New Zealand constitutes the subaerially exposed part of Zealandia astride the Pacific and Australian plate boundary. The combination of tectonic movement along the boundary and erosion has resulted in a young, rugged, dissected landscape. This means New Zealand has spectacular and varied scenery that displays a diverse range of Cambrian to modern depositional and diagenetic systems in a relatively small geographic area. Fully terrestrial to deep marine deposits can be viewed, in some places close to their modern analogues. The interplay between tectonics, and volcanism and erosion can locally be tracked from source to sink. Many sedimentological localities are globally significant (e.g., Taranaki coast, East Coast), superbly exposed, with high geoheritage values and geodiversity. In the short human history of New Zealand, from the early Polynesian settlers to more recent immigrants, this geology has had a profound effect on New Zealanders, determining how we live in such a highly dynamic, and diverse environment. Understanding the sedimentary environment, modern and ancient, is a fundamental component to planning our future in the face of factors such as climate change, seismicity, volcanism, and their associated hazards. All these things are what this small part of the 8th continent of the world, Zealandia, will attempt to demonstrate hosting the ISC 2026 Congress.

Sedimentary record associated with atoll growth: exploratory modeling approach

Shu Gao[1*]
1. School of Geographic and Oceanographic Sciences, Nanjing University, Nanjing, Jiangsu, CHINA
E-mail: shugao@nju.edu.cn

Keywords: reef platform, submarine terrace, sediment supply, annual layers, event deposits, environmental changes

The general characteristics of the sedimentary record of atoll systems depend on the biological material supply from the reef platform and the subsequent allocation of the materials. An exploratory model (EMASS. Exploratory Modeling of Atoll Sedimentary System) is used to investigate the sedimentary patterns of the atoll proper and the submarine terrace, based on budgeting analysis and geometric assumptions. The definition domains of reef sediment productivity, background water depth, initial atoll magnitude, and a material allocation ratio of atoll retention to submarine terrace accumulation are incorporated to generate the various outcomes representing the deposition product. A synthesis of the outcome spectrum indicates that annual layers of fine-grained sediment escaping from the platform may heave a thickness of up to 10^{-1} mm/yr, and the event layers related to sediment gravity flow due to the self-organization process of reef growth may reach 10^{2} mm in thickness. Furthermore, the reef platform contains well-defined information on sea-level changes. The assumption that any large atoll system results from the growth of a small atoll is not supported by the simulation, since the temporal scale of the sedimentary record often does not fit into the scale of atoll growth with such an assumption. These observations should be taken into account when interpreting environmental changes in the past.

E-mail: huxm@nju.edu.cn

Keywords: Modern fluvial sediments, Sand petrography, Heavy minerals, Hydraulic processes, End-member numerical modeling, Lhasa and Himalaya

Studying the grain-size dependent compositional variability in modern river sediments provides us with a key to decipher the information stored in the sedimentary archive and reconstruct the evolution of the Earth's surface in the past. Bedload sand along the Xigaze cross section of Yarlung Tsangpo mainstem ranges in mean grain size from 0.5Φ to 3 Φ and displays a marked variability in the relative abundances of detrital components. Such variability does not depend only on hydrodynamic progress, but is controlled as well by the mineralogy of parent rocks in source areas, by the seasonal migration of the rainfall belt, wind reworking, and hydraulic-sorting processes. End-member numerical modeling suggested that the random mixing of wind or river dynamic processes took charge of the random variation of sediments from the Xigaze cross section of Yarlung Tsangpo.

Revisiting the concept of wave base: a marine sediment dynamic approach

Qian Yu[1*], Yunwei Wang[2], Shu Gao[1]
1. School of Geography and Ocean Science, Nanjing University, Nanjing , Jiangsu, CHINA
2. School of Marine Science and Engineering, Nanjing Normal University, Nanjing, Jiangsu, CHINA
E-mail: qianyu.nju@gmail.com

Keywords: wave base, marine sedimentary dynamics, wavelength, critical wave orbital velocity of motion

Wave base is an important concept in sedimentology. It is classically defined as the maximum depth at which bottom sediments are stirred by the wave motion and distinguished into fair-weather wave base (FWWB) and storm wave base (SWB), the latter being deeper than the former. In some textbooks, SWB refers to the upper boundary of muddy deposition, FWWB indicates the lower boundary of sandy deposition, and the area between them is associated with mixed sediment deposition. This concept of wave base has been widely applied in analyses of sedimentary environment and stratigraphy, and becomes a powerful tool to recover ancient water depth from the sedimentary rocks and strata.

It has been perceived for a long time that the depth of wave base is equal to half of the wavelength. The theoretical basis for which is that, when the water depth is smaller than half of the wavelength, waves change from deep water waves to shallow water waves and begin to be influenced by the bed. Contradict to the original definition, the wave base refers to the depth from which waves start to stir up the bottom sediments, but not where the bed begin to influnce the waves. Thus, it is incorrect to use half of the wavelength as the depth of the wave base.

From the perspective of marine sedimentary dynamics, this study provides another approach to calculate the wave base. Firstly, the relationship between sand particle size and critical wave orbital velocity is established. Thereafter, the probabilities of sand movement driven by ocean waves in 10 representative shelf sea regions around the world were calculated. The results show that the calculated wave bases are approximately 40% of those estimated by the trational method in the textbooks. The trational method which defines the wave base as half of the wavelengh brings great overestimations, which will cause considerable errors in field applications.

Keywords: Stratigraphy, dynamics, complexity

Deltas are intricate landforms that contain distributary channel networks, which transport water, sediment, and nutrients to coastal or inland water bodies. The dynamics of such networks are complex and can result in highly variable and nonlinear spatio-temporal erosional and depositional patterns. In this study, we quantify how the probabilistic structure of these erosional and depositional patterns relate to the probabilistic structure of the temporally preserved stratigraphic record. The data used in this study are obtained from the large-scale experiments conducted at the National Center of Earth-surface Dynamics, University of Minnesota. Based on a statistical framework that quantifies scale-dependent variability and intrinsic nonlinearity in the elevation fluctuations, we show a transition in the surface dynamics and complexity from a channel-dominated regime to a floodplain-dominated regime. In particular, we show two distinct regimes in the power spectral density, which characterizes variability across a range of scales, of elevation transects at different time instants. We further show that channelized features introduce more complexity (higher nonlinearity) to the structural arrangement of elevation fluctuations on a topographic surface. These observations indicate that scale-dependent processes governing channel and floodplain dynamics require different time scales to create surface topography and the resulting heterogeneity seen in associated strata.

Where and Why Do Submarine Canyons Remain Connected to the Shore During Sea-level Rise? – Insights from Global Topographic Analysis and Bayesian Regression

Anne Bernhardt[1*], Wolfgang Schwanghart[2]

1. Institute of Geological Sciences, Freie Universität Berlin, Berlin , Berlin, GERMANY

2. Institute of Environmental Sciences and Geography, Potsdam University, Potsdam, Brandenburg, GERMANY

E-mail: anne.bernhardt@fu-berlin.de

Keywords: submarine canyons, Erosion, Bayesian regression, marine geomorphology

Since the last glaciation, sea level has risen by about 120 meters. As a consequence, most coastlines have migrated landward, inundating large shelf areas. Some of these areas are now dissected by submarine canyons. However, with only 4% of the world's submarine canyons reaching todays coastline, these canyons remain the exception. This has important consequences as the efficiency of sediment routing from land to the ocean largely depends on the position of submarine canyon heads with regard to terrestrial sediment sources. Here, we aim to identify the environmental factors and Earth surface processes that control whether rates of headward submarine canyon incision can keep pace with landward migration of the coastline during the Holocene.

Globally, we identified 798 submarine canyon heads that are currently located at the 120m-depth contour (the Last Glacial Maximum shoreline) and 183 canyon heads that are connected to the shore (within a distance of 6km) during present-day highstand. Regional hotspots of shore-connected canyons are the Mediterranean active margin and the Pacific coast of Central and South America. We used 34 terrestrial and marine predictor variables to predict shore-connected canyon occurrence using Bayesian regression. Our analysis shows that steep and narrow shelves facilitate canyon-head connectivity to the shore. Moreover, our analysis supports the occurrence of such submarine canyons offshore river basins, that are characterized by resistant bedrock and high water discharge. Such rivers deliver coarse-grained sediment to submarine canyons, which can erode the canyon head and floor. To this end, our analysis offers new insights into the formation and maintenance of submarine canyons that are required to efficiently transport sediments, pollutants and organic carbon from rivers to the ocean floor.

Multiple Time-scales Ocean Front Variations in the Yellow Sea

Chunyu Ren[1], Jianhua Gao[1*]
1. School of Geography and Ocean Science, Ministry of Education Key Laboratory for Coast and Island Development, Nanjing University, Nan Jing, Jiang Su Province, CHINA
E-mail: jhgao@nju.edu.cn

Keywords: Yellow Sea, Ocean Front, Big Data, Deep Learning

Ocean fronts are an important barrier to material exchange between nearshore and deep oceans, and its variations in strength exert significant role in the terrestrial material transport and global material cycle. Affected by winter storm, ocean temperature fronts are formed between the branches of West Pacific Boundary Current and the coastal current during the winter and spring seasons in the eastern shelf of China (ESC). Therefore, in order to investigate the terrestrial material transport and cycle in the ECS, it is necessary to understand the relationship between winter storm and temperature ocean fronts.

Deep learning and Signal decomposition are new technologies to process big data. On the weather scale, we investigate the coupling of low-latitude driven circulation systems and high-latitude driven winter storms on frontal variability with the moethods of deep learning. On the decadal (20 years) scale, we analyze how the frontal strength response to the Yellow Sea Warm Current (YSWC), using EOFs and EEMD to analyze potential temperature data in Yellow Sea.

The results indicate that only one mode of EOF dominates the sea surface temperature changes in the Yellow Sea, and its corresponding spatial pattern is significantly characterized by the YSWC and coastal currents. The time series of this mode is highly correlated with the inter-annual variability (derived from EEMD). In addition, the decadal mode of the YSWC is strongly correlated with the ENSO3 index, which dominates the low frequency variations of sea surface temperature pattern. These two results further reveal that, although the inter-decadal frontal variation was predominated by the strength of the YSWC, the strength of fronts positively correlated with that of YSWC in the southern part of the Liaoning Peninsula, while the front intensity increases and then decreases with the YSWC enhancing in Northern Shandong Peninsula and Western Korean Peninsula.

On the weather scale, in order to get the output of Sea Surface Temperature, a CNN-LSTM model is trained through inputting sea surface height and flow field at a water depth of 20 metres. Subsequently, the integrated gradient method is used to explore the dominating influence factor of ocean frontal variations triggered by winter storms. The results show that, in windless conditions, the strength of ocean front is maintained by the combination of pressure gradient forces resulted from sea surface height and Coriolis forces caused by flow field. However, in the storm conditions, influenced by Kelvin wave propagation and shear front fragmentation, the flow field is responsible for the ocean front variation.

The above results show that big data is a valuable tool to investigate climate change and the response of ocean system from different time scales. In practical cognition, our conclusion demonstrate that climate change will significantly influence the process of material cycle through altering ocean front intensity. Therefore, under the condition of future climate changes, the strength of material transport between near-shore and deep sea, together with its impact on ocean system is worth of further attention.

E-mail: sarah.mosser@fu-berlin.de

Keywords: quaternary climate, earth surface dynamics, inverse modeling, XRF, dynamical systems

Climate is one of the dominant controls shaping landscapes on interglacial time scales and has a long-term and non-linear impact on landscape dynamics. However, stratigraphic records of landscapes store information on both, past climates and the adjustment of landscapes to new climatic boundary conditions in the same sedimentary archive. The superposition of climate forcing and landscape response signals in sediment records challenge straightforward climatic interpretations. Here, we combine independent records of precipitation, sediment accumulation rates and composition offshore Western Sumatra to reconstruct landscape adjustment to climate over the past ~ 13 ka.

Using an inverse modeling approach, we show that an abrupt precipitation increase following the last deglaciation approximately 12 ka ago initiated a trajectory of landscape processes. The abrupt shift in climatic boundary conditions led to cyclic variations of enhanced deposition of terrestrial particulates and marine authigenic sediment. The landscape trajectory acts as an ongoing memory of landscape adjustment processes that will eventually fade out approximately 20 ka after the initial precipitation increase (~ 8 ka from now). These findings call for extending the conceptual models of landscape adjustment times and processes and to incorporate landscape trajectories as long-term feedback processes into landscape evolution models to predict future landscape adjustment to climate change.

Reconciling inconsistent trends of environmental magnetic, Li isotope and elemental records from East Asian sediments based on modern calibration and paleoclimate analysis

Junsheng Nie[1*], Li Xing[1], Peng Gao[1], Su Li[2], Xueping Ren[1]
1. College of Earth and Environmental Sciences, Lanzhou University, Lanzhou, Gansu, CHINA
2. School of Earth Sciences, Lanzhou University, Lanzhou, Gansu, CHINA
E-mail: jnie@lzu.edu.cn

Keywords: Magnetic parameters, Li isotope, elemental weathering proxy, Qilian Shan

Accurately reconstructing the evolution of the Asian monsoon is predicated on understanding the impact of temperature, precipitation, and tectonic paleogeography on silicate weathering and environmental magnetic proxies over million year timescales. Here we present transfer functions between precipitation/temperature and magnetic parameters, Li isotopes, and element-based chemical weathering proxies, from an elevation transect from the Qilian Shan. The results show that all of these parameters are more sensitive to precipitation than temperature. However, when applying them to Neogene strata of the Qaidam Basin, strikingly different trends are observed. We compare the generated records with established temperature and CO_2 records in order to reconcile the different trends. The comparison reveals that variations of the elemental weathering proxy records in the Qaidam Basin were likely controlled by temperature, whereas magnetic parameter variations were mostly controlled by precipitation amount which is in turn determined by CO_2 and tectonic paleogeography conditions. Interestingly, the Li isotopes in the Qaidam Basin indicate low degree of chemical weathering intensity over well-established warm periods, which we interpret as a result of intensified congruent weathering. This case demonstrates the advantages of combining geochemical and magnetic proxies in terrestrial paleoclimate reconstruction and we conclude that an integrated approach is the best one to reconstruct temperature and precipitation history from terrestrial records.

Effects of wave-current interactions on sediment dynamics in Hangzhou Bay during Typhoon Mitag

Li Li[1*], Jiayang Xu[1], Yihan Ren[1], Xiao Hua Wang[1], Yuezhang Xia[1]
1. Ocean College, Zhejiang University, Zhoushan, Zhejiang, CHINA
E-mail: lilizju@zju.edu.cn

Keywords: sediment dynamics, wave-current interactions, Typhoon Mitag, Hangzhou Bay

The hydrodynamics and sediment characteristics of muddy estuaries and coasts during typhoons are closely related to geomorphic evolution, ecological environment, and economic development of coastal zones. Taking the macro-tidal turbid Hangzhou Bay (HZB) as an example, the sediment characteristics and the effects of wave-current interactions on sediment dynamics during Typhoon Mitag were studied using a well-calibrated numerical model. The model considers tides-wave-sediment interactions and the reconstructed typhoon wind field. The net sediment fluxes were controlled by residual currents and SSC. The combined interactions of currents and waves led to high SSC during the typhoon. In calm conditions, the impact of wave-current interactions was small except for the combined bottom stresses. The combined bottom stress was the primary wave-current interaction changing the sediment resuspension and increasing SSC, especially in shallow waters or during storms. The advection term, which played an essential role in reducing the SSC in HZB, mainly affected the SSC by enlarging the velocity. The wave dissipation term enhanced the vertical mixing, which involved the vertical exchange of suspended sediment and the currents. In the shallow waters of the southern bay, the wave dissipation term mostly led to the decrease of bottom stresses, the increase of currents, and the decrease of SSC, while the rise of SSC in the deep waters. The effects of the form drag, wave radiation stress, and refraction terms on suspended sediment dynamics were relatively small. The findings provide the theoretical foundations for the study of dynamics geomorphology in macro-tidal estuaries.

2. Geology & Geophysics, Woods Hole Oceanographic Institution, Woods Hole, Massachusetts, UNITED STATES

E-mail: yananli.nju@gmail.com

Keywords: tsunami, sedimentary, lagoon, volcanic, Kuwae

Both tropical cyclones and tsunamis have been causing significant damages and loss of human lives and resources in heavily populated coastal regions, and they have gained extensive attention. Their frequent occurrence in the South Pacific highlights the necessity of distinguishing their event deposition. In this study, a sediment core was recovered from Marou Lagoon in Emao Island, Vanuatu. A special event bed with multiple stacking sub-layers (total thickness, 36 cm) was identified. According to the sedimentary characteristics and material source analysis of the sub-layers, this bed was confirmed to be left by a tsunami event rather than a storm landfall. The dynamic process of its formation was deduced based on material source information and the local environment settings. Considering the radiocarbon results and volcano eruption records in this area, it probably points to the tsunami caused by Kuwae's explosive eruption in 1452 CE. Because of the peculiar sedimentary facies of this event bed compared to previous studies in similar environments, it is more substantial to use dynamic methods rather than merely rely on sedimentary characteristics.

Impacts of sediments on dissolved oxygen concentration in macro-tidal turbid Hangzhou Bay

Jiayang Xu[1], Li Li[1], Yuezhang Xia[1*]
1. Ocean College, Zhejiang University, Zhoushan, Zhejiang, CHINA
E-mail: yzxia@zju.edu.cn

Keywords: Hangzhou Bay,Numerical simulation,Dissolved oxygen,Sediment

Estuaries and coastal areas connect the terrestrial and oceanic environments, and are essential for both marine economy and ecosystem. Hangzhou Bay located in the east coast of China and is known as its macro-tides and high turbidity. In this study, a three-dimensional numerical model, coupling tide-wave-sediment-ecology, is established and validated using field data in both calm and extreme weather conditions. The impacts of sediment on the key parameters of ecosystem are studied using the numerical model and field data. The results show that the dissolved oxygen concentration (DOC) near the surface decreases from the north to the south, and the DOC near the bottom decreases from the northwest to the southeast. The bottom DOC is higher in the open sea than in the coastal waters. The DOC in the southeast of Zhoushan sea area is lower than the surrounding areas, and the bottom seawater tends to hypoxia. The DOC changes periodically with the flood-ebb and spring-neap tidal cycles. There are seasonal changes in the DOC, with higher values occur in winter. Water stratification is obvious in summer, and the pycnocline of DOC is obvious. The winds enhance the mixing of surface and bottom seawater, causing the bottom DOC rise. The temperature has an important influence on the distribution of DOC.

E-mail: mengli.chen@nus.edu.sg

Keywords: lead, particulate exchange, boundary exchange

Material fluxes at the land-ocean interface modulate seawater composition and the global cycling of elements. Lead (Pb), for example, tends to have fluvial particulate fluxes into the ocean that are two orders of magnitude higher than the dissolved counterpart. However, the role of particulates as a source of seawater Pb is not understood thoroughly, limiting our interpretation for sedimentary records. Here, using field measurements of Pb concentration and isotope in seawater around Peninsular Malaysia, together with model simulations, we show that particulate-dissolved exchange an important mechanism controlling the concentration and isotopic composition of Pb in the dissolved pool. This particulate exchange can deliver much of the Pb to the ocean, especially before the Anthropocene. Our model indicate that particulate-exchange flux is larger than, or at least comparable to, other natural Pb sources to the ocean. Our work demonstrates the need for further investigations on particulate-dissolved element exchanges to better interpret the weathering-climate feedback in sedimentary records.

Surface oxygen isotope seasonality of the South China Sea revealed by individual foraminifers collected in a sediment trap

Ning Zhao[1,2*], Hubert Vonhof[2], Hui-Ling Lin[3], Gerald Haug[2]

1. SKLEC, School of Marine Sciences, East China Normal University, Shanghai, CHINA
2. Climate Geochemistry Department, Max Planck Institute for Chemistry, Mainz, Rheinland-Pfalz, GERMANY
3. Department of Oceanography, National Sun Yat-Sen University, Kaohsiung, CHINA TAIWAN

E-mail: nzhao@sklec.ecnu.edu.cn

Keywords: Oxygen isotope, Individual foraminifer analysis, Seasonality, Sediment trap, South China Sea

Most paleoceanographic studies using planktic foraminifera (PF) are based on multi-shell analyses, but seasonal signals buried by the measurements of lumped specimens are very valuable. Oxygen isotope measurements on individual PF shells could potentially reveal seasonal changes in density and stratification, which is controlled by temperature and precipitation-evaporation imbalance. However, verification of this application is still missing. Based on foraminifers collected by a sediment trap in the northern South China Sea, we show that oxygen isotope data of individual PF shells faithfully record the seasonality of density in the surface ocean, and the seasonal stratification strength when data from species dwelling at different depths are combined. Flux data of the sediment trap suggest that most of the PF shells calcify in winter, so individual shell analyses of sediment samples downcore are needed to reconstruct paleo surface ocean processes of the summer and the annual mean in the northern South China Sea.

Pyrite sulfur content and isotope reveal marine transgressions of the east coast of China since MIS5

Xiting Liu[1*], Xin Chang[1], Mingyu Zhang[1], Jing Chen[2], Houjie Wang[1]
1. College of Marine Geosciences, Ocean University of China, Qingdao, Shandong, CHINA
2. State Key Laboratory of Estuarine and Coastal Research, East China Normal University, Shanghai, CHINA
E-mail: liuxiting@ouc.edu.cn

Keywords: Pyrite, Sulfur isotope, C/S ratio, Climate change, Marine transgression

Sea-level history reconstruction of the coastal area during geological history is the key to understanding how these areas respond to marine transgression. Here we attempt to use pyrite sulfur contents and its isotopic compositions to trace the marine transgression of the east coast of China since MIS5 (Liu et al., 2019; 2020; 2021). Our results suggest that the ratio of total organic carbon and pyrite sulfur contents (C/S) could distinguish between freshwater and marine environments, which are represented by high and low C/S ratios. In addition, pyrite production in sediments deposited at the beginning of the sea-level rise might be limited by sulfate supply as reflected by more positive values of $\delta^{34}S_{pyr}$. Therefore, our new findings provide a new perspective for identifying the marine transgression in stratigraphic records, especially when the sedimentary strata lack obvious lithologic and paleontological differences.

Episodic erosions on the Changjiang River subaqueous delta clinoform since mid-Holocene: sub-bottom stratigraphic evidences

Wei Feng[1], Shihao Liu[1], Yaping Wang[1*]
1. State Key Laboratory of Estuarine and Coastal Research , East China Normal University, Shanghai, CHINA
E-mail: ypwang@sklec.ecnu.edu.cn

Keywords: erosion, subaqueous delta, sub-bottom seismic profile, Changjiang River, clinoform

In recent years, under the dual pressure of climate change and human activities, the estuarine delta regions have faced a significant systemic state transition, as well as the risks of erosion and saltwater invasion have intensified. The erosion of estuarine deltas on short- and medium-term time scales (seasonal, annual, decadal scales) has attracted much attention worldwide. However, the sedimentary system of the estuarine delta is formed at a longer time scale, and the clinoform of the subaqueous delta is generally considered to be a stable sedimentary environment, which is heavily used for the acquisition and study of sedimentary records. Through sub-bottom seismic profiles, boreholes and gravity cores studies, we found that under the condition of stable sea-level since the Middle-Holocene (about 7 ka B.P.), there has been episodic large-scale erosions of the Changjiang River subaqueous delta. The upper strata of the erosion interface present a downlap, and the clinoforms appears to be truncated, which area is huge, and extends tens to hundreds of kilometers from north to south of the subaqueous delta. Simultaneously, the truncation is relatively flat, which seems to be a long-term and continuous erosion process. The age of the borehole shows that the older erosion interface was formed between 5-3 ka B.P., while the overlying sediments is eroded between 3-1.7 ka B.P., and there is a diachronous between the north and south subaqueous delta, and a time-lag in the south. This erosion phenomenon may be due to the narrowing of the estuary of the Changjiang River, resulting in a decrease of sediments to the sea. Meanwhile, it might due to the Changjiang River Delta has been in a stable of accumulation, forming a U-shaped terrain during the stacking process, which leads to changes in coastal flow, resulting in erosion of the clinoforms.

Observation and Study on the Initiation of Sand-muddy Sediments Influenced by Coastal Constructions

Jian Chen[1*]

1. Geology, Third Institute of Oceanography, Ministry of Natrual Resources, Xiamen, Fujian, CHINA

E-mail: chenjian@tio.org.cn

Keywords: Initiation velocity, Resuspended flux, Sedimentary environment, Sediment resuspension

The construction of large-scale inshore projects such as reclamation and channel dredging will inevitably change the composition of seabed sediments around the project area, which will have a huge impact on the nearshore ecosystem, especially the protected areas with important ecological value. The seabed surface of such areas affected by engineering construction is often settled with suspended particles of abnormal origin, which are quite different from the original natural sediments in terms of sediment source and sedimentary dynamic characteristics. To study the differences of sedimen between natural and influenced by the offshore engineering construction and the possibility of benthic environments restoration, a submarine tripod observation system, with OBS, ADCP and ADV was deployed for near bottom currents and suspended sediment, and with the collection and analysis of surface sediment samples, the initiation velocity and re-suspension flux of seabed sediment were studied in west of Dadeng Island in the Xiamen Bay, which is close to reclamation area of the Xiamen New Airport. The observed results show that (1) there is a significant re-suspension phenomenon in the study area, and the measured initiation velocity is between the value calculated by the existing initiation velocity formula for viscous sand and non-viscous sand. (2) During the spring tide, the sediment eroded flux near the observation point is greater than the sedimentation flux, and the sedimentary environment is mainly in eroded condition. (3) The fine particles in the surface of seabed sediment will be carried away by the tide during the spring tide, which is beneficial to the reconstruction of the benthic environment in the future.

Zooplankton fecal pellet characteristics and contribution to the deep-sea carbon export in the southern South China Sea

Jiaying Li[1], Zhifei Liu[1*], Baozhi Lin[1], Yulong Zhao[1], Junyuan Cao[1], Xiaodong Zhang[1], Jingwen Zhang[1]
1. State Key Laboratory of Marine Geology, Tongji University, Shanghai, CHINA
E-mail: lzhifei@tongji.edu.cn

Keywords: Zooplankton fecal pellet, Carbon flux, Carbon export, South China Sea

Zooplankton fecal pellets sinking from the sea surface and water column constitute an important component of the marine biological pump and play a significant role in particulate organic carbon (POC) export, which has been widely reported in different ocean regions. However, fecal pellet carbon flux in the tropical marginal seas and its contribution to the total POC flux has not been deeply explored yet. Here, for the first time we studied zooplankton fecal pellet carbon flux in the South China Sea via one mooring with two sediment traps deployed at 500 m and 2190 m in the Nansha area from June 2020 to May 2021. Zooplankton fecal pellets were identified, counted, and measured according to three shapes: ellipsoidal, cylindrical, and spherical, which are most likely produced by various zooplankton communities including copepod, appendicularia, pteropod, euphausiid, amphipod, ostracod, and crustacean nauplii. Average fecal pellet numerical flux was $2.30*10^4$ and $4.22*10^4$ pellets m^{-2} d^{-1} at 500 m and 2190 m respectively, corresponding to average fecal pellet carbon fluxes from 0.31 to 0.71 mg C m^{-2} d^{-1}. Small ellipsoidal and spherical pellets accounted for more than 90% of the total numerical flux, while larger cylindrical pellets, although relatively rare (6%), accounted for almost 15% of the overall pellet carbon flux. Both fecal pellet numerical and carbon fluxes were lower in summer and higher in winter, with highest values showing up in December to early January, when the strong northeast winds and heavy rainfall increased the marine productivity and promoted the growth of zooplankton communities. Higher fecal pellet fluxes combining with the presence of extra-large pellets at 2190 m compared to those at 500 m suggested the in-situ repackaging of deep-dwelling communities as well as the zooplankton diel vertical migration in mesopelagic and bathypelagic zones. Contribution of identifiable fecal pellets to total POC flux in the southern South China Sea ranged from 0.4% to 30.0% (averaging 9.0%), with higher values occurring during winter monsoon, at which time fecal pellets became a critical conveyor of carbon to the deep sea. Our study confirms the significant role of zooplankton fecal pellet in local carbon export and provides new insight into the processes controlling the marine carbon cycle.

Spatiotemporal distribution of diatom-derived oxylipins in coastal oceans: Implications for coastal hypoxia and carbon export

Zhengchao Wu[1], Qian P. Li[1*], Jie Xu[1], Bangqin Huang[2], Chunming Dong[3]
1. State Key Laboratory of Tropical Oceanography, South China Sea Institute of Oceanology, Chinese Academy of Sciences, Guangzhou, Guangdong, CHINA
2. State Key Laboratory of Marine Environmental Science, Xiamen University, Xiamen, Fujian, CHINA
3. Key Laboratory of Marine Genetic Resources, Third Institute of Oceanography, MNR, Xiamen, Fujian, CHINA
E-mail: qianli@scsio.ac.cn

Keywords: Diatoms, Oxylipins, Coastal ocean, Hypoxia, Particle export

The biological pump is driven by the interaction of biological processes, which is of great significance to carbon sink and global climate change. Diatoms play an important role in the export flux of particles through vertical sinking in benthic and pelagic food webs [1], accounting for 20-40% of the total primary production of the earth. Marine diatoms respond to environmental stress by producing bioactive oxylipins, which are the enzyme-catalyzed oxidation products of membrane lipids and can reflect the environmental conditions of their biosynthesis. Polyunsaturated aldehydes (PUAs) are very important and well studied components in diatom oxylipins. Although PUAs account for only a small proportion of biogenic organic carbon, they serve as allelochemicals to potentially influence the behavior of diatom grazers and competitive phytoplankton, as well as microbial remineralization of phytoplankton-derived sinking particles [2, 3].

Due to the influence of large river input, the coastal ocean has high primary productivity and export flux of particles. There are intense phytoplankton blooms outside the Pearl River Estuary (PRE) with the predominant species being PUAs-producing diatoms. We preliminarily report the high-resolution spatiotemporal distribution patterns of PUAs, their physical and biological controlling factors, and their potential biogeochemical effects, including those related to particulate matters in the PRE [3, 4]. The spatial distribution change of PUAs composition percentage at the surface frontal zone is consistent with the cross-front shift of the dominant PUAs-producing diatoms population. In addition, the particulate PUAs were significantly correlated with the turbidity in the bottom boundary of the front during the cross-front transect, which indicated a biological source of a sedimentary source of bottom PUAs. Biogeochemical implications of PUAs on the coastal ecosystem include not only the deleterious restriction of high PUAs-producing diatom bloom on copepod population and particulate carbon transfer but also the profound influence of particulate PUAs on the microbial cycling of organic carbon in the PRE [3, 4]. The particle-adsorbed PUAs (micromolar level) associated with sinking or suspended particles retrieved from hypoxic waters have been found to have the potential to affect the growth, metabolism, and community structure of particle-attached bacteria. The change in bacterial activity and composition could lead to an enhancement of oxygen utilization during the remineralization of particulate organic matter. Therefore, the export of particles will decrease, the consumption of dissolved oxygen in the water will increase, and thus the formation of coastal hypoxia may be aggravated [5].

Keywords: sinking POC, radiocarbon, stable carbon isotopes, source assessment, lateral transport

Lateral particle transport in shelf/slope settings of marginal sea systems have been reported as a widespread phenomenon, and may potentially supply allochthonous particulate organic carbon (POC) to the ocean interior. The magnitude and prevalence of such processes has implications for our understanding of the functioning and efficiency of modern biological carbon pump (BCP) processes, as well as for interpretation of deep ocean sediment records. Yet, ages, and relative contribution of POC from different sources to deep ocean basins are much less understood than those in the shallower regions. Here, based on radiocarbon (F_m, fraction modern), stable carbon ($\delta^{13}C_{org}$) and other geochemical analysis of particles intercepted by time-series sediment traps deployed at three different depths (1000 m, 2150 m, 3200 m), we constrain the source of the sinking POC in the deep basin of northern South China Sea (SCS). POC fluxes at the study site range from 1.3~12.5 mg m^{-2} d^{-1} (n=59) with significant temporal variations in each depths, while the C/N mole ratios, δ13Corg values and Fm values of sinking POC range from 6.6~9.6 (n=59), −23.2‰~−22.1‰ (n=59), 0.90~1.04 (n=59), respectively, indicating relatively constant characteristics dominated by modern marine productivity. Employing a Fm-LM/POC binary mixing model, we find that the modern POC derived from surface ocean productivity, acting as the vertical vector, accounts for 86.7±3.6% of sinking POC on average, while the lateral vector (aged POC hosted on resuspended sediment) comprises the remainder (13.3%), suggesting that sinking POC in the mesopelagic and bathypelagic realm of the northern SCS basin (1000~3200 m) predominantly derives from vertical export via the BCP. The contribution of laterally-supplied POC increases with depth, and is comprised of aged POC derived from several sources. The majority stems from sediment resuspension of the northeastern SCS slope, that entrains aged marine POC (dominant), fossil OC, and soil OC (least significant). The diminished proportion of fossil OC relative to deep basin sinking POC in Taiwan-proximal areas is likely due to its dispersion via resuspension-deposition loops and dilution by POC stemming from modern surface ocean productivity during the delivery. These results, which represent a first assessment on the age and source of sinking POC in the deep northern SCS basin, indicates that laterally supplied aged POC has minimal impact on the strength and temporal dynamics of BCP processes in the mesopelagic ocean. However, the importance of laterally supplied POC and complexity of POC sources increases with depth, underlining the importance of considering sedimentary OC resuspension and dispersion in bathypelagic and sedimentary records of these dynamic marginal sea systems.

Keywords: Sinking particulate organic matter, Compound specific amino acid isotope, Sediment trap, Degradation

The sources and undergoing biogeochemical processes of sinking particulate organic carbon in the marginal seas are crucial to the budget of global. Yet, the provenance and dynamic particle processes in the northern South China Sea remain poorly understood. In this paper, based on particulate organic carbon (POC), amino acid (AA), total carbon isotopes ($\delta^{13}C_{bulk}$) and amino acid carbon isotopes ($\delta^{13}C_{AA}$) in the sinking particles intercepted by a sediment trap deployed at the mesopelagic layer of the northern South China Sea (SCS) from June 2009 to May 2010, as well as contemporaneous remote sensing data, we identify that the significant seasonal changes of POC flux and AA flux reflect the dynamic controls of multi-physical processes in the upper layer. The AA contents (% in POC) during the periods of winter monsoon and summer monsoon are 7.20 and 6.49, respectively. The relative fresh organic matter (OM) in winter is likely due to the higher productivity and subsequent faster POC export. Compound-specific $\delta^{13}C$ values of AA indicate that: (1) non-essential amino acid $\delta^{13}C$ values ($\delta^{13}C_{NEAA}$) reflect the effect of bacterial degradation, the significant relationships between $\delta^{13}C_{NEAA}$ and $\delta^{13}C_{bulk}$ values ($r = 0.67$, $p<0.05$), as well as the degradation indicator (Asp/β-Ala ratio) ($r = 0.54$, $p<0.05$), suggest that the sinking OM in the mesopelagic layer of northern SCS endures strong microbial alteration; (2) The normalizing measured pattern of essential amino acid $\delta^{13}C$ values ($\delta^{13}C_{EAA}$) in the sinking OM are consistent with those in phytoplankton, show a weak relationship with Asp/β-Ala and Glu/γ-Aba ratios, indicating that the EAA is mainly produced by primary production and the bio-modification of microbial is small during its vertical settling processes. Additionally, by combined analyzing of $\delta^{13}C_{EAA}$ linear discrimination and the bivariate scatter plot of the normalized $\delta^{13}C$ values of leucine and isoleucine, we find that the sinking POC is predominantly from picoplankton and diatom, while cyanobacteria, coccolithophore, dinoflagellate and chrysophyceae make a minor contribution.

Trace metal fluxes in mesopelagic sinking particles from the northern South China Sea: The importance of anthropogenic aerosol deposition

Weiying Li[1], Jingjing Zhang[1], Hongliang Li[1], Jianfang Chen[1,2*]

1. Key Laboratory of Marine Ecosystem Dynamics, Second Institute of Oceanography, Ministry of Natural Resources, Hangzhou, Zhejiang, CHINA

2. State Key Laboratory of Satellite Ocean Environment Dynamics, Second Institute of Oceanography, Ministry of Natural Resources, Hangzhou, Zhejiang, CHINA

E-mail: jfchen@sio.org.cn

Keywords: Anthropogenic aerosol, trace metal, sinking particles, the northern South China Sea

Anthropogenic aerosol deposition has become the dominant source of the particulate trace metal in the surface layer of South China Sea (SCS). However, it remains unclear that if the trace metals from anthropogenic aerosol can be transported into the ocean interior. In this study, time-series samples intercepted by three synchronized moored sediment traps deployed at 1000 m, 2150 m and 3200 m in the northern SCS during June 2009-May 2010 were analyzed to quantify the mesopelagic particulate trace metal fluxes and investigate their sources. The ratios of Fe, Ti, V, Cr to Al in sinking particles were very close to their continental crustal ratios, indicating that they were originated from a lithogenic source. Whereas the ratios of Mn, Co, Ni, Cu, Zn, Mo, Cd and Pb to Al showed various degrees of enrichment over their continental crustal ratios (enrichment factor, i.e. EF>2). Meanwhile, the characteristics of these trace metals were consistent with the high EF values in the surface layer, which is likely due to the influences of natural and anthropogenic processes. Using a mass balance approach, anthropogenic aerosol Zn was estimated to account for 63±16%, 65±10%, 56±11% of the total Zn in the sinking particles at three depths, respectively, while anthropogenic aerosol Co was responsible for 27±10%, 42±8%, 52±5%, respectively. These results suggest that trace metals input from anthropogenic aerosols as an important source can be transported from surface to the deep waters via sinking particles. Further investigations are needed to elucidate how anthropogenic aerosol deposition affect trace metal fluxes and cycling.

Keywords: Sinking flux, Particulate organic carbon, South China Sea

The settling processes of organic carbon in the ocean comprise a major component of the global carbon cycle. However, studies on long-term time series change in the sinking flux and nature of particulate organic carbon (POC) in the deep ocean remain scarce and is required to better understand the ocean carbon cycle. Here, we present a 10-year (2011-2021) sediment-trap mooring observation on the flux and source of POC at water depths of 500 and 1960 m in the northern South China Sea. The POC fluxes at 500 and 1960 m showed considerable seasonal and interannual variations, ranging from 0.19 to 18.93 mg m-2 d-1 and from 0.75 to 63.59 mg m-2 d-1, respectively, with increased fluxes in the winter. Higher fluxes of POC also occurred occasionally in the spring (2014 and 2017) and the summer (2012) at 500 m and in most of the summer at 1960 m. The POC fluxes were higher at the 1960 m than those at 500 m (10.29±9.14 vs. 3.79±3.43 mg m-2 d-1), indicating additional inputs from mesopelagic/bathypelagic zones and/or horizontal advection in this region. δ13C values of POC showed no seasonal and interannual changes, ranging from –24.1 to –19.6‰ (–22.4±0.06‰) at 500 m and from –22.8 to –21.3‰ (–22.3±0.2‰) at 1960 m, respectively. The Fm values (14C activity) of POC with a mean of 1.04±0.01 (n=3) at 500 m in 2015 indicate a source of newly formed primary production from the euphotic zone above, while slightly lower Fm values (0.89–0.97) found at 1960 m during 2014–2016 were attributed to horizonal addition of terrestrial materials (Blattmann et al., 2018). The mixing model shows that primary productivity-sourced POC played a key role in the significant increase of organic carbon flux in the mesopelagic/bathypelagic deep ocean.

Coupling regulation of surface mixing and thermocline on the biological pump in the Asian monsoonal marginal seas

Jinping Yu[1], Hongliang Li[1*]

1. Key Laboratory of Marine Ecosystem and Biogeochemistry , Second Institute of Oceanography, Hangzhou City, Zhejiang Province, CHINA

E-mail: lihongliang@sio.org.cn

Keywords: biological carbon pump, Asian monsoon areas, sediment traps, mixed layer depth, thermocline

East Asian monsoon is regarded as the primary driver of seasonal fluctuations in the biological pump strength of the tropical marginal seas, such as Arabian Sea (AS), Bay of Bengal (BoB), and South China Sea (SCS). However, biogeochemical similarities and differences among the three areas, as well as the mechanisms of physical forcings on the seasonality in the fluxes and characteristics of sinking particles remain poorly understood. In this study, compiled time series sediment trap data (sinking particle fluxes and components) from three stations at central AS, BoB and SCS, respectively, were used in combination with climatological data from remote sensing and models to evaluate the combined effect of mixing and thermocline variation on the strength and efficiency of biological pump. The results showed that seasonal monsoon produces a distinct seasonality in the vertical fluxes of sinking particles, the fluxes during monsoon periods were generally higher than those during inter-monsoon periods. Significant relationships between the fluxes (fluxes anomaly as well) of sinking particles and the depths-difference (differences calculated between mixing layer depth and thermocline depth) were also observed, indicating that seasonally enhanced mixing and shoaled thermocline (nutricline) would replenish more nutrient into the euphotic layer, and therefore trigger higher primary production and subsequent higher sinking particle fluxes in the marginal seas. However, the efficiency of biological pump in the central BoB was relative higher than those in the central AS and central SCS, which is likely due to the stronger ballast effects, resulted by the dominant species of diatom and chlorophyte clades and the extremely high lithogenic matter fluxes.

Time-series variations of zooplankton fecal pellet flux in the western South China Sea

Junyuan Cao[1], Zhifei Liu[1*], Jiaying Li[1], Yulong Zhao[1], Baozhi Lin[1], Xiaodong Zhang[1], Jingwen Zhang[1]
1. State Key Laboratory of Marine Geology, Tongji University, Shanghai, CHINA
E-mail: lzhifei@tongji.edu.cn

Keywords: Zooplankton fecal pellects, Particulate organic carbon, Seasonal variation, Western South China Sea, Sediment trap

Zooplankton fecal pellets are important vehicles for the transfer of particulate organic carbon to the deep sea, acting as a key contributor to the marine biological pump. Here, we studied time-series variation of zooplankton fecal pellet flux via one mooring with two sediment traps deployed at 500 m and 1170 m water depth from June 2020 to May 2021 in the western South China Sea. By counting, measuring, and biovolume calculating, we obtained numerical and carbon fluxes of fecal pellets of these sediment-trap samples. The numerical flux of fecal pellets was averagely 2.04 and $1.52*10^4$ m^{-2} d^{-1} at 500 m and 1170 m, respectively, and the carbon flux of fecal pellets was averagely 0.18 and 0.26 mg C m^{-2} d^{-1}, respectively. Both numerical and carbon fluxes varied greatly through time, exhibiting clear seasonal variations, with a primary peak in the spring at both depths and a secondary peak in the winter at 1170 m water depth. Distinct morphological types of fecal pellets contribute differently to the numerical and carbon fluxes. Ellipsoidal and spherical pellets accounted for 96% of the numerical flux at both water depths. Cylindrical pellets were rare in abundance (4%), but accounted for more than 10% of the total fecal pellet carbon flux. During the sampling period, the proportion of particulate organic carbon flux attributed to zooplankton fecal pellets ranged from 1.7 to 10.9%, with higher values occurring during periods when the water column was vertically mixed and the phytoplankton bloomed. Multiple mechanisms may be responsible for the production and fate of fecal pellets as well as their contribution to settling particulate organic carbon.

E-mail: thomas.blattmann@erdw.ethz.ch

Keywords: Rietveld, sediment trap, mineralogy, XRD, X-ray diffraction, mooring

Sediment represents a complex mixture of minerals and organic matter including products of physical and chemical weathering, biomineralization, and others. The mineral fraction typically comprises the majority of sediment mass and frequently includes crystalline minerals such as phyllosilicates, tectosilicates, carbonates, and others as well as amorphous minerals. These minerals differ greatly in their properties and genetic origin (e.g., lithosphere, pedosphere, ocean). Furthermore, they carry and record distinctly separate signatures of Earth's lithosphere, biosphere, climate, ocean chemistry, etc. By conducting Rietveld refinement of X-ray diffraction patterns, fully quantitative mineralogical composition of a mineral matrix can be disentangled. Using this tool, we report on a one-year time series of sedimentary particles intercepted by sediment traps between 1900 and 3800 m water depth in the northeastern South China Sea. We obtain quantitative contents of major mineral species such as calcite, chlorite, kaolinite, muscovite, plagioclase, quartz, and smectite, quantify contents of minor mineral species such as clinoptilolite, hornblende, laumontite, magnetite, and rutile, and also quantitatively constrain the content of X-ray amorphous material. We find that the mineralogical compositions are strongly correlated with the surface properties (surface area and cation exchange capacity) of the bulk sediment and are systematically related to the provenance of associated sedimentary organic matter. We will report on our progress in this congress. The application of Rietveld refinement for computing mineralogical composition is relatively new in geosciences and it is leading to intriguing new insights related to sediments on Earth (Blattmann et al., 2019) and Mars (Rampe et al., 2020).

E-mail: elena.bruni@erdw.ethz.ch

Keywords: SLOB hypothesis, sediment threshold of motion, organic matter, EROMES erosion chamber

The onset of sediment erosion in is governed by sediment properties such as grain size, density, and environmental controls such as current strength. Investigating the relevance of each of these parameters has been an ongoing part of experimental sedimentology, resulting in several empirical threshold of motion curves [1,2]. These are used for different geotechnical applications, but so far, none of these include the effects of organic matter (OM) on particle motion, a draw-back that has been identified early on and limits the applicability in natural systems [e.g., 3]. We perform sediment erosion experiments on natural, untreated OM-rich sediments to investigate the impact of high OM concentrations on the sediment threshold of motion. Six sediment cores from Swiss lakes were inserted to EROMES, a resuspension chamber using a propeller to produce and control shear stress [4,5]. By incrementally increasing propeller rotation rates, the first and second erosion thresholds were identified. Measuring OC (%) revealed the fluff eroded at er I has higher concentrations than the suspended particles at er II and consists of labile aggregates and free OM (e.g., leaves). Moreover, the presence of benthic organisms (tube worms) resulted in a measurable strengthening of the sediment surface. The measurements of er I and II are plotted against calibration measurements performed with standardized (quartz) grains of known grain size distribution, which reveals the lower threshold of motion of particles associated with OM. Consequently, we argue for the recalibration of threshold motion curves to include low-density, OM-rich particles and the stabilising effects of benthic organisms [6].

Sedimentary Evolution Characteristics of Different Type Basins — A Quantitative Evaluation Using Stratigraphic Forward Modelling

Huiling Yang[1*], Jianmin zhu[1], Zhenpeng Li[1], Chunyuan Shi[1]
1. Development Research Institute, Cnooc (China) Co., LTD. Tianjin Branch, Tianjin, CHINA
E-mail: yanghl28@cnooc.com.cn

Keywords: sedimentary evolution characteristics, controlling factors, quantitative evaluation, different basin types, stratigraphic forward modelling

Passive continental margin basins, rift basins, and cratonic basins are three major types of petroliferous basins in mid-east China. The sedimentary filling processes and the stratigraphic configurations produced are unique for each basin type and the main controlling geological factors may differ significantly. Adequate understanding of the temporal and spatial differences in the stratigraphic architecture and sedimentation filling process of different types of basin, as well as the main controlling geological factors that cause the differences, will help revealing the evolution of the sequence formation and changes in the sedimentary filling patterns in the basins. and thus has important theoretical and practical significances on petroleum exploration.

The Pearl River Mouth Basin, the Bohai Bay Basin, and the Ordos Basin were selected as three representative basin types to investigate their sedimentary and sequence characteristics based on the data accumulated during scientific research and exploration practice over the past decades. Three-dimensional stratigraphic architectures and sedimentary facies of these basins are established using a quantitative stratigraphic modelling program. The temporal and spatial differences of sedimentary filling characteristics of the three types of basin are also comparatively modelled and quantitative evaluated. By varying the input geological parameters, the characteristics of the sequence stratigraphic development and sedimentary evolution are quantitatively evaluated. The main controlling factors are also determined by a quantitative examination of responses of the sedimentation and filling process to various controlling factors.

The research results show that the filling of the Pearl River Mouth Basin is mainly controlled by the supply of sediments and the fluctuations of sea level. The steep slope segment (side) and the gentle slope segment of the Dongying Sag in the Bohai Bay Basin have different sedimentation filling characteristics and are controlled by different factors. For the gentle slope segment, sequence development is mainly determined by the amount of the accommodating space formed by the fluctuations of the lake level and the sediment supply. The sediment filling of the steep slope segment is mainly controlled by the rate of tectonic subsidence, in contrasting to the gentle slope segment, and its sedimentary filling is less sensitive to lake level fluctuations. In the Ordos Basin, the changes in lake level and sediment supply are equally important parameters that affect the filling of the basin. The filling pattern of the basin is exceptionally sensitive to the changes of the lake level due to its very gentle topography. Fluctuations of the lake level can affect a wide range areally.

Comparative simulations and quantitative evaluation of the sedimentary filling and evolution characteristics of the three-type basins under the control of tectonics, sea (lake) level changes, and provenance supply indicate: (1) rift basins appear to be most significantly affected by the tectonic subsidence/uplift; (2) The fluctuation amplitudes and frequencies of sea (lake) levels have obvious impacts on the sedimentary facies variabilities of the cratonic basin and the passive continental margin basins; (3) Rift basins are most significantly impacted by changes in sediment supply, followed by cratonic basins, the passive continental margin basins are leastly affected.

Illizi – Ghadames basin diagenetic evolution modeling

Silvia Tamburelli[1*], Andrea Di Giulio[1], Alberto Consonni[2], Andrea Ortenzi[2]
1. Earth and environmental sciences, University of Pavia (Italy), Pavia, ITALY
2. GEOLAB – Geology and Geochemistry Laboratories, ENI, San Donato Milanese, (Milano), ITALY
E-mail: silvia.tamburelli01@universitadipavia.it

Keywords: Diagenesis, Modeling, Evolution, Oil and gas, Illizi-Ghadames basin

Reservoir quality prediction and the reconstruction of the history of the pore network is an important feature for the study and comprehension of a hydrocarbon region and its potential. It controls the storage, distribution, and flow of fluids within a reservoir, and depends upon rock texture, depositional setting, burial, and thermal history of the basin. These characteristics affect diagenesis that may either improve or degrade original reservoir quality through geologic time.

Unfortunately, the exact reconstruction of this evolution is not easy to achieve, as it needs to constrain several key factors, with regional heat-flow through time probably being the trickiest constraint to challenge.

The Illizi-Ghadames basin (IGB) is one of the most prolific hydrocarbons regions in North Africa. Even if it has been widely studied, the possible thermal effect on the petroleum system of the Tertiary magmatic activity occurred in the region in two major cycles, Paleocene-Eocene and Miocene-Quaternary in age, is still debated (Di Giulio et al., 2021).

In this work, the modelling of the diagenetic evolution of Devonian reservoir rocks in a sector of the Illizi-Gadames Basin is used to check which thermal scenario can be considered more likely, because better reproduces experimental data; based on this, the impact on the time evolution of the petrophysical features of the studied reservoir rocks is investigated, and a detailed history of reservoir petrophysics due to the combined effects of compaction, cement precipitation and grain dissolution since Devonian time to present day is obtained.

Study on the genesis and main controlling factors of low resistivity reservoirs in Bohai Bay Basin

Yang Wei[1*]

1. National Offshore Oil Corporation (CNOOC) Limited, Bohai Oilfield Research InstituteChina , Tianjin, CHINA
E-mail: yangwei2@cnooc.com.cn

Keywords: low resistivity reservoirs, parent rock, diagenetic evolution, paleoclimate, Bohai Bay Basin

A large number of low resistivity reservoirs are intensively developed in Neogene strata in the west of Bohai Bay Basin, which has great exploration and development potential. In order to improve the exploration and development effect of low resistivity reservoir, this study analyzes the genesis and main controlling factors of low resistivity reservoir in this area from the perspectives of the microstructure of the rock, sedimentation, parent rock and diagenetic evolution. The study shows that high shale content, fine lithology, additional conductivity of clay minerals and complex pore structure are the main causes of low resistivity reservoirs in this area. Due to weak tectonic activity, dry climate and poor material supply capacity, the sedimentary types of low resistivity reservoirs are mainly edge beach and flood plain, and this is the main controlling factor for the formation of regional stable low resistivity oil reservoir. For the formation of low resistivity reservoirs with high content of illite mixed layers, it is mainly controlled by the rock type of acidic extrusive volcanic rock and weak hydrodynamic facies. The cementation type is mainly argillaceous cementation, which produces a large number of micro-pores and micro-throats, thus complicates the pore structure and further reduces the resistivity. In recent years, under the guidance of the main control factors of low resistivity reservoir, more than 100 million tons of high-quality geological reserves have been successfully found in Bohai oilfield, and excellent development results have been achieved.

Diagenesis and the authigenic minerals occupying the pores of the sandstone reservoirs of the Coastal Swamp Depobelt, Niger Delta Basin

Gloria Ogochukwu Otosigbo[1*], Olugbenga Ajayi Ehinola[2], Murray Gingras[3]
1. Geology/Geophysics, Alex Ekwueme Federal University, Abakaliki, 480, NIGERIA
2. Geology, University of Ibadan, Ibadan, 200005, NIGERIA
3. Earth and Atmospheric Sciences, University of Alberta, Edmonton, Alberta, CANADA
E-mail: gloriaotosigbo@gmail.com

Keywords: Diagenetic reactions, authigenic, kaolinization, pore sizes, enhancement, reduction

Earlier researchers have designated the Niger Delta sandstone as quartz arenites and also stated that diagenesis rarely occurred owing to early calcite cementation at depth shallower than 2500 meters. This study focused on diagenesis and identification of authigenic minerals occupying the pores of the sandstone reservoirs of the Coastal Swamp Depobelt, Niger Delta Basin in order to determine the reservoir quality.

Core samples were collected from depth between 2500 to about 3500 meters from two wells situated in coastal swamp depobelt of Niger Delta. End trim samples were cut into thin sections, later polished for advanced microscopic study and Scan Electron Microscopy (SEM). The remnants from thin sections were milled for X-Ray Diffractometry (XRD) and bulk mineral quantification using Reference Intensity Ratio.

The Niger Delta sandstone compositions from both microscopic counts and XRD revealed both quartz arenites and feldspathic arenites, with compositions; Q: 83 to 95%, F: 5 to 20%, RF: 0 to 5%. Different diagenetic reactions had taken place, such as feldspar dissolution, kaolinitization, sericitization, albitization and quartz cementation. These reactions had shape the pore sizes and pore throat of the sandstone reservoir. The dissolution voids created by partial and complete dissolution of feldspar minerals increased the pore sizes as much as 2 to >100µm leading to secondary porosities. The resultant authigenic clays from kaolinitization and sericitization such as kaolinites and its polymorphs; dickite and nacrite are resident in the pore grains and occur as book-form and stacked platelets. Mechanical compaction is minimized by framework grains (quartz and feldspar). Moderate chemical compaction resulted in tangential contacts, convex-concave contacts relationship between the grains. Authigenic albite rhombs float in many pores of the massive sandstone facies of delta plain to delta front deposit. The authigenic anhydrite/albite crystals act as interlocking cements and also displacing the feldspar minerals of delta front-mouthbar deposits at the deeper depth. The existence of quartz overgrowth is proven by euhedral extension into dissolution voids. Pore destructive authigenic illite is only identified in SEM as fibrous and membranous textured crystals in the quartz-deficient heterolithic facies of delta front facies. The abundant micro-fracture porosity observed in quartz grains showed a preferred orientation that suggests an impact force possibly from the growth faulting episodes in Niger Delta. Pore enhancement diagenetic reactions had exceeded the poor reduction ones leading to good reservoir quality sandstones with permeability values ranging from 0.26 to 6647mD.

An optimized hydrocarbon generation potential method for evaluating both conventional and unconventional hydrocarbon resources: Implication for the Paleogene Shahejie Formation in the Niuxintuo area, Liaohe Western Depression

Shasha Hui[1], Xiongqi Pang[1*], Hong Pang[1], Changrong Li[1], Xiaolong Zhou[1]
1. College of Geosciences, China University of Petroleum (Beijing), Beijing, CHINA
E-mail: pangxq@cup.edu.cn

Keywords: Optimized hydrocarbon generation potential method, Resource evaluation, low mature source rock, the Niuxintuo area

The hydrocarbon generation potential method is vital to estimate hydrocarbon resources. However, the method is susceptible to subjective influence, and the determination of hydrocarbon generation threshold (HGT) fails to consider the low-mature source rock. This study uses a data-driven approach to optimize the method by multiple nonlinear fitting, which greatly enhances the accuracy of resources assessment, especially for low-mature source rock. This method was applied to the low mature source rocks from the Member 4 of the Shahejie Formation (Es4) in the Niuxintuo area, Liaohe Western Depression, which can be subdivided into the Es4d, Es4g, and Es4n submembers from top to bottom. Results indicate that the Es4 source rocks were thick (>250 m) and mainly in the low-mature to mature stage (Ro=0.26% ~ 0.63%). The TOC was high (>3%). The kerogen was mainly types II and I. The crude oil shows typical characteristics of low mature oil, which exhibits an excellent genetic relationship with the Es4g and Es4n source rocks. The HGT was 0.3%Ro. The hydrocarbon expulsion threshold (HET) was 0.42%Ro. The Es4g source rock had the largest hydrocarbon generation amount (Qg = 13.94 × 10^8 t), but an extremely limited hydrocarbon expulsion amount (Qe = 0.94 × 10^8 t) and range. By contrast, the Qg and Qe from the Es4n source rock were 11.44 × 10^8 t and 3.28 × 10^8 t. The Ro value corresponding to the buoyancy-driven hydrocarbon accumulation depth (BHAD) in the Niuxintuo area was determined as 0.49%. In the Es4n submember, considering the accumulation coefficients of different types of reservoirs, the conventional oil resource which is formed above the BHAD was 0.35 × 10^8 t. The unconventional tight oil resource formed below the BHAD was 0.95 × 10^8 t. The shale oil resource was 4.41 × 10^8 t. Therefore, exploration in the Niuxintuo area should be dominated by tight oil and shale oil exploration.

Saline lacustrine formation overpressure and its origin mechanism of the Paleogene and Neogene in the Western Qaidam Basin, NW China

Chenglin Liu[1,2*], Jixian Tian[3], Yuxin Zhu[4], Taozheng Yang[1,2]
1. State Key Laboratory of Petroleum Resources and Prospecting, China University of Petroleum, Beijing, Beijing, CHINA
2. College of Geosciences, China University of Petroleum, Beijing, Beijing, CHINA

4. Exploration and Development Research Institute, Changqing Oilfield Company, PetroChina, Xi'an, Shanxi, CHINA
E-mail: liucl@cup.edu.cn

Keywords: Saline lacustrine basin, overpressure, disequilibrium compaction, hydrocarbon generation, Qaidam

Previous research has shown that the origin and distribution of formation overpressure are governed by several dominant factors including disequilibrium compaction, hydrocarbon generation, tectonic compression, and diagenesis. These factors are influenced by salt components and their concentration in saline lacustrine basins, but it is unclear how salts affect formation overpressure via these factors. This paper investigates the effect of salts on formation overpressure based on organic geochemistry, rock mineralogy, and other analyses. The top surface of the overpressure ranges from 2300 to 2500 meters in depth, and the proportion of abnormal high pressures increases from the Paleogene to Neogene in the Western Qaidam Basin. The centers of the overpressure migrate from west to east, consistent with the migration of the basin's subsidence and sedimentary centers. Strong overpressure with a pressure coefficient of 1.82.0 mainly occurs in the upper Oligocene, where deep and semi-deep lacks are developed. Disequilibrium compaction is the most important controlling factor, with a contribution rate of more than 60% in the intersalt and subsalt strata, followed by tectonic compression, with a contribution rate of 20-30%. The contribution of organic matter to hydrocarbon generation is greater in the subsalt strata. Fracture reducing by salt filling and fluid volume expanding by gypsum dehydration increase the fluid volume in the formation, which promotes formation overpressure. The gypsum salt rocks also have strong plasticity and sealing effect, thus providing a good sealing condition for the formation of overpressure.

3D Quantitative In-situ Modeling of Deep Shale Poroperm Characteristics

Ou Chenghua[1*]

1. State Key Laboratory of Oil and Gas Reservoir Geology and Exploitation, Petroleum Engineering School, Southwest Petroleum University, Chengdu, SiChuan, CHINA

E-mail: chomm@swpu.edu.cn

Keywords: deep shale, poroperm characteristics, heterogeneity, in-situ modeling, 3D characterization

With the increase of the buried depth, the reservoir temperature and pressure, and the strength of the reservoir diagenesis evolution in deep shale, the poroperm control mechanism become more complex, the poroperm heterogeneity is more strong, the 3D quantitative in-situ modeling of deep shale poroperm characteristics faces huge challenges. The oil / gas storage and production capacity commonly relies on TOC, porosity and permeability, that come from the development and construction of natural or artificial pore and fracture system in deep shale. Therefore, how to accurately and reliably implement 3D quantitative in-situ modeling of deep shale poroperm characteristics, has become the breakthrough to solve the problem of efficient exploration and development of deep shale oil / gas.

The 3D quantitative in-situ modeling of deep shale poroperm characteristics can not be achieved by a single theory and technique. to this end, by fully absorbing the theoretical nutrients of fine-grain sedimentology and shale reservoir geology, integrating the advantages of existing shale geology, well logging and seismic interpretation technique, and exercising the poroperm heterogeneity of typical deep shale oil / gas example areas in Sichuan Basin, Junggar Basin, Ordos Basin and Qaidam Basin, the 3D in-situ modeling technique with heterogeneous rock-well-seismic coupling in deep shale was established. Specifically include: (1) shale lithofacies classification and logging quantitative identification method; (2) 3D visual discrete network modeling technique of bedding fractures, structural fractures and artificial fractures in deep shale ; (3) in-situ interpretation method of shale poroperm characteristics based on rock-rock-well coupling; (4) 3D in-situ modeling technique of shale poroperm characteristics relying on well-seismic coupling and genetic inversion; (5) Shale layer correlation and 3D visual structure characterization; (6) 3D quantitative in-situ poroperm characterization relying on seismic-lithofacies-fracture constraints.

Relying on the technique of 3D quantitative in-situ poroperm modeling, many 3D quantitative in-situ poroperm models distributed in the Jiaoshiba and the Weiyuan shale gas production area in Sichuan Basin, the Jimusar shale oil production area in Junggar Basin, the Xiasiwan shale gas exploration area in Ordos Basin, and the Fengxi shale oil production area in Qaidam Basin, have been gradually built, which verified the reliability and applicability of the present technique.

Sedimentary Evolution and Petroleum Potential of the Cretaceous to Paleogene in Linhe depression, Hetao Basin, western China

Lu Lu[1*], Zhuangfu Li[1]

1. College of Resources and Geosciences, China University of Mining and Technology, Xuzhou, Jiangsu, CHINA
E-mail: geollulu@cumt.edu.cn

Keywords: sedimentary facies, petroleum reservoir, Cretaceous-Paleogene, Linhe depression, Hetao Basin, western China

Hetao Basin is a Mesozoic-Cenozoic superimposed sedimentary basin developed in the northwestern margin of the North China Plate. Depite a great sheer of studies, the sedimentary evolution of the Cretaceous and Paleogene strata in the basin, which has important oil and gas exploration potential, is poorly understood. In this study, we present a interated dataset in terms of sedimentology, mineralogy, petrology and geochemistry on the Cretaceous to Paleogene strata in the Linhe Depression, Hetao Basin. Using these data, we determined the sedimentary facies where the strata deposited, constrained the temporal-spatial distribution and evolution of individual facies in the sequence stratigraphic framework, and explore its petroleum significance. The results show that: 1) The Cretaceous to Paleogene sedimentation in Linhe Depression, Hetao Basin was characterized by sub-tropical arid and semi-arid climate. The sedimentary water was oxygen-rich as a whole but locally anaerobic, and fresh water and brackish water appeared alternately. 2) There are five types of sedimentary facies where the Cretaceous to Paleogene sedimentation happened, including alluvial fan, braided river, braided river delta, fan delta, and lacustrine facies, which can be further divided into 12 types of sedimentary subfacies and 22 types of sedimentary microfacies. In the northwestern margion of the depression, the fault activity was strong, the topographic height difference was large, and the alluvial fan-delta-lacustrine sedimentary system was developed. In the southeastern margin of the depression, the tectonic activity was weak, the topographic height difference was gentle, and the braided river-braided river delta-lacustrine sedimentary system was developed. The sedimentary pattern of each period is similar as a whole, only showing variations in the scale of fan body at the basin margin relative to the lacustrine facies in the basin. 3) The Cretaceous to Paleogene sedimentation of Linhe Formation was characterized by arid and semi-arid, shallow water, dual provenances controlled by weak episodic tectonic activity. In the early stage of basin development, the tectonic activity was strong, but the basin was small and shallow. The clastic materials on both sides rapidly advanced into the basin, and even converged in the center of the basin, forming a situation of "full basin sands". With the weakening of tectonic activity and the rapid rise of lake water, the supply of clastic materials was insufficient, and the lacustrine deposition began to dominate, thus forming a sedimentary pattern dominated by lake facies. 4) Sedimentary facies zones in the depression controlled the development scales and architectures of sand bodies, and further determined the spatial distribution characteristics of effective petroleum reservoirs. Under the dual controlling factors of sedimentary facies and faulting, the favorable reservoirs in the Cretaceous to Paleogene strata in the Linhe Depression of the Hetao Basin are mainly distributed in the central tectonic belt, where the shore-shallow lake deposits and normal faults are dominated.

Study on Early Hydrocarbon Generation Characteristics of the Dongying Formation Source Rock in the Bozhong Sag, Bohai Bay

Guoxiong Li[1,2], Chenglin Liu[1,2*], Feilong Wang[3], Hong Yang[1,2], Xiaoxiang Zeng[1,2]
1. State Key Laboratory of Petroleum Resources and Prospecting, China University of Petroleum-Beijing, Beijing, CHINA
2. College of Geosciences, China University of Petroleum-Beijing, Beijing, CHINA
3. Tianjin Branch, CNOOC China Limited, Tianjin, CHINA
E-mail: 869221614@qq.com

Keywords: Bozhong Sag, Dongying Formation, Early hydrocarbon generation, Low-maturity oil

The Bozhong sag is the largest hydrocarbon-rich sag in the Bohai Sea in the eastern Bohai Bay Basin, and the Dongying Formation is a typical high-quality source rock of freshwater lacustrine facies. However, the hydrocarbon generation evolution of this set of source rocks has not been systematically studied by previous researchers, resulting in insufficient evaluation of its hydrocarbon generation contribution rate. In this paper, through scanning electron microscopy, XRD characterization, maceral identification, palynological analysis, combined with rock pyrolysis evaluation, TOC determination, gold tube thermal simulation, chromatography-mass spectrometry analysis and other methods, the hydrocarbon evolution characteristics of the Dongying Formation source rocks were studied, and the hydrocarbon generation mechanism of the Dongying Formation source rocks was discussed. The results show that the lithology of the Dongying Formation in the Bozhong Sag is mainly grey and black shale, and the content of pine pollen in paleontology is large. The benthic algae in the exinite account for a large proportion, which is an important part of the hydrocarbon generating parent materials. The organic matter type is mainly II_1 ~ II_2, and the whole source rock reaches good quality. The source rock of the Dongying Formation has two hydrocarbon generation peaks of low maturity stage and mature stage. The first hydrocarbon generation peak corresponds to about 0.6% of Ro, generating low maturity oil. The second hydrocarbon generation peak corresponds to about 1.0 % Ro, generating mature oil. The comprehensive analyses show that the reasons for the formation of low-mature oil in the source rocks of the Dongying Formation are as follows: (1) The benthic algae content has good matching with the bimodal evolution of source rocks, which is conducive to early hydrocarbon generation; (2) the protoplasm (pollen and lipids) in pine pollen participates in early hydrocarbon generation and forms low-mature oil; (3) the catalytic effect of carbonate at low temperature is conducive to the formation of low-mature oil; (4) overpressure is widely developed in mudstone of the Dongying Formation. The pressure coefficient of a strong overpressure zone can reach 1.5 ~ 1.7, which inhibits the thermal evolution of organic matter significantly. The overpressure extends the hydrocarbon generation period of the Dongying Formation. The understanding of the hydrocarbon generation mechanism of the Dongying Formation enriches the hydrocarbon generation theory of organic matter and contributes to the assessment of hydrocarbon generation contribution rate and potential of the Dongying Formation source rocks in the Bozhong Sag.

Characteristics of Miocene source rocks and mechanism of organic matter enrichment in Yinggehai Basin

Jinliang Yan[1*]
1. School of Geosciences, China University of Petroleum (East China), Qingdao, ShanDong, CHINA
E-mail: 350058622@qq.com

Keywords: source rock, sedimentary environment, Yinggehai Basin

The Yinggehai Basin is a passive continental margin basin located in the northwestern part of the South China Sea. It is a typical Cenozoic strike-slip extensional basin with a diamond-shaped distribution in the NNW direction and is rich in natural gas. In this study, Miocene mudstone samples from the Yinggehai Basin were selected for testing and analysis, and the characteristics of source rocks and organic matter enrichment factors were comprehensively analyzed in combination with previous research results.

In this study, Miocene mudstone samples from different areas of the Yinggehai Basin were selected, and the organic carbon content (TOC), pyrolysis hydrocarbon generation potential (Pg), hydrogen index (HI), carbon-hydrogen-oxygen ratio (H/C, O/C), vitrinite reflectance (R_o) and pyrolysis peak temperature (T_{max}) comprehensively evaluate the characteristics of source rocks in the Meishan Formation and Sanya Formation in the study area. Based on the sporopollen assemblage, saturated hydrocarbon light-weight ratio $(C_{21}+C_{22})/(C_{28}+C_{29})$, Sr/Ba ratio, pristane/phytan and kaolinite content and other parameters, the paleoclimate environment, The source of organic matter, paleo-salinity, redox conditions and changes in paleo-sea level and other organic matter enrichment factors.

The research results show that the Miocene marine source rocks in the Yinggehai Basin are generally low in organic matter abundance and low in maturity, all of which have entered the hydrocarbon generation threshold and have good hydrocarbon generation potential. The organic matter types are mainly II_2-III types. Mainly, the type of natural gas is mainly coal-derived gas. On the plane, the abundance of organic matter in the Ledong and Dongfang areas located in the central depression is significantly higher than that in the Yingdong slope belt. Vertically, the organic matter abundance in the Meishan Formation was significantly higher than that in the Sanya Formation. The Meishan Formation was generally warm and humid during its development, while the Sanya Formation was generally dry and low temperature. The paleo-water environment in the Meishan and Sanya periods was salt water, the salinity in the eastern area was higher than that in the Yingdong slope area, and in the Meishan period was higher than that in the Sanya period. The sources of organic matter in the Meishan Formation and Sanya Formation in the Central Sag are both from aquatic organisms and from terrestrial higher plants, which are typical dual-source inputs. During the period of Meishan Formation and Sanya Formation, the sea level gradually increased from Yingdong slope to Ledong District to Dongfang District, and the sea level of Meishan Formation was higher than that of Sanya Formation vertically.Although the source rock characteristics and organic matter enrichment factors have been reported, the input ratio of terrestrial and endogenous organic matter, the main controlling factors of organic matter enrichment and the development of high-quality marine dual-source source rock area still require further research.

Quantitive analysis and evaluation of source-to-sink system of a low uplift area in Bohai Bay Basin: Insights for further hydrocarbon exploration

Xinyuan Ji[1], Hongliang Wang[1*]
1. School of Energy Resources, China University of Geosciences (Beijing), Beijing, Student, CHINA
E-mail: whliang@cugb.edu.cn

Keywords: Source-to-sink,Analytic network process analysis, Chengbei Low Uplift, BoHai Bay Basin

The source-to-sink (S2S) system analysis of rifted lacustrine basins is one of the focus content of hydrocarbon exploration and development. Currently, most S2S studies are conducted based on statistical calculations of the parameters of S2S systems. However, few studies focused on the S2S system evaluation. Located in the western Bohai Bay basin, the Chengbei low uplift (CBLU) was an integrated S2S system, which provides a natural experimental condition for exploring the relationship between provenance system, transportation system, and sedimentary system. The results show that the eastern CBLU can be divided into three sub-level S2S systems, including one first-level system, two second-level systems and ten third-level systems. There are two types of sediment dispersion patterns in the study area: 1) the proximal-fan-delta sedimentary pattern and 2) the distal-braided-delta sedimentary pattern. Furthermore, we constructed a multivariate quantitative relationship between the influencing factors of source and sink. Additionally, utilizing the analytic network process analysis, the S2S systems can be quantified and ranked. Finally, based on the tectonic activity, sediment migration trajectory, and sediment dispersion pattern, we established two coupling models of S2S system. This study proposes a quantitative method to analyze and evaluate the S2S system, which not only deepens our understanding of the structure and sedimentary evolution on the temporal and spatial scales, but also generates positive significance for the prediction of favorable reservoir and stratigraphic-lithologic traps.

Sedimentary genesis and distribution of high argillaceous sandstone

Xudong Liu[1*]
1. , , , , CHINA
E-mail: 884116475@qq.com

Keywords: Hanjiang Formation,high argillaceous sandstone,Genesis,Distribution

Area A is located in the east of Yangjiang Sag in Zhusan Depression, Pearl River Mouth Basin. The Neogene Hanjiang Formation in this area has deposited a large number of sand, silt and mud mixed clastic sediments, with different particle sizes and complex composition. Predecessors have done some research on lithology, sedimentation and reservoir of this Formation, but the understanding of genesis and distribution of high argillaceous sandstone is not clear. In this paper, the genesis and vertical distribution of high argillaceous sandstone in Hanjiang Formation are analyzed by core, logging and analytical test data. Combined with high resolution seismic data, the density and seismic elastic parameters inversion method are used to clarify the plane distribution characteristics. The results show that high argillaceous sandstone is mainly distributed in deltaic front underwater distributary channel, interdistributary bay and distal bar. Sediment deposition rate of deltaic front underwater distributary channel is fast, low energy hydrodynamic can not be fully scoured sediment screening, resulting in high mud content. The hydrodynamic conditions of deltaic front interdistributary bay and distal bar are weak, and fine-grained and argillaceous sediments are deposited in large quantities, so the argillaceous content of sandstone is high.

Genesis and distribution prediction of high-calcium and low-permeability sandstone

Wei Zheng[1*]
1. , , , , CHINA
E-mail: 2139636322@qq.com

Keywords: high-calcium and low-permeability sandstone,genesis,distribution,seismic inversion,Zhujiang Formation

The reservoir-caprock assemblage of Zhujiang Formation in A Oilfield of Yangjiang Sag, Pearl River Mouth Basin is superior and has excellent reservoir formation conditions. However, the process of oil and gas exploration is restricted due to the frequent drilling of high-calcium and low-permeability sandstones, and the unclear understanding of the causes of high-calcium and low-permeability sandstones and the distribution of sand bodies. In this paper, the causes and vertical distribution of high-calcium and low-permeability sandstones are studied by using rock cores, logging, analysis and testing data combined with the sedimentary background of the region. And the reservoir seismic inversion is carried out by using seismic data combined with permeability, so as to realize the plane distribution prediction of high-calcium and low-permeability sandstones. The study shows that the Zhujiang Formation in the study area mostly develops underwater distributary bay microfacies, which provides abundant carbonate provenance conditions for high calcium content of sand bodies. And the sand bodies in the microfacies of underwater distributary channel are closely embedded with the mudstone rich in calcium at the top and bottom, and the migration and related chemical reactions of carbonate from mudstone to sandstone occur at the junction, which further increases the calcium content of sand body. Combined with the study of permeability inversion model, it is considered that high-calcium and low-permeability sandstones are mainly distributed in the underwater distributary channel near the provenance region in the northern part of the study area.

Origin and evolution of overpressure in upper Member of Xiaganchaigou Formation, western Qaidam Basin

Taozheng Yang[1], Chenglin Liu[1*], Jixian Tian[1], Yu Ran[1]
1. College of Geosciences, China University of Petroleum, Beijing, Beijing, CHINA
E-mail: 1243206413@qq.com

Keywords: Abnormal pressure, Overpressure characteristics, Origin of overpressure, Overpressure evolution, Western Qaidam Basin

This research analyzes the distribution and causes of overpressure in the upper segment of the Xiaganchaigou Formation (E32) from the western Qaidam Basin through pressure test data, well logging data, and geological conditions of the area. Different causes of overpressure are quantified in this research.According to the deposition rate, organic matter abundance, organic matter type, organic matter maturity, tectonic compression stress, geothermal gradient, and clay mineral characteristics of the upper lower Ganchaigou Formation in three secondary structural belts in the western Qaidam Basin. It is considered that the main controlling factors of overpressure in the western Qaidam Basin are disequilibrium compaction, hydrocarbon generation and tectonic extrusion. This view is further verified by the analysis results of the combination of logging curves and the acoustic velocity-density cross plot. The residual pressure evolution in the western Qaidam basin is reconstructed by basin simulation. The results show that part E32 can be divided into five evolution stages: Normal compaction stage (before 25Ma), Weak overpressure stage (25-12Ma), Mixed pressurization stage (12-5Ma), Rapid pressurization stage (5-1.5Ma), Pressure release stage (1.5Ma-present).

Analysis of Oil and Gas Source and Reservoir Forming Evolution History of Maokou Formation of Middle Permian in Center-North of Sichuan Basin

Chen Shen[1], Haifeng Yuan[1*]
1. College of Energy, Chengdu University of Technology, Chengdu, Sichuan, CHINA
E-mail: yuanhaifeng08@cdut.cn

Keywords: Sichuan Basin,Source of Oil and Gas,Hydrocarbon Accumulation Stages,Fluid Inclusion

Abstract: There is a common gas-bearing phenomenon in Maokou Formation of Middle Permian in the center-north of Sichuan Basin. Vertically, source rocks like those of Cambrian, Silurian and Permian are mainly developed in the study area. Hydrocarbon source faults and unconformities are relatively developed, which have superior reservoir forming conditions. However, due to the different structural characteristics and reservoir development degree in different areas of the basin, there are some differences in natural gas sources and oil and gas accumulation periods. At present, the source of natural gas in Maokou Formation in the study area is not sufficiently understood, and the contribution of Cambrian, Silurian and Permian source rocks to different gas reservoirs needs to be further studied. Based on the analysis of natural gas composition, stable isotope and biomarker characteristics of asphalt, and combined with the previous understanding of hydrocarbon source rocks of various strata in Sichuan Basin, the gas sources of Gaoshiti Moxi, longnusi, Yuanba and Jiulongshan Maokou Formation in the study area are analyzed in detail; At the same time, fluid inclusion analysis and other means are used to determine the hydrocarbon charging period and hydrocarbon accumulation history.

In this study, the differences in natural gas accumulation in the Middle Permian Maokou Formation in different structures in the central and northern Sichuan regions were taken as the research object. Through a large number of core observations and field outcrop sampling, combined with drilling, logging, seismic and organic geochemical data, the source and accumulation period of natural gas in the Maokou Formation of different structures in the study area were studied. On this basis, the law of oil and gas enrichment is analyzed, and favorable target areas are predicted. It provides an important theoretical basis and direction for the next exploration and development.

Main controlling factors of petroleum differential distribution in the onshore area of the Niger Delta

Ye Tao[1], YouBin He[1*]
1. School of Earth Sciences, Yangtze University, Wuhan, Hubei Province, CHINA
E-mail: heyb122@163.com

Keywords: Niger Delta, Petroleum distribution, Control factors, Source rock, Organic matter maturity

In order to prove the influence of source rocks in the Niger Delta on the differential distribution of oil and gas, we take "source control theory" as the theoretical guide, and then use drilling and geochemical data to analyze the characteristics of source rocks, the distribution characteristics of petroleum fields (reservoirs) and the influence of source rocks on petroleum distribution. The results show that: (1) The petroleum distribution in the study area can be divided into five petroleum accumulation areas and four gas accumulation areas, which are shaped like a belt; The source rock development area corresponds well with petroleum accumulation area and gas accumulation area on the plane. (2) The organic matter abundance of source rocks in the study area is high, and the organic matter types are mainly II and III, which came from both land and sea, and the maturity is mature to over mature. (3) The main controlling factors of petroleum differential distribution have obvious segmentation. The differential distribution of petroleum in the study area is mainly controlled by three factors: the type of organic matter, organic matter preservation conditions, and the maturity of organic matter. The distribution of petroleum reservoirs (fields) in the northwest section is mainly controlled by two factors: organic matter maturity and organic matter preservation conditions; The middle section is mainly controlled by the maturity of organic matter; The distribution of petroleum reservoirs (fields) in the southeast section is mainly controlled by the type of organic matter. The results of this study can provide a theoretical basis for petroleum exploration and development in the study area and other areas with similar geological background.

Reservoir Modeling Research Based On Convolution-Recurrent Neural Network

HaoSen Quan[1], ChengHua Ou[1*], Bo Yan[1]
1. Petroleum Engineering School, Southwest Petroleum University, Chengdu, Sichuan, CHINA
E-mail: chomm@163.com

Keywords: Deep Learning, Reservoir Modeling, Convolution Neural Network, Recurrent Neural Network

Traditional reservoir stochastic modeling methods mainly use two-point geostatistics or multi-point geostatistics. Two-point geostatistics cannot use existing model data, and multi-point geostatistics is difficult to use because of the complicated generation process of training images. Recently, deep learning has made an excellent achievement in many fields, but it is rarely used by researchers in the field of reservoir modeling. The successful application of deep learning to reservoir modeling requires consideration of both the model data structure for input and the structure of the algorithm model. We proposed a combined algorithm model of convolution-recurrent neural network to mine the features of existing model data. The convolution part can effectively extract the spatial features of the model data, while the recurrent part can effectively extract the sequential features of the model data. We also compared the performance of the algorithm models under different hyperparameters, and selected a better model to train and predict the reservoir model of an oilfield in Qinghai. The prediction results are compared with the result generated by a commercial modeling software, and the comparison results effectively prove the feasibility of deep learning reservoir modeling.

Quantitatively identify sedimentary microfacies of the Ng3-4 sand group in Bo61 fault block, southern area of Gudao Oilfield

li jun[1*]

1. College of Earth Science and Technology, China University of PetroleumEast China, Qingdao, shandong province, CHINA
E-mail: 779001699@qq.com

Keywords: South area of Gudao Oilfield, Ng3-4 sand group, Quantitatively identifySedimentary microfacies, reservoir characteristics

The work area is located in the Bohai 61 block in the northwestern part of Gudao oilfield, which is a key development block. In recent years, a batch of new well has been drilled. However, there are not enough studies on the division, contrast, sedimentary microfacies and reservoir characteristics of the key stratum such as Ng3-4 sand group, which affects the whole development effect to a certain extent. Based on the theories and methods of sedimentology, oil and gas field underground geology and logging geology, combined with core, logging, analysis and laboratory data, the sedimentary microfacies and reservoir characteristics of the Ng3-4 sand group in the working area are studied in depth to provide a reliable geological basis for further tapping the potential of oil fields.

In this study,the high-precision stratigraphic framework of the work area is established; the sedimentary microfacies types and vertical evolution rules of the study interval in the area are determined through the systematic analysis of single well facies, profile facies and flat facies. In addition, the Bayes discriminant method is used to quantitatively identify sedimentary microfacies, and a multi parameter discriminant model for 6 main sedimentary microfacies in the area is established.

In view of the limited log data of cores and cuttings, it is difficult to meet the fine characterization of sedimentary microfacies in the development block. Logging curves have various types, rich geological information, high vertical resolution, and can meet quantitative analysis. Therefore, in oilfield exploration and development, it is important to make full use of logging data to accurately and comprehensively divide sedimentary microfacies. Based on the above knowledge, in order to maximize the use of logging data and quantitatively characterize the sedimentary microfacies, the Bayes discriminant method was used to quantitatively identify the upper sedimentary microfacies of the Guantao Formation in Gudao Oilfield, laying a solid geological foundation for the fine development of the oilfield. In this paper, representative well sections with sedimentary microfacies in 3 coring wells in the study area and the corresponding 58 sets of logging data are used to establish the Bayes discriminant model. SP, COND, and AC logging curves are selected and optimized. Normalize and extract feature parameters, and use them as the input set for Bayes discrimination, and use the interpretation of sedimentary microfacies as the output to establish the Bayes discrimination model. The cross-validation method is used to verify the established model. The results show that: The accuracy of the training results is 98.3%, the accuracy of the cross-validation is 96.6%, and the accuracy of the prediction results is 93.3%, which indicates that the model has a good application effect on the identification of microfacies of river facies and sediments in the upper part of the Guantao Formation in Gudao Oilfield.

An integrated workflow for diagenetic facies, microfacies analysis and petrophysical characterization of Zhuhai Formation tight sandstone from Zhu-III sag, Pearl River Mouth Basin, South China Sea

Sandong Zhou[1*], Junfeng Zhang[1], Hua Wang[1], Detian Yan[1]
1. School of Earth Sciences, China University of Geosciences, Wuhan, Wuhan, Hubei, CHINA
E-mail: zhousandong@cug.edu.cn

Keywords: Petrophysics, Reservoir quality, Diagenetic facies, Pearl River Mouth Basin

Zhu-III sag is a key area of resources exploration with great potential of resources in the Pearl River Mouth Basin. Reservoir in Zhuhai Formation (Oligocene) is a typical tight sandstone reservoir. These exposed Zhuhai Formation outcrops, of the intercalated continental and marine sediments, allow us to conduct more detailed and integrated studies on the various depositional settings with diverse lithologies as analogous for the subsurface reservoirs. The proposed workflow allowed the extension of our knowledge to Zhuhai Formation in Zhu-III sag into some hydraulic fluid flow units and reservoir rock types. The present stud enabled developing a static model for the Zhuhai Formation reservoirs in Zhu-III sag which exhibits heterogeneities in the fluid flow and microfacies at micro and macro scales. The present study concerns the implication of the mineralogical components and the diagenetic controls on the petrophysical properties and the reservoir characteristics. Diagenetic facies are a significant tool to indicate the key parameters of tight sandstone reservoir properties. In this work, diagenesis of tight sandstone reservoir of Zhuhai Formation is investigated by multiple experiments of borehole core, thin section, scanning electron microscope, X-ray diffract ion and conventional rock analysis to discuss the influence of main diagenesis and minerals. Four diagenetic facies are identified as strong compaction facies, medium compaction facies, carbonate cemented facies and clay mineral filling facies. We quantitatively determine the correlation between diagenetic facies with well logging and petrophysical parameters. The strong compaction and cements are the primary reason for the development of low-quality reservoirs. Cementation and compaction are the main reservoir quality-reducing factors, as dissolution and fracturing enhanced its quality. We establish the facies prediction system and predict the favorable reservoir via well logs. The relationship between porosity and permeability is controlled by diagenetic facies. A further correlation between the Zhuhai Formation outcrop data and the analogous subsurface reservoirs is critical for modeling and simulating the Zhuhai Formation reservoirs, which will improve the reservoir behavior and prediction during the appraisal, development, and production phases. The findings of this study point to the presence of some prospective flow units that should be traced in the nearby analogous subsurface reservoirs in the Pearl River Mouth Basin.

Analysis of hydrocarbon generation characteristics based on S2 parameter correction of Rock-Eval-Taking the first member of Qingshankou Formation in Gulong sag, Songliao Basin as an example

Zhang Yuchen[1*]
1. School of Geosciences, China University of Petroleum (East China), Qingdao, Shandong, CHINA
E-mail: 1092931908@qq.com

Keywords: hydrocarbon generation, S2 correction, Qingshankou Formation

Shale oil and gas is an important part of future energy pattern, quantitative characterization of its formation process is of great scientific significance. As one of the effective methods to quantitatively characterize the hydrocarbon generation of shale organic matter, the hydrocarbon generation potential method is affected by the high boiling point of heavy components and the difficulty of volatilization at 300 °C in the Rock-Eval experiment. Therefore, the measured S2 before extraction can not accurately reflect the pyrolysis hydrocarbon content of solid organic matter, so it directly affects the applicability of this method. In this study, taking the first member of Qingshankou Formation in Gulong Sag, Songliao Basin as an example, the hydrocarbon generation potential method is further improved by establishing the heavy components correction model of pyrolysis hydrocarbon content S2. By selecting shale samples with different maturities to carry out Rock-Eval experiments, the heavy hydrocarbon correction model is established based on the ratio evolution of pyrolysis hydrocarbon difference ΔS2 before and after extraction to pyrolysis hydrocarbon S2' after extraction. The experimental data of Rock-Eval in the target layer of study area are corrected and restored, and then the hydrocarbon generation model of organic matter in the first member of Qingshankou formation is analyzed and revealed. The results show that: the difference of pyrolysis hydrocarbons before and after correction is obvious. The proportion of adsorbed heavy components ΔS2 / S2' increases with increasing maturity, showing an exponential growth trend; ΔS2 content is controlled by the evolution stage of hydrocarbon generation, showing a trend of "first increasing, then stabilizing and finally decreasing", which is related to the adsorption capacity of organic matter; The corrected evolution model of hydrocarbon generation in the first member of Qingshankou Formation shows that the organic matter begins to generate hydrocarbon at the maturity of Ro ~ 0.5%, reaches the peak of hydrocarbon generation at about Ro ~ 0.9%, and the pyrolysis of soild organic matter basically ends at Ro ~ 1.3%; The heavy components begin to crack at maturity of Ro ~ 1.2%, with a large number of nano organic pores formed.

Establishment of retrograde fan delta sedimentary model of Upper Urho Formation in Junggar Basin and discovery of large stratigraphic lithologic traps

xiang shan[1*]

1. Department of Laboratory Research, Petrochina Hangzhou Research Institute of Geology, Hangzhou, Zhejiang, CHINA
E-mail: 472515756@qq.com

Keywords: Fan delta, Sedimentary model, lithologic traps, Upper Urho Formation, Junggra Basin

In recent years, major oil and gas discoveries have been archived in the Upper Permian Upper Urho Formation (P3w) in major petroliferous sag of Junggar Basin, including Mahu Sag, Fukang sag and Shawan Sag. The sedimentary system and sedimentary evolution of Upper Urho Formation are studied through field outcrop, core, drilling and logging data. The results show that: Upper Urho Formation mainly developed fan delta sedimentary system. The lithology gradually becomes thinner from bottom to top, reflecting the sedimentary characteristics of lake transgression. The sand body regress and overlap each other to provenance area. The distribution of fan body is controlled by sedimentary paleo-channel and paleo-provenance, and the fan body is divided by paleo-uplift. Ten fan delta sedimentary bodies are developed in the Upper Urho Formation of the Junggar Basin. The sedimentary model of retrograde fan delta of Upper Urho Formation is established. This mode has revealed following geological lawsslope break control sand distribution; fan delta plain dense conglomerate and lacustrine mudstone control the forming of the lithologic trap. Conglomerate with poor mud matrix developed in fan delta front control good reservoir. It is pointed out that the sand body developed in the channel between paleo-uplift can form effective lithologic traps. The sedimentary model of retrograde fan delta can provide geological basis for further oil and gas exploration and reference for oil and gas exploration in areas with similar background.

The role of quantitative characterization of small source and sink system sand bodies in oil and gas exploration -- Taking Huilu low uplift in Pearl River Mouth Basin as an example

Qiongling Wu[1*]
1. Research Institute, China National Offshore Oil Corporation, Shenzhen Branch, Shenzhen, Guangdong, CHINA
E-mail: wuqiongling190@163.com

Keywords: small source-to-sink system, quantitative characterization of sand body, Huilu low uplift, restoration of ancient landscape, sand body scale

At present, oil and gas exploration in the Pearl River Mouth Basin is gradually turning to the deep layer, the Paleogene, when terrestrial source-to-sink system was mainly developed. With the deepening of the exploration process, such source-to-sink systems in the peripheral low uplift area also show great exploration potential. Compared with marine material source, the material source of low uplift area is proximal and unstable, which is called small source-to-sink system. Besides, complex evolutionary process leads to strong denudation and transformation of the source area, then leads to differentiated transportation systems and complex sedimentary systems, thus the scale of sand bodies is difficult to predict.

According to the characteristics of small source-to-sink system, the research quantitatively characterizes the whole process of source-to-sink system in Huilu low uplift by integrating three-dimensional full coverage seismic data and drilled wells, combined with logging data, core data, and laboratory data. Firstly, according to the different restoration technologies of denudation area and super stripping zone, the research restores the ancient landscape before denudation. The denudation area of upper Wenchang Formation is nearly 1700km2 and the denudation thickness is up to 300m. Then, the research finely traces various source-rock combinations and the provenance systems by the comprehensive analysis method of genesis, morphology and age of clastic zircon, thus finely characterize the dynamic source supplies of different uplift groups. Secondly, based on comprehensive analysis of the ancient valleys, slope-break belts and fault systems, the research quantitatively characterizes each transport channel's scale of multi-source differential supplies, thus optimizes the transport channels by seismic sedimentology method. Finally, the research refines the boundary and inside description of sedimentary bodies, and establishes the identification mode, response characteristics and temporal and spatial evolution law of typical sedimentary sand bodies in high-frequency sequence units, thus precisely depicts and quantitative characterizes the scale of sedimentary sand bodies under the coupling of source-to-sink system in Huilu low uplift area.

After the quantitative prediction of sand bodies, the catchment area(mainly sand bodies) of upper Wenchang formation is three times larger than before, which reveals great exploration potential of this stratum. Soon afterwards the preliminary well LF-A and evaluation wells encountered nearly 100 meters medium-coarse sandstones rich in oil and gas after drilling. This greatly increases exploration confidence of Huilu low uplift area while nearly all the original drillings nearby encountered mudstones in upper Wenchang formation. This technological innovation has a good guiding role for the exploration of small source-to-sink system in the Pearl River Mouth Basin, which opens up a new exploration direction and shows great exploration prospect.

Key words: small source-to-sink system; quantitative characterization of sand body; Huilu low uplift; restoration of ancient landscape; sand body scale.

E-mail: 122046544@qq.com

Keywords: oil saturation,seismic inversion,fluid classification facies,geological modeling

Lacustrine mixed shale reservoirs are widely distributed in global sedimentary basins, such as the Western Siberia Basin, Newark Rift Basin, Junggar Basin, Songliao Basin, Ordos Basin, etc. Although the shale oil in many basins has entered the stage of industrial development,there are many technical difficulties restricted the development.Firstly, the traditional methods (Logging data method and Seismic data method) cannot satisfied the accuracy of characterization due to the variable structure, complexed oil-water relationship and Strong heterogeneity of lacustrine mixed shale oil reservoir.Secondly, the number of exploration wells and production wells is small, and the sparse well pattern also seriously affects the prediction accuracy between wells. There are still many difficulties in the fine quantitative characterization of oil saturation.

To solve the problems above, a “three-stage”modeling method based on dual control of seismic inversion and fluid classification phase is proposed:(1)Using log data to invert the formation, and using the “horizontal trend” method to overcome the variable structure problem of Lacustrine mixed shale oil reservoir ,which cannot be representated by log data alone,improve lateral resolution, and ensure the accuracy of horizontal extension;(2)Controlling Reservoirs with Fluid Classified Phasesusing the "vertical trend" technology to overcome problems that thin layer and strong heterogeneity of lacustrine mixed shale reservoir and improve the vertical resolution;(3) Through the dual control of seismic inversion and fluid classification phase, integrating the log data, the seismic data , the fluid classification phase and physical property parameters together.By “three-stage” modeling method, we can make full use of the advantages of "seismic control" which have a high lateral resolution and"horizontal trend" which have a high vertical resolution. The advantages of this method improve the quantitative characterization accuracy of the oil saturation model in an all-round way.

The method is used to study the oil saturation of a saltwater lacustrine reservoir in western China, the results show that the calculation is fast, the accuracy is high, and the error is small.Under the dual constraints of seismic inversion and fluid classification phase, the entire technical system can found optimal solutions for different problems quickly. It has strong advantages in the analysis of oil saturation in the reservoir, which provides better data support for the refined study of the reservoir.The 3D modeling method which has high application value and and can provide a reference for describe the distribution regulations of oil saturation in lacustrine mixed shale reservoirs quantitatively in similar areas.

E-mail: 3341405558@qq.com

Keywords: Sedimentary Sand Body,Complex Structure, Thin Interbeds, Spatial Distribution of Oil and Water, Heterogeneity

Thin interbedded sandstone reservoirs are one of the key points for unconventional reservoirs in the world; for example, the Berkin Basin in Algeria, the Oriente Basin in Ecuador, the Qaidam Basin and the Bohai Bay Basin in China all have typical thin interbeds Sandstone oil reservoirs, The number of vertical layers is large, the thickness of the single layer is thin, and the plane distribution is wide, highly developed faults, extremely complex tectonic systems, and the diverse sedimentary sand bodies and the influence of diagenesis factors, resulting in strong spatial distribution of oil and water heterogeneity and The distribution law is unclear, which brings great difficulties to the subsequent efficient development of such reservoirs. Therefore, a set of effective technical methods for characterizing the heterogeneous distribution of oil and water in thin interbedded sandstone reservoirs is urgently needed.

In order to solve the above problems, this paper proposes a technical process for the characterization of the heterogeneous three-dimensional distribution of oil and water in thin interbedded sandstone reservoirs under complex structural systems. It mainly includes: (1)Detailed description of complex tectonic systems, proposed technical methods for classification and analysis of complex fault systems, and completed stratigraphic division and comparison of target areas and detailed structural interpretation; (2) described the distribution characteristics of complex sedimentary sand bodies, proposed a set of technical methods for the characterization and modeling of the microfacies distribution of complex sand bodies, and completed the deposition of the target area. The vertical, horizontal and plane distribution characteristics of sand bodies are described; (3) Oil-water identification and heterogeneous three-dimensional distribution characterization, in-depth analysis of the control effects of complex structures, sedimentary sand bodies and gravity differentiation on oil-water spatial distribution, and a set of technical and method flow for single well oil-water characteristic analysis-longitudinal analysis of multi-well oil-water profiles in sub-wells and sub-blocks-analysis of distribution law of layered oil level in the whole region is proposed; completed the vertical, horizontal and plane distribution characteristics of oil and water under the control of complex structures and sedimentary systems, three-dimensional The distribution law of oil-water space heterogeneity is revealed.

The above-mentioned technical process has effectively completed the heterogeneous distribution and Characterization of oil and water in the upper and lower Youshashan Formation of Yingdong Oilfield, Qaidam Basin, aiming at the characteristics of thin interbedded sandstone reservoirs, such as many and thin layers, large plane distribution, diverse sedimentary sand bodies and developed faults. and achieved good results; thus providing a reliable theoretical basis for a series of production processes such as follow-up injection and production.

Quantitative identification and analysis of lithology in shale reservoirs in Lucaogou Formation, Junggar Basin

Zhiyue Zhang[1], Chenghua Ou[1,2*], Baiqiang Shi[1], Haosen Quan[1], Bo Yan[1], Furun Xiao[1], Peipei Guo[1], Hang Li[1], Zeyu Wang[1]
1. School of Oil and Natural Gas Engineering, Southwest Petroleum University, Chengdu, Sichuan, CHINA
2. State Key Laboratory of Oil and Gas Reservoir Geology and Exploitation, Southwest Petroleum University, Chengdu, Sichuan, CHINA
E-mail: chomm@163.com

Keywords: Lucaogou Formation,shale reservoirs,quantitative identification of lithology

As the shale oil reservoirs of Lucaogou Formation in the Junggar Basin belong to lacustrine mixing, the petrology is characterized as diverse lithology, varied minerals, and multiple transitional rock categories, resulting in the increasing inconsistency of lithology reflected by conventional logging. The identification of sweet spots is of great significance to the exploration and development of shale oil reservoirs in this area. Previous studies have analyzed the genetic mode of the dessert reservoir, but the lithographic classification and identification have not been studied before, thus it is urgent to study it.

According to the lithology of the well above and below the dessert, the lithology of the area is divided into three categories: mud shale, dolomite and sandstone. On this basis, it is further divided into six subcategories, namely silty mud shale, dolomitic mud shale, sandy dolomite, dolomicrite, silty sandstone and dolomitic-argillaceous siltstone. All the six subtypes of lithology exist in the upper desserts, and no dolomicrite exist in the lower desserts. Based on lithology division and conventional logging sensitivity analysis, the top and the bottom desserts are quite different.

By analyzing the curve values of lithologies, GR and RT curves of lithology with high sensitivity were selected for research. The first step is the logging curve data processing to determine the effective cut-off value of logging curve data; the second step is the single core curve reading; the third step establishes the sensitive curve GR-RT crossplots; the fourth step is to confirm the identification rules of lithological logging boundary parameters. In the upper sweet spot, the identified GR range of dolomicrite and sandy dolomite is less than or equal to 75API, and the RT ranges of them are larger than 190Ω.m and from 60 to 190Ω.m. The rules for dolomitic mud shale is GR greater than 75API and RT greater than 60Ω.m. For silty sandstone, dolomitic-argillaceous

siltstone and silty mud shale, the GR values are less than or equal to 60API, between 60API and 80API, and larger than 80API, while the RT range of these three subtypes is less than or equal to 60Ω.m. In the lower sweet spot, the RT ranges of silty muddy shale and sandy dolomite are both greater than 55Ω.m, while the GR for them are greater than and less than or equal to 75API. The RT values for silty sandstone, dolomitic-argillaceous siltstone and silty mud shale are all less than or equal to 55Ω.m, and GR values are less than or equal to 60API, from 60 to 80API and greater than 80API. Finally, compared with SPSS lithology identification rule, lithology analysis analysis, the recognition rate of dessert area was 92.58% and that of dessert area was 94.43%.

E-mail: 122046544@qq.com

Keywords: Feixianguan Formation in Tieshanpo area,Gypsum layer; Control on the reservoir,Heterogeneous distribution,Quantitative characterization

Tieshanpo is located in the Huangjinkou structural belt at the front of the Daba Mountains, Sichuan Basin, and the Feixianguan Formation in the area is developed on the edge of the carbonate platform in the east of the Kaijiang-Liangping Trough. Affected by both the paleogeomorphology of the ocean trough and the depositional environment, the Feixianguan Formation in Tieshanpo area is rich in natural gas resources, but the reservoir formation mechanism, and its temporal and spatial distribution characteristics are unclear, which seriously affects the development prospects of the gas reservoir.

On the basis of abundant core, well log, logging and 3D seismic data in Tieshanpo area, a large amount of evidence of paleosedimentary environment evolution was found by core description and thin section analysis. Combined with previous achievements, a geological model of sedimentary microfacies was established. Based on the geological model calibration logging and well log data, the longitudinal evolution sequence of sedimentary microfacies was established. Furthermore, genetic inversion method is used to obtain the distribution of interwell sedimentary microfacies by logging constrained seismic.

The results of the above geology-log-seismic integrated interpretation and analysis show that :(1) the gypsum layer produced by heavy brine reflects the arid and low-lying gypsum lagoon sedimentary microenvironment near the surface, with shallow seawater and high salinity; (2) The vertical and horizontal heterogeneous distribution of gypsum layer indicates that the sedimentary microenvironment of gypsum lagoon changes rapidly, resulting in the rapid change of seawater energy, which makes gypsum lagoon coexist with oolitic beach at the edge of platform, forming the interbedded structure of gypsum layer and oolitic beach vertically and horizontally. (3) Based on the significant response of gypsum layer logging and seismic, a three-dimensional model of gypsum layer and oolitic beach of Feixianguan Formation was established by sequential indicator simulation, revealing the distribution law of gypsum layer and oolitic beach, quantitatively characterizing the favorable reservoir-cap assemblage of gas reservoir in three-dimensional space, indicating the direction of efficient development of gas reservoir.

E-mail: xnyqt001@163.com

Keywords: CO2-enhanced shale gas, adsorption behaviors, kerogen and minerals, CH4 and CO2

Recently, CO_2-enhanced shale gas development technology has received more and more attention since it can realize CO_2 sequestration while increasing the recovery of shale gas. However, the adsorption behaviors between different gases and the nanopore system in shales are still poorly understood. In this study, different kerogen models as well as clay minerals were built by the molecular dynamic method. The adsorption behaviors of CH_4, CO_2 as well as their mixtures on these models with different water saturation were examined by the grand canonical Monte Carlo simulation. Excess adsorption curves were achieved and fitted by the DRk model. The result show that the adsorption of CH_4 and CO_2 in shale components belongs to physical adsorption and the adsorption capacity of kerogen increases with the increasing maturity. The interaction between CO_2 and kerogen is stronger than that of CH_4, indicating that CO_2 can effectively replace CH_4 in kerogen. A similar phenomenon can be seen in the interaction of clay minerals and CO_2. Furthermore, it is found that kaolinite has the strongest adsorption capacity for CH_4, while montmorillonite is more inclined to adsorb CO_2. Moisture significantly reduce the adsorption capacity of the gases on kerogen and minerals since the water molecules crowd out the adsorption sites as well as storage space for the gases. These findings will provide theoretical evidence for further assessment of the mechanisms for CO_2 geological sequestration with enhanced shale gas recovery.

Keywords: CUS and CS,Low porosity and ultra-low permeability reservoirs,Hierarchical classification evaluation,Classification facies modeling,Facies control attribute modeling

At present, the world is facing serious challenges of the greenhouse effect. my country is in the critical period and window period of "carbon peak". Carbon capture, utilization and storage technology (CCUS) is the most widely used frontier in the oil and gas industry. The technology can effectively and economically realize CO_2 sequestration while exploiting the potential of oil reservoirs, and solve the pressing environmental problems. However, at present, there is no complete set of supporting technologies at home and abroad to realize the CCUS classification and evaluation of reservoirs, so that there is no sufficient technical reference for CCUS operations in oilfields.

Based on this urgent need, this paper proposes a complete set of reservoir CUS and CS classification and evaluation techniques. (1) Relying on basic data such as logging interpretation data to understand the basic geological characteristics of the oil reservoir, formulate a set of scientific and reasonable classification standards for the classification of reservoir facies and oil layers, and divide the strata into reservoirs and interlayers. According to the pros and cons of reservoir capacity and flow capacity, it is further divided into good reservoir C1, reservoir C2, and poor reservoir C3, and the barrier and interlayer are divided into barrier and interlayer G1 and good barrier and interlayer G2 according to the tightness and plugging capacity of the formation. The oil saturation of the fluid in the layer divides the reservoir fluid into three types: oil layer, oil-water layer and water layer. (2) Establish a single well classified facies model and the corresponding classified facies model. On this basis, a facies-controlled attribute model of porosity, permeability and saturation is established. (3) Considering the effective thickness and caprock factors on the basis of the existing model, establish a corresponding model according to the two-stage classification standard of CUS and CS, and calculate the reserves of crude oil and the storage amount of CO_2.

In this paper, a two-stage classification and evaluation of CUS and CS is carried out for a low-porosity and ultra-low permeability reservoir in central my country. The crude oil output of the reservoir is about 9.16 million tons, the CO_2 storage in the CUS stage is about 22.66 million tons, the CO_2 storage in the CS stage is about 70,000 tons, and the total CO_2 storage in the CUS and CS stages is about 22.73 million tons. The results are scientific, valid, reliable, economical, and quantifiable.

AI-based Quantification of Sedimentary Facies and 3D Reservoir Architecture of Fan Delta Front in the Du66 Block in the Lacustrine Liaohe Sub-Basin, Bohai Bay Basin

Shu Jiang[1*], Haitao Shi[2]

1. School of Earth Resources, China University of Geosciences at Wuhan, Wuhan, Hubei, CHINA
2. Research Institute of Exploration and Development, Liaohe Oilfield, Panjin, Liaoning, CHINA

E-mail: jiangsu@cug.edu.cn

Keywords: Sedimentary Facies, Reservoir Architecture, AI-based Quantification, Sandbody Connectivity

The sandstone in the upper 4th member of the Paleogene Shahejie Formation in the Du66 Block in the Liaohe Sub-Basin, Bohai Bay Basin is a shallow heavy oil reservoir. Previous studies indicated this reservoir is lacustrine fan delta front sandstones. The heterogeneity of the reservoir needs to be characterized for the identification of permeable reservoirs and barriers for a better development plan using in-situ combustion. According to the well-logs motifs corresponding to the sedimentary facies, acoustic log (AC), shallow resistivity (RS), and deep resistivity (RT) are selected as supervised logs to predict the facies using the neural network method. Then the six seismic attributes including original seismic reflection, coherence, RMS, signal envelope, 40 HZ spectral decomposition, and dip near the wellbore are selected to predict the lithofacies based on the neural network training of seismic attribute waves tied to the logs with frequency reduction. The 3D lithological bodies are then reconstructed based on the artificial intelligence with deep learning, which is way faster than the traditional geostatistics method. The fine-grained, medium-grained, coarse-grained, and sandy gravel sandstone bodies, structure, and thickness can then be rendered from the seismic attributes, clearly showing the connectivity and trap volume of reservoirs. The accuracy of the prediction ranges from 76% to 96%. The results reveal that the thick fine to medium-grained sandstone is very heterogenous and could be a channel for the steam breakthrough, the thick connected sandy gravel is a primary permeable channel for heavy oil flow.

Sequence-lithofacies paleogeographic characteristics and geological significance of Lower Permian Chihsia stage in upper Yangtze region

Minglong Li[1], Xiucheng Tan[1*], Qiang Xu[1]
1. School of geoscience and technology, Southwest Petroleum University, Chengdu, Sichuan, CHINA
E-mail: TANXIUCHENG70@163.COM

Keywords: upper Yangtze region, Sichuan Basin, Lower Permian, Chihsia stage, Sequence-lithofacies paleogeography

The dolomite reservoir of Permian Chihsia Formation in Sichuan Basin located in the Upper Yangtze region is a hot spot of exploration and has been making breakthroughs in recent years. In the early Permian, The area is in the extension-compression transition period of Hercynian tectonic cycle. The tectonic-sedimentary process is complex, and there exist differences in regional lithofacies and paleogeography, which greatly limited the large-scale exploration of Chihsia Formation. Through the massive collection of logging, field outcrops, core and isotope geochemical data, based on the study of the relationship among sea-level change, sequence filling, paleogeomorphology and lithofacies, the lithofacies paleogeography and evolution of Liangshan-Chihsia Formation of lower Permian in Sichuan Basin and its periphery were restored, and its sedimentary tectonic dynamic process was revealed. The results show that the periphery of Sichuan Basin is characterized by "four uplifts and four depressions", which is characterized by four paleo-uplifts (or paleo-lands) of Kangdian, Hannan, Shennongjia and Xuefeng mountain, and four depressions of Chengdu-Mianyang, Kangdian front, Xuefeng mountain front and Yichang, while inside the basin, it is a paleogeographic pattern of "alternating sub-convex and sub-concave". Under the influence of continuous and gradual transgression and overlap in Hercynian period, there are three third-order sequences (SQ0, SQ1 and SQ2) developed in the depression area, while only two third-order sequences (SQ1 and SQ2) in the uplift area. The continuous development of the uplift-depression reflected by the strata in each sequence filling period generally presents different degrees of stratigraphic thickness differentiation in the northeast and northwest directions in different stages, which indicates that the NE and NW extensional structures developed simultaneously in the Sichuan Basin control the paleo-geomorphic pattern and sequence filling mode of the basin under the background of the oblique subduction of the Jinshajiang-Ailaoshan ocean and the North-South expansion of the Mianlue ocean. Meanwhile, SQ2, as the main development period of mound-shoals of Chihsia Formation, the distribution of dolomitic reservoirs (dolomite, calcareous dolomite and dolomitic limestone) has a good correlation with the concave-convex conversion slope break zone of sedimentary landform. On the basis of this, a new understanding was put forward that the favorable mound-shoals and dolomitic reservoirs are distributed in the scale of "platform-margin surrounded by the depression and sags surrounded by uplands in the basin", and it was pointed out that the platform-margin area in western Sichuan is still the focus for exploration at present, while Chengdu-Mianyang and Guangwang depressions within the platform and central Sichuan-southern Sichuan are favorable exploration areas for dolomite reservoirs of Chihsia Formation in the next step. The research results redefine the tectonic paleogeographic framework of the key tectonic transformation period of the lower Permian, which has important reference significance for re understanding the tectonic and sedimentary evolution of the upper Yangtze Permian. By using the four elements “sea-level change, sequence filling, paleogeomorphology and lithofacies" obtained from the study, a mapping method of oil and gas lithofacies paleogeography could be used for effectively predicting the distribution of favorable reservoir zones, which greatly expands the exploration field of Chihsia Formation.

Influence of the Emeishan basalt eruption on hydrocarbon generation and expulsion characteristics of Sinian algal dolomite in Sichuan Basin

Bo Pang[1], Xiongqi Pang[1,2*]
1. State Key Laboratory of Petroleum Resources and Prospecting, China University of Petroleum (Beijing), Beijing, CHINA
2. College of Geosciences, China University of Petroleum (Beijing), Beijing, CHINA
E-mail: pangxq@cup.edu.cn

Keywords: Oil and gas resources, Emeishan mantle plume, Geothermal effect, Hydrocarbon generation and expulsion, Sichuan Bsin

The Sichuan Basin is rich in marine oil and gas resources, and the amount of resources is affected by source rocks (Zou et al., 2014; Dai et al., 2018; Hu et al., 2019). The Emeishan mantle plume is an important tectonic thermal event in the Sichuan Basin, which has an important influence on the source rocks under the Middle-Lower Permian in the Sichuan Basin (Zhu et al., 2007; Aarnes et al., 2011; Agirrezabala et al., 2014; Li et al., 2016). Therefore, the better understanding of the effect of Emeishan basalt eruption on source rock is vital for the exploration of marine oil and gas resources. Based on the thermal history study of the Sichuan Basin (Cao et al., 2015; Jiang et al., 2018; Liu et al., 2018; Qiu et al., 2021), this study restored the thermal maturity of the algal dolomite of the Dengying Formation in the Sichuan Basin to the maturity of normal evolution. The hydrocarbon generation and expulsion characteristics of normally evolved algal dolomite and algal dolomite affected by basalt eruption were calculated by the hydrocarbon generation potential method (Jiang et al., 2016; Li et al., 2020). Through comparison, the influence of the Emeishan mantle plume on the algal dolomite of the Sinian Dengying Formation is analyzed. The research indicates that the Emeishan mantle plume has an important influence on the algal dolomites of the Sinian Dengying Formation. The thermal effect of the Emeishan mantle plume promotes the maturation of algal dolomite, which leads to the shortening of the oil generation period and the early arrival of the gas generation peak. The main hydrocarbon expulsion period of the normally evolved algal dolomite should be from the end of the Triassic to the end of the Jurassic, while the main hydrocarbon expulsion period of the algal dolomite affected to basalt eruption was advanced to the end of Silurian to the end of Triassic. In the current period, due to the high maturity of algal dolomite, the Emeishan mantle plume has little impact on the total resources.

Variation of Precambrian seawater environments and related microbial hydrocarbon source – reservoir assemblage system

Dongya Zhu[1*], Quanyou Liu[1], Jingbin Wang[1], Guang Hu[2], Zhiliang He[1]
1. Basic Geology Department, Petroleum Exploration and Production Exploration Research Institute, SINOPEC, Beijing, CHINA
2. School of Geoscience and Technology, Southwestern Petroleum University, Chengdu, Sichuan, CHINA
E-mail: zhudy.syky@sinopec.com

Keywords: Microorganism, seawater environment, Ediacaran, hydrocarbon source-reservoir assemblage, Sichuan Basin

Several commercial Precambrian petroleum systems have been discovered worldwide. Various types of microorganisms have been identified in Precambrian successions contributing to the development of high-quality hydrocarbon source rocks and microbialites with high reservoir porosity. However, there are still some key issues which need to be thoroughly explored. For example, what is the role of microbes and which oceanic conditions lead to the development of organic-rich hydrocarbon source rocks and microbialite reservoirs? And, how did the microbial source rock and reservoir constitute an effective hydrocarbon source-reservoir assemblage system. Fortunately, widespread black shale source rocks in the Edicaran Doushantuo Formation, and the directly overlying Dengying Formation microbialite reservoirs in the Sichuan Basin (China), provide the ideal material to address these key issues. During the Edicaran Doushantuo Formation period, high-quality black shale source rocks were widely developed, and the organic matter in the source rocks was mainly derived from microbes including filamentous bacteria and planktonic algae. The thickness of the source rocks is up to 200 m, and the total organic carbon (TOC) value is ~17.9%. During the Dengying Formation period, thick-layered microbialites, including microbial stromatolite, thrombolite, and botryoidal dolomite were developed extensively, with the abundant primary framework and secondary dissolution pores. The transition of the seawater environment controlled the development of microbial source rocks or microbialite reservoirs. In a deep, euxinic reducing seawater conditions, microbial organic matter was well preserved and accumulated in fine-grain sediments, thus forming the high-quality microbial source rocks. Meanwhile, under such a reducing condition, a large amount of layered, nodular, granular, and strawberry pyrites were precipitated due to the effect of BSR reaction with extremely positive δ34S values (up to 39.0‰). Meanwhile, in a shallow turbulent high-energy oxidized seawater conditions, especially in the intermittent "Dolomite Sea" environment, microbial dolomitization promoted the massive development of microbial dolomite mound/shoal frameworks, constituting the matrix for the development of large-scale microbialite reservoirs. During the later burial evolution process, oil and gas generated from the Doushantuo Formation microbial source rocks migrated along faults and accumulated into the overlying Dengying Formation microbialite reservoirs, and was sealed by the Lower Cambrian mudstone caprocks, thus forming an effective microbial source-reservoir assemblage system. The areas surrounding the Mianyang, west side of the Chengkou, and northwest side of the western Hubei troughs are considered as favorable areas for the microbial source-reservoir system. The black shales of the Mesoproterozoic Xiamaling Formation and the overlying microbial stromatolites in North China, and the source rocks of the Ara Group and the overlying microbialites in the Salt Basin of South Oman also constitute a similar potential effective microbial source-reservoir system.

Terminal Ediacaran Microbial Carbonates in a High-frequency Sequence Stratigraphic Framework — A Case Study of the 4th Member of Dengying Formation, Central Sichuan Basin, SW China

Yuanquan Zhou[1], Zhong Li[1*]
1. State Key Laboratory of Lithospheric Evolution, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, CHINA
E-mail: lizhong@mail.igcas.ac.cn

Keywords: Terminal Ediacaran, fourth-order depositional sequence, thrombolite, stromatolite, depositional environment

Objectives

Because of their significance in earth's biological and environment co-evolution and reservoir potential, the terminal Ediacaran shallow marine microbial carbonates have been paid great attention in sedimentological research as well as oil and gas exploration. Current study is largely focused on the general depositional environment and paleooceanography of the microbial carbonates, while the lithofacies association and environmental transition during higher-frequency sea level fluctuation deserve further investigation. A series of wells from the 4th member of Dengying Formation in Gaoshiti-Moxi area, Sichuan Basin, SW China enables us to conduct research on terminal Ediacaran microbial carbonate lithofacies and related environmental characteristics and evaluate their reservoir potential within a fourth-order depositional sequence.

Methods and Procedures

1 Through detailed core and thin section observation, the lithology and lithofacies association modes of microbial carbonates and non-microbial carbonates are identified.

2Combining the lithofacies characteristics with logging data interpretation, we divide fourth-order depostional sequences of the 4th Member of Dengying Formation and conclude the lithofacies distribution in a fourth-order sequence. The spatial lithofaices association modes in the study area are also compared.

3According to lithofacies distribution, typical samples are selected to conduct in-situ trace elements analysis to explore the corresponding environmental features. Trace element content, ratio and REE+Y normalized patterns are applied to characterize salinity and redox variation in during the fourth-order sea level change.

4Combining the lithofacies and environmental characteristics, we establish a depositonal and environmental model during fourth-order sea-level fluctuations for terminal Ediacaran microbial carbonates of the study area. Additionally, by matching the collected porosity and permeability of with typical lithofacies associations, the reservoir potential of the typical lithofacies associations are summarized.

Results and Conclusions

(1) Clotted thrombolite, planar thrombolite and wavy stromatolite are three types of microbial carbonates in the 4th member of the Dengying Formation in Gaoshiti-Moxi area, Sichuan Basin. The microbial carbonates and non-microbial carbonates (mainly including mudstone and grainstone) were developed on a carbonate platform in a shallow subtidal - intertidal environment during terminal Ediacaran.

(2) In a fourth-order depositional sequence, during late TST - early HST, thin-layered mudstone - clotted thrombolite association dominates the platform margin, while thin-layered mudstone - wavy stromatolite association dominates the platform interior. From late HST of the last sequence to early TST of the next, the platform margin develops thick-layered clotted thrombolite - grainstone association, while the carbonate interior develops thin-layered planar thrombolite - wavy stromatolite association.

(3) Variation occurs in salinity and redox during fourth-order sea level change. Specifically, during late HST, the platform margin is characterized by low-salinity and with high less reduced environment, where clotted

thrombolites dominate. The platform interior develops several high-salinity and more reduced areas, where planar thrombolites and wavy stromatolites dominate. Overall, the carbonate platform became more oxygenated during terminal Ediacaran.

(4) In a fourth-order depositional sequence during terminal Ediacaran, the late HST platform margin clotted thrombolite - grainstone association and platform interior planar thrombolite - wavy stromatolite association contribute the most reservoir potential. late TST - early HST microbial carbonates deserve further study for potential favorable reservoirs.

E-mail: hebizhu@cags.ac.cn

Keywords: tectono-sedimentary sequence, petroleum system, Exploration direction, Neoproterozoic, Tarim Basin

The investigation shows that the Neoproterozoic to Early Cambrian source rocks are widely distributed in the world, forming many large oil and gas fields. On the Precambrian basement, the Neoproterozoic Cryogenian-Ediacaran tectono-sedimentary layers are widely developed in the Tarim Basin. After rifting-depression evolution, a huge thickness of moraine-shelf slop-shore and carbonate platform sedimentary system is formed, accompanied by the multiple-phase igneous facies. The early deep water shelf facies and late carbonate platform facies can form high-quality ancient source rocks and reservoirs and form a good combination of source, reservoir and cap rocks with the mudstones and shales distributed widely in the early Cambrian shelf facies. According to the comprehensive evaluation of basin evolution and petroleum geological conditions, well LT1, LT3 and TS5 in the structural high of Tabei Uplift encountered good oil and gas shows in the Ediacaran System. The Ediacaran Qigebrak Formation and Lower Cambrian Yuertusi Formation form a good reservoir-cap assemblies in northeast part of ancient Tabei uplift. In the eastern part of the area Cryogenian System Aulacogen is developed, which may be able to form two types of reservoirs. The high part of platform in the reef-shoal facies belt of platform margin and the slope area is a favorable exploration area and targets.

Keywords: various ooids, nucleation via microbial mineralization,storm turbulencediagenetic alterationQigebulake formation in Upper Sinian

Ooid in carbonate rocks is one of the important carriers to reconstruct the ancient depositional environment. The co-occurrence of various ooids have been found in the microbial mat and shoal bar of lagoon, Qigebulake formation in Upper Sinian at Xinghuo 1 well area, northern Tarim Basin. Ooids can be divided into 12 sub-types, including bacteria (algae) complex ooids, thin-skinned heteromorphic micritic giant ooids , thin-skinned micritic giant ooids , cerebroid ooids, coniatoid ooids (oval to irregular large) , radial-cerebroid giant complex ooids, broken and regenerated thin-skinned eccentric complex ooids, selective dolomitization ooids, radial micritic (envelope) ooids, concentric radial ooids, spiny radial-concentric ooids, recrystallization ooids, in which the bacterial (algae) complex ooids , micritic giant ooids, spiny radial-concentric ooids are dominated. This paper elaborates the structure of the cortex and core, as well as cement, matrix and formation condition of the above ooids, and discusses the effects of nucleation induced by microbial mediation, tidal-current or storm surges in a warm, alkaline saline lagoons environment and diagenetic overprint on their symbiosis and evolution. The nucleation via microbial mineralization occurs extensively. The tidal current and the storm turbulence caused aragonite- and organic matter-riched micrite limestone which precipitated in low-energy and anoxia bottom water to tear, roll or grind into debris, and further promoted the formation of large and giant micritic ooids and other associated ooids. Marine cementation, metabolic activities (colonization), meteoric water dissolution, quasi contemporaneous dolomitization of the aragonite or high-Mg calcite are widely developed in the aragonite sea through accretion processes and diagenetic reformation, which play an important role in the formation and evolution of ooids. Therefore, the main factors controlling the origins of multiple types of ooids are nucleation induced by microbial mediation or biofilm calcification, the suspension and accretion process under certain marine hydrodynamic conditions, and a variety of diagenetic alteration. Moreover, mold pores, intergranular (intragranular) solution pores, intergranular pores and organic micropores presented in the above ooids have certain reservoir significances for the petroleum explore.

Source environment and hydrocarbon source quality during Ediacaran - Cambrian transition period: A case study of Qinglinkou outcrop in Zigui, western Hubei, China

Kun Yuan[1*], Qianglu Chen[1]
1. Wuxi Research Institute of Petroleum Geology, Sinopec Petroleum Exploation and Production Research Institute, Wuxi, Jiangsu, CHINA
E-mail: zelu_yk@163.com

Keywords: Ediacaran - Cambrian, Qinglinkou outcrop, Hydrocarbon-Forming Organism, mineral assemblage, sedimentary environment

The paleomarine environment and biomes changed significantly during the Ediacaran-Cambrian transition period. Varied studies have been carried out on environmental evolution, biometric identification, accurate correlation of stratigraphic chronology, palaeogeographic pattern and development environment of source rocks. However, the controlling factors of sedimentary environment evolution on the development of source rocks during the E-C transition period remains to be systematically studied. In this paper, the Qinglinkou outcrop in Zigui, which continuously exposes the lower Ediacaran-Lower Cambrian strata in the Middle Yangtze region, is selected. On the basis of field observation and sedimentary facies analysis, combined with microscopic section analysis, X-ray diffraction, SEM and other experimental methods, the relationship between sedimentary environment changes and source rock quality of Doushantuo Formation in the Upper Ediacaran- Yanjiahe Formation of the Lower Cambrian was studied systematically. The results show that the content of clay is less than 30% in all source rocks, the content of carbonate (mainly dolomite) is more than 40%, and the Doushantuo formation and the Yanjiahe Formation both show a high level of silicon content. The organic carbon content of source rocks is positively correlated with the silicon content, but when the silicon content exceeds 70%, it reverses, showing a Parabolic pattern which deviating to the right. The hydrocarbon-forming organisms of Doushantuo Fm., Dengying Fm. and Yanjiahe Fm. were found to contain planktonic algae, benthic algae, radiolarians and acritarchs. In the source rock of Doushantuo Fm., there are a large number of characteristic large spiny acritarchs, which can be found only in the lower member of Dengying Fm. Large spiny acritarchs disappear completely in the Lower Cambrian in this outcrop. The vertical variation of sedimentary environment in Qinglinkou area was analyzed based on the characteristics of hydrocarbon forming organism assemblages and mineral assemblage in different layers, indicating that the sedimentary environments contains shallow water shelf, tidal flat, deep water shelf and open platform developed successively from bottom to top. The internal relationship between the sedimentary environment and the quality of source rocks is also discussed tentatively based on this research.

Seabed mineral deposits as a sustainable resource for rare earth elements

Fani Sakellariadou[1*], James R Hein[2], Francisco J. Gonzalez[3]
1. Maritime Studies, University of Piraeus, Piraeus, GREECE
2. Pacific Coastal and Marine Science Center, USGS, Santa Cruz, CA 95060, UNITED STATES
3. Marine Geology Division, Geological Survey of Spain, Madrid, 28003, SPAIN
E-mail: fsakelar@unipi.gr

Keywords: crusts, nodules, placer deposits, rare earth elements, seafloor minerals, sustainable blue economy.

By 2050, the global economy and population are expected to grow significantly, requiring more food, energy, and raw materials that will put great pressure on the environment. To limit global warming and the climate crisis, modern society is focusing on “net-zero emissions” targets based on the use of clean-energy technologies, which will require new sources of rare earth elements (REEs) and other E-metals. Promising new sources for these essential REEs are seafloor minerals, especially ferromanganese crusts (crusts), polymetallic nodules (nodules), phosphorite, and placer deposits [1].

The Clarion Clipperton fracture zone (CCZ) in the northeast Pacific Ocean was the first extensive nodule field discovered, followed by crusts rich in cobalt on seamounts in the Pacific Ocean. Thirty International Seabed Authority contractors signed 15-year contracts for the exploration of nodules, crusts, and polymetallic sulphides in the international seabed area of the Atlantic, Pacific, and Indian oceans [2].

The most extensive nodule fields occur in the CCZ, the Penrhyn Basin (South Pacific), Peru Basin, Central Indian Ocean basin, and NW Pacific. REE-rich deep-sea muds occur in many places in the Pacific Ocean and have been well studied near Minamitorishima Island in the western North Pacific Ocean [3]. Potential targets for crust exploration occur in the NW equatorial Pacific Prime Crust Zone, the NE Atlantic, Arctic and Indian oceans [4, 5, 6].

The major concern associated with deep-sea mining is the extent and nature of environmental impacts. Mining strategies should incorporate activities to support the restoration of disturbed ecosystems, like the setting of un-mined biological corridors, larval dispersal routes, and the positioning of artificial substrates in the case of nodules [7]. Collecting biological baseline data and further progress in restoration science, technology, and training will reduce the potential ecological impacts of REE mining.

Placer deposits composed of heavy and weathering-resistant minerals are distributed in numerous sites along continental shelves. Potential areas for exploitation of REE-rich placer deposits occur along the SE coast of Madagascar, on beaches and offshore China, coastal areas of India, at Aksu Diamas in Turkey, Atlantic coasts of Galicia in Spain and the Nea Peramos shallow-marine environment in Greece [8]. High concentrations of thorium and uranium make monazite a restricted ‘atomic’ mineral for the exploration of many beach placers.

Seabed mineral resources have relatively low TREO grades and significant TREO yields compared to the large terrestrial LREE-rich carbonatite-hosted deposits and are comparable to the terrestrial HREE-rich ion-adsorption clay deposits. These marine deposits offer a promising alternative to the land-based REE-rich deposits even though extracting minerals from the deep ocean presents a technological challenge. However, two advantages of the deep-ocean deposits are their polymetallic nature, and the relative ease of extracting the REEs from the ore compared to the complex processing of carbonatites for their REE content.

The achievement of the Sustainable Blue Economy objectives, where environmental protection and economic activities go hand in hand, demands the formal establishment of regulations and practices for ocean mining and the effective management and exploitation of deep-sea mineral resources.

Enhanced Bottom Currents Promoted the Enrichment of Rare Earth Elements (REYs) in Pelagic Sediments from the Northwestern Pacific Ocean at ~11.5–9.5 Ma

Dongjie Bi[1,2], Xuefa Shi[1,2*], Mu Huang[1,2], Miao Yu[1,2], Jianxing Liu[1,2], Tianyu Chen[3]

E-mail: xfshi@fio.org.cn

Keywords: Deep-sea REY-rich sediments, Bottom currents, Abyssal ventilation, Northwestern Pacific Ocean

Pelagic sediments enriched in rare earth elements (REY) widely distributed in the Pacific Ocean (e.g., Kato et al., 2011; Shi et al., 2021), which have gained extensive attention as economically valuable resources. However, the REY enrichment mechanisms in pelagic sediments remain controversial. An active bottom current and a low sedimentation accumulation rate (SAR) seem to be important for the formation of REY-rich sediment (e.g., Ohta et al., 2020; Bi et al., 2021; Shi et al., 2021), but related studies on such links are still lacking, partly related to the difficulty in obtaining reliable geochronology for the slowly accumulating, essentially carbonate-free sediments. Here, we present refined chronostratigraphic framework for a sediment core taken from the pelagic environment of the western North Pacific Ocean combing authigenic $^{10}Be/^{9}Be$ dating, $^{230}Th_{ex}$ dating, and magnetostratigraphy. Furthermore, neodymium isotopic signal of the authigenic Fe–Mn oxyhydroxide fraction together with the Mn/Al and Mn/Ti ratios and grain sizes of bulk sediments, were used to reconstruct the variability of deep ocean currents. Multiple lines of evidences from Nd isotopic values, the Mn/Al and Mn/Ti ratios, and grain sizes consistently indicated that distinct enhancement of bottom currents occurred in the study area between 11.5 Ma and 9.5 Ma, presumably resulting in intensified deep-water ventilation. Our results thus established the link between enhanced bottom current and enrichment of REY in the pelagic sediments of the study area. We suggest that intensified abyssal ventilation and the associated increase in primary productivity around seamounts might increase the flux of micronodules and fish debris into the pelagic sediments, promoting the scavenge of REY from bottom seawater.

E-mail: renxiangwen@163.com

Keywords: Polymetallic nodules, Specific surface area, hydrogenetic nodules

Polymetallic nodules (nodules) are predominant deep sea sedimentary mineral resources due to the enrichment of critical metals. Polymetallic nodules are loose and porous, which is the critical material feature that contributes the adsorption and then enrichment and mineralization of trace metals from seawater and pore water. Furthermore, this feature has potential to be utilized in industrial water disposal by adsorption. Therefore, specific surface area (SSA) is one of key factors deserved further study. At present, the technology and methods for analyzing SSA are well-developed. However, it is less applied in the analysis of the specific surface of polymetallic nodules, and the pretreatment conditions are various according to various research targets. Consequently, the researches on controls of SSA of nodules are still needs to be investigated. In order to achieve the SSA of nodules and to investigate controls, this study explored the pretreatment conditions for the BET SSA analysis of polymetallic nodules, and analyzed the mineralogy and geochemistry of nodules from various areas. The polymetallic nodules from the Atlantic, Indian, and Pacific oceans were recovered for this research. The pretreatment conditions including temperature, duration, and particle size for SSA analysis of polymetallic nodules were studies by applying temperature programming, heating accumulating, and particle size comparing methods. Mineralogical compositions of nodules were analyzed by XRD, and geochemical concentrations were determined by ICP-MS and ICP-OES. The results show that the analysis values of SSA reach plateau when the heating temperature is above 210℃ till 350 ℃; The analysis values of SSA keep consistent after heating for 3 hours by a step of 1 hour at 210℃. The SSA values of samples with a size of several millimeters are 1.027~28.535 m2/g higher compared with those of the same samples crushed into microns. The SSA of nodules correlated positively Co, δCe, and LREEs, and negatively with intensity of XRD 10Å peak, Ni, and Cu. The SSA of nodules from the western Pacific is 329.440~418.711 m2/g, comparable to the SSA of Co-rich crusts. We suggest that consistent SSA values can be obtained when the polymetallic nodules with sizes of several millimeters are heated in vacuum system for 3 hours at 210℃, which is the pretreatment condition to analyze SSA of polymetallic nodules for the research of the mineralization. We proposed that SSA of nodules is controlled by its genesis, and hydrogenetic nodules have higher SSA.

Keywords: Metalliferous Sediment (MS), South Mid-Atlantic Ridge (SMAR), clay mineral, smectite

Abstract: Clay minerals are usually considered as important indicators to identify sources in both terrigenous and marine sediments. In particular, clay minerals in metalliferous sediments (MS) have long been researched in global oceans except in South Mid-Atlantic Ridge (SMAR) due to few explorations arrived there before. Thus, thirty-two MS and thirty-four non-MS (NMS) were studied to shed light on the distribution characteristics and mineral compositions of clay minerals. All the sediments were collected along the SMAR between 10 °S and 27 °S. After removal of organic matter and carbonate, clay fractions (<2 μ m) were investigated by X-ray diffraction (XRD) analysis. The results show that clay mineral assemblages of surface MS consist dominantly of smectite, less abundant illite, chlorite and kaolinite, with average weight percentages of 30%,21%,18% and 16%, respectively. On the other hand, clay mineral assemblages in the NMS consist mainly of illite, less abundant kaolinite, chlorite and very scarce smectite, with the average weight percentages of 47%, 29%, 24% and 0.2%, respectively. The clay fraction in MS comprise amorphous or poorly crystallized Fe/Mn oxyhydroxides, clay mineral, quartz and plagioclase. However, the counterparts in the NMS are mainly composed of well crystallized clay minerals, quartz and plagioclase without the presence of Fe/Mn oxyhydroxides. It is suggested that most of the illite, kaolinite, and chlorite in both MS and NMS are likely belong to aeolian dust originated from South Africa continent. In addition, the abundance of kaolinite dominates the clay mineral assemblage at low latitudes, where the intensive chemical weathering of continental source rocks facilitate the formation of kaolinite. In terms of smectite, it is indicated of authigenic origin with consideration of only smectite is available in several MS and the very scarce in NMS. Moreover, the MS samples with only smectite available are always accompanied by goethite. Therefore, it is believed that most of smectite occurred in studied area is the results of interaction between hydrothermal Fe-oxyhydroxide, silica, and seawater.

Geological setting and seafloor features of the Tongguan field discovered on the Southern Mid-Atlantic Ridge

Bing Li[1], Chuanshun Li[1], Jun Ye[1], Yuan Dang[1], Sai Wang[1], Xuefa Shi[1*]
1. Key Laboratory of Marine Geology and Metallogeny, First Insititute of Oceanology, Ministry of Natural Resources, Qingdao, Shandong, CHINA

Keywords: Southern Mid-Atlantic Ridge, Tongguan field, new volcanic zone

Tongguan field is the southernmost field discovered in the SMAR to date. This field is located in a continuous new volcanic zone within a deep and wide rift valley. The ridge segment is approximately 380 km long and has developed a continuous rift valley with an average width of approximately 30 km. The Tongguan hydrothermal field is located in the rift valley which has a full spreading rate (based on the NUVEL-1 model) of 35.98 mm/yr (V-lat=-7.3 mm/yr, V-lon=-35.2 mm/yr) and is located at an azimuth of N258.3E (DeMets et al.,1990, http://www.ldeo.columbia.edu/ ~menke/plates.html). Meanwhile, two prominent pseudo-fault scarps have been identified on the non-transform offsets at both tips of this segment; such morphological characteristics suggest that along-axis propagation has occurred toward each tip.

The rift valley is characterized by a graben-like structure with an inner valley that is controlled by a series of normal bounding faults; at least three major steep normal fault walls were identified between each flank crest. The height of the rift valley walls, which corresponds to the average height of the two walls between the inner floor and the flank crests (Thibaud et al., 1998), is ~1000m. Meanwhile, the distance between the summits of the first steep walls on both sides is ~18 km. The symmetrical development of three steep walls on each rift valley wall, in conjunction with the presence of flanked abyssal hills that are parallel to the axis on both sides, reflects a symmetrically accreting ridge section. Furthermore, at the center of the inner floor of the rift, a continuous axial ridge rising to a height of 220 m above the inner floor is undergoing accretion.

Guided by the signature of the water temperature anomaly, we performed a surveying line using a towed deep-sea camera body. From this seafloor observation, we found that the new volcanic zone where the Tongguan field was located mainly comprised fresh pillow lava, along with some rifts/fissures that probably developed due to crustal cooling. No significant structural faults were seen, nor were large areas of rock breccia. The unique feature of the Tongguan field, which has a lateral extent of ~200 m, is that it directly overlies pillow lavas, and there is no significant transition zone between them. Through this surveying line, massive sulfide accumulations, altered sulfides, hydrothermal sediments and hydrothermal biota were identified; however, neither vents nor chimneys were observed. Massive sulfide accumulations, mainly comprising breccia deposits, extend for ~100 m through the surveying line, and they show lithological mutation contact relations with their surrounding rocks. A large area (~100 m) of hydrothermal yellowish-brown sediments was also observed along the surveying line; these sediments overlie sulfides, altered sulfides and pillow lavas, and they vary widely in thickness, generally becoming thinner moving away from the direction of the sulfides. Additionally, large populations of hydrothermal biota, particularly blind shrimp, were continuously observed in the water above the hydrothermal sediments and pillow lavas, thus implying that active hydrothermal venting is occurring nearby.

Constraints on fluid evolution and growth processes of black smoker chimneys by pyrite geochemistry: A case study of the Tongguan hydrothermal field, South Mid-Atlantic Ridge

Sai Wang[1*]
1. Key Laboratory of Marine Geology and Metallogeny, First Institute of Oceanography, Ministry of Natural and Resources, Qingdao, Shandong, CHINA
E-mail: wangsai@fio.org.cn

Keywords: Pyrite, Trace element, Black smoker chimney, Tongguan hydrothermal field, South Mid-Atlantic Ridge

The Tongguan hydrothermal field is a modern submarine massive sulfide discovered on the South Mid-Atlantic Ridge. A well-preserved black smoker chimney was collected from the active vent field. Pyrite represents the most abundant sulfide phase, and amorphous silica is the dominant non-sulfide phase in the black smoker chimney. Sulfide phases are commonly rimmed by amorphous silica.

Based on the mineral associations and morphology, the black smoker chimney can be broadly divided into three different concentric zones from the outer wall to the axial hydrothermal flow conduit. The external outer wall of the chimney contains mainly pyrite with minor sphalerite, chalcopyrite and galena. The sulfides within the internal middle layer consist of predominant pyrite, with lesser amounts of marcasite. The axial conduit is dominated by chalcopyrite, with minor pyrite. Seven types of pyrite: framboidal, relict, colloform, dendritic, massive, euhedral and lined pyrites, are identified from exterior to interior of the chimney.

Previous studies have shown that framboidal and colloform pyrites are generally considered to form during the early stage of chimney growth, while massive and euhedral pyrites as well as massive chalcopyrite commonly precipitate during the mature stage of black smoker chimney growth indicating higher fluid temperatures and less fluid-seawater mixing during precipitation (Keith et al., 2016).

As shown by the results of LA-ICPMS, geochemical compositions of pyrite vary across the chimney. Generally, low-temperature elements (Mg, V, Mn, Pb, Zn, Ag and Tl) are enriched in pyrite in the outer wall of the chimney and decrease toward the interior zones. Elements indicative of high temperature conditions, such as Se and Te, show opposite trends and are enriched in pyrite within the inner zones of the chimney. Framboidal, relict, colloform and dendritic pyrites precipitate from low to mid temperature fluids, while massive and euhedral pyrites are products of ore-forming fluids characterized by mid to high temperature (Hannington et al., 2005). The observed patterns are resulted from the changes in temperature and fluid chemistry caused by interactions of between seawater and hydrothermal fluids with each other in the chimney.

Previous studies revealed that Co concentration in hydrothermal pyrite was largely dependent on its contents in parental fluids. Liu et al. (2011) proposed that a drop in temperature and/or a small drop in salinity could result in the decrease of stability of CoCl in low-saline fluids, leading to the precipitation of Co. During the formation of the black smoker chimney, the fluid temperatures increase from rim to core, while the Co concentration in pyrite decrease gradually, which can be explained by drop in salinity of the parental fluids. The extremely low Co contents in the pyrite in our study indicates that the hydrothermal fluids vented from the black smoker chimney are significantly depleted in Cl- compared to seawater, which is generally attributed to phase separation.

The systematic variations in geochemistry and morphology of the pyrite across the chimney reflect multiple stages of mineralization. Different degrees of fluid-seawater mixing and phase separation are the main controlling factors during the chimney formation.

Metallogeny of Xunmei hydrothermal field (26°S), South Mid-Atlantic Ridge: Constraint from in-situ sulfur isotope of sulfides

Yuan Dang[1*]
1. Key Laboratory of Marine Geology and Metallogeny, First Institute of Oceanography, Ministry of Natural Resources, Qingdao, Shandong, CHINA
E-mail: dangyuan1120@163.com

Keywords: Sulfur isotope, Xunmei hydrothermal field, South Mid-Atlantic Ridge

Demand for mineral raw materials is increasing as a result of population growth, rising living standards, urbanization and, more recently, the transition to a low-carbon economy (Zepf et al., 2014). Yet the mining industry faces numerous challenges including rising costs, reducing ore grades and declining discovery rates of new deposits (Calvo et al., 2016). As a result, alternative sources of these minerals are being considered, including the deep-ocean (Murton et al., 2019). Modern seafloor hydrothermal sulfides are rich in Cu, Pb, Zn, Au, Ag, Co, etc. which show good prospecting potential, important economic values and strategic significance. More than ten submarine hydrothermal fields were discovered in South Mid-Atlantic Ridge (SMAR) by China. Up to now, Xunmei (26°S) is one of largest hydrothermal fields in SMAR. In order to tracing the metallogenetic process, *in-situ* sulfur isotopes of 118 spots/minerals (pyrite, chalcopyrite, sphalerite) from 8 sulfide samples, including 3 well-preserved sulfide chimneys, 3 massive sulfides and 2 disseminated sulfides, were ananlysed by laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS). The results exhibit a range of $\delta^{34}S$ values from 2.1 to 8.2‰ (mostly range from 4 to 5‰), with an average value of 4.4‰ (n = 118), falling between the $\delta^{34}S$ values for basalt ($\delta^{34}S = +0.3 \pm 0.5$‰) and seawater ($\delta^{34}S = +20.99$‰), and within overall range of $\delta^{34}S$ values for sulfide samples from other seafloor hydrothermal field (from 1 to 9‰; n = 1841). Pyrites from one of the typical sulfide chimney sample display a relatively large variation in $\delta^{34}S$ values (2.98.2‰, average = 4.3‰, n=26), while chalcopyrites show narrow variation (4.65.1‰, average = 4.5‰, n=21). Variation of sphalerite (4.06.0‰, average = 4.6‰, n=17) are between pyrites and chalcopyrites. This phenomenon is consistent with the distribution of sulfide minerals, of which pyrites commonly occur from low to moderate to high temperature stage, chalcopyrite mainly growth in high temperature stage, sphalerite mainly deposited at (low to) medium (to high) temperature stage. Therefore, the variations of $\delta^{34}S$ value are similar to the temperature ranges of sulfide mineral from the Xunmei hydrothermal field. Two component mixing model was utilized to reveal the contribution of reduced seawater sulfate and basalt (Ono et al., 2007). We can estimate the varying proportions of sulfur derived from seawater in the sulfide chimney, massive sulfide, and disseminated sulfide (1238%, 927%, and 1119%, respectively) and from basalt (6288%, 7391%, and 8189%, respectively), indicating the source of sulfur is mainly derived from magma with little contribution from seawater.

The extremely enrichment mechanism of REY for REY-rich sediments from Central Indian Ocean Basin

M iao Yu[1*], xuefa Shi[1], Mu Huang[1], Dongjie Bi[1]

1. Key Laboratory of Marine Geology and Metallogeny, MNR, China, First Institute of Oceanography, Ministry of Natural Resources , Qingdao, Shandong, CHINA

E-mail: yumiao0950@163.com

Keywords: REY-rich sediments, Early diagenesis, Formation models, Central Indian Ocean Basin, Antarctic bottom water

Rare earth element and yttrium (REY)-rich deep-sea sediments are recently discovered potential undersea rare earth element (REE) resources. Here, we present the results of the mineralogical and geochemical characterization of REY-rich sediments collected from the Central Indian Ocean Basin (CIOB). These data were used to discuss the formation mechanism of REY-rich sediments. The research results show that the REY-rich sediments distributed in the CIOB mainly consist of phillipsite-bearing pelagic clay and pelagic clay, and are characterized by enrichments in middle REEs (MREEs) and heavy REEs (HREEs), negative Ce anomalies and positive Y anomalies. The REY in these sediments are mainly captured dirtcely from overlying seawater by bioapatite and micronodules at the water-sediment interface. After burial, driven by the redox reaction between organic matter and an oxidizer (free O2 and Mn and Fe oxides), the REY-rich sediments experienced weak early diagenesis, and the REY released from hydrogenetic micronodules were captured by the bioapatite (the final host mineral). The REY absorbing mechanism of bioapatite suggest that the post-mortem bioapatites need a long time to keep in touch with seawater, so the low sedimentation rate is the basic condition for the formation of REY-rich sediments. In the low sedimentation rate deep-sea basin (below the sedimentation rate threshold: about 1.5mm/ka), the variation of AABW could affected the contents of REY in REY-rich sediments by controlling the contents of bioapatite.

Mineralogical and geochemical characteristics of near-vent metalliferous sediments along the southern Mid-Atlantic Ridge (12°S–28°S)

Baoju Yang[1,2*], Jihua Liu[1], Chuanshun Li[1], Xuefa Shi[1], Jun Ye[1], Xiangwen Ren[1]
1. Key Laboratory of Marine Geology and Metallogeny, First Institute of Oceanography, Ministry of Natural Resources, Qingdao, Shandong, CHINA
2. School of resources and environmental engineering, Ludong University, Yantai, Shandong, CHINA
E-mail: bjyang0535@163.com

Keywords: Metalliferous sediments, Southern Mid-Atlantic Ridge (12°S–28°S), Mineralogy, Rare earth elements, Hydrothermal mineralization

Mineral and geochemical compositions of surface sediments at 50 sites collected from six hydrothermal fields along the southern Mid-Atlantic Ridge (SMAR) 12°S–28°S were analyzed. The study area can be divided into two segments with Zouyu, Taij, Caifan, and Deyin hydrothermal fields in the northern segment and Xunmei, Tongguan hydrothermal fields in the southern segment. Mineral composition shows that MS in the southern segment contain large amounts of metallic minerals. The features of the sulfides show that a stable high temperature mineralization environment in the Xunmei field and an unstable ore-forming environment in the Tongguan field. Major and trace element geochemistry indicates that hydrothermal materials, terrestrial and volcanic materials are the major sources in these sediments along the SMAR. Rare earth element geochemistry shows that the sulfide-rich MS (metalliferous sediments) have a similar sulfide composition. However, some sulfide-rich MS samples in the Xunmei field show clear positive Eu anomalies, indicating that the rare earth elements (REEs) concentrations in these samples are derived directly from the hydrothermal fluids with high temperature. The other sulfide-rich MS samples in the Xunmei and Tongguan field show nearly "flat" REE patterns with an absence of Eu anomalies. The change in conditions including decreased temperature and increased fO2 when the sulfides precipitate from the hydrothermal fluids can be used to explain the absent Eu anomalies. The Si-Fe-Mn oxide-rich MS have positive Eu anomalies, which also indicate that these oxides are derived from hydrothermal fluids with high temperature. When the oxides precipitate, although the temperature and composition may change, the low-temperature fluids still produce the REE patterns of the high-temperature endmember black smoker fluid and exhibit a clear positive Eu anomalies. The chlorite-rich MS show nearly “flat” REE patterns similar to the volcanic material-rich sample and MORB, which reflects the origin of the hydrothermal alteration of volcanic materials. In the southern segment of SMAR, the geochemical and mineralogical characteristics indicate that the MS are mainly derived from the collapse of sulfide and Si-Fe-Mn chimneys. In the northern segment, most of the MS are derived from plume fall-out particles that have been in contact with large volumes of seawater. In addition, the chlorite-rich MS in the Taiji field are derived from hydrothermal alteration.

Significance of chronology for exploration and evaluation of hydrothermal sulfides on Mid-Atlantic Ridge

Jun Ye[1*]
1. Lab of Marine Geology and Geophysics, First Institute of Oceanography, Ministry of Natural Resources, Qingdao, Shandong, CHINA
E-mail: yejun@fio.org.cn

Keywords: hydrothermal sulfide, chronology, mid-ocean ridge, Atlantic ridge, sulfide deposit, mineral resources

The Mid-Atlantic ridge(MAR) is the most potential area for modern seafloor sulfides mineral resource. Since 2009, COMRA has carried out a series of hydrothermal activity survey cruises in the South Atlantic, and 10 hydrothermal sites have been found there. By far, more than 100 hydrothermal sites have been found on MAR. Among these hydrothermal points, which have more resource prospects has always been a question explored by ore deposit scientists. Cherkshov (2017) proposed that the geochronology of sulfide deposits in ultramafic environment has a positive correlation with the outcrop area, which has certain significance for resource potential. However, the resource potential of sulfide deposits in basaltic environment cannot be judged. In this study, we firstly analyzes the geological controlling factors of hydrothermal systems on MAR, and divides them into four geological controlling types: detachment fault-related type, high dip normal fault-related type on the valley wall, dot magmatic dome-related type in the axis rift and linear magmatic neovolcanic ridge-related type in the axis rift. On this basis, the exposure characteristics and U-Th chronological characteristics of different types of the hydrothermal sulfide deposits are studied. The results show that:

The longer the maximum cumulative metallogenic time of the detachment fault-related deposits, the larger the outcrop area (e.g. pebeda-2). This is related to the fact that the heat source of this kind of hydrothermal system is directly under the OCC. Because most of these deposits are active, the exploration can mainly focus on the water column detection.

The older the high angle normal fault-related deposits on the valley wall, the smaller the outcrop area (e.g. Peterburgskoe). The mechanism for this relationship is related to the distance between the initial ore-forming position and the heat source which is under the ridge axis. The farther the initial ore-forming location, the smaller the heat source support, then is the worse the metallogenic sustainability and the smaller outcrop scale. Most of these deposits are inactive, so the exploration of these deposits can be dominated by electromagnetic method & geochemical exploration.

Dot magmatic dome-related deposits in the middle valley may have an unexpected outcrop scale(e.g. Xunmei hydrothermal field, which is located on 26°S MAR), while linear magmatism neovolcanic-related deposits generally have a very small size. This is mainly related to the stability of heat source and fault for the fluid passway. Most of these deposits are active, the water column anomaly may be the mainly objectives.

Electrical Structure of Seafloor Massive Sulfide Deposits in the South Mid-Atlantic Ridge Based on Marine Transient Electromagnetic Method

yue yang[1*]
1. Marine geology and geophysics, First Institute of Oceanography, Ministry of Natural Resources, Qingdao, Shandong, CHINA
E-mail: jlyangyue@126.com

Keywords: seafloor massive sulfide deposit, South Mid-Atlantic, transient electromagnetic method, resource assessment

The Mid-Atlantic Ridge is a typical slow spreading ridge, with great potential for the formation of seafloor massive sulfide deposits. At present, the international investigation and research on hydrothermal activities in the Mid-Atlantic Ridge is mainly concentrated in the North Mid-Atlantic Ridge, while the research on the South Mid-Atlantic Ridge is a few. In addition, the traditional methods mainly used can only detect the surface characteristics of the deposit, and its morphology, scale and occurrence state still need to be solved. Marine transient electromagnetic method (MTEM) has become one of the emerging methods for the detection and evaluation of seafloor massive sulfide deposits because of its sensitivity to shallow conductivity. In order to study the submarine hydrothermal system in the South Atlantic, China has carried out several cruises in the South Atlantic. We have conducted a transient electromagnetic survey in the South Atlantic Ridge during cruise DY52 segment 2, using a central loop method towed by a ship. The Occam method is used for inversion. The results show that the shallow resistivity of the survey area is low, while the deep resistivity is higher. The conductivity in the shallow is distributed along the line, while the deep resistivity varies unevenly. Between No. 840-880 and No. 1060-1080, there are two continuous low-resistance anomalies ranging from shallow to deep, and the corresponding secondary field response is relatively strong, which is speculated to be seafloor massive sulfide deposits. The seafloor massive sulfide deposit has a tubular shape, extending down about 30m. It proves that the marine transient electromagnetic method can be used to locate hydrothermal sulfide ore, delineate the scope of sulfide ore, study the spatial structure of sulfide ore, etc., and finally serve the evaluation of seafloor massive sulfide deposits.

Genesis of REY-rich deep-sea sediments in the Tiki Basin, eastern South Pacific Ocean: Evidence from geochemistry, mineralogy and isotope systematics

Tiancheng Zhou[1], Xuefa Shi[2*]
1. Mine environment investigation and monitoring department, China Institute of Geo-Environment Monitoring, Beijing, CHINA
2. Key Laboratory of Marine Geology and Metallogeny, First Institute of Oceanography, Ministry of Natural Resources, Qingdao, Shandong, CHINA
E-mail: xfshi@fio.org.cn

Keywords: REY-rich sediment, Bioapatite fossi, Sedimentation rate, Tiki basin

Deep-sea sediments in the eastern South Pacific Ocean were recently found to contain high concentrations of rare-earth elements and yttrium (REY). To understand the genesis of REY enrichment in the sediments, we performed detailed element and isotope geochemical analyses on samples from gravity core S028GC23 recovered from the Tiki Basin in the eastern South Pacific Ocean.

The REY-rich sediments in core S028GC23 are dark-brown to black zeolite clays, with REY (∑REY) contents of 1136–2213 ppm (average of 1857 ppm). The ∑REY contents in the sediments are positively correlated with P2O5 and negatively correlated with Ce anomalies. The REY-rich sediments display obvious Ce depletion and positive Y anomalies in the post-Archean Australian shale (PAAS)-normalized REY diagrams. Bioapatite fossils contain the highest REY concentrations (average of 8921 ppm) among the constituents, indicating that they are the primary hosts of REY. The REY enter through the roots and diffuse to the tops in the bioapatite fossils. Fe–Mn micronodules are divided into two different types based on Ce and Y anomalies in the PAAS-normalized REY patterns, and they have average REY concentrations of 781 ppm and 937 ppm, respectively. The phillipsite has low REY contents (average of 106 ppm) and is associated with a low sedimentation rate. REY patterns and Sr-Nd isotopic signatures show that seawater was the main ore-forming fluids during the formation of REY-rich sediments. The average sedimentation rate of the sediments in the core (0-41 cm) obtained by the best fit exponential regression line based on 230Thex data versus depth profiles was 0.8 mm/Ka, which provided sufficient exposure time for co-precipitated materials to scavenge REY from seawater. The REY accumulation process can be explained by two-stage fluid-bioapatite fossil interactions and small contributions of Fe-Mn micronodules in an oxidized environment with slow sedimentation rate. The strong absorption capacities of bioapatite fossils, the two-stage of fluids effects, and the low sedimentation rate are the key factors in the formation of REY-rich sediments in the Tiki Basin.

Formation mechanism of ocean anoxic environments driven by global ocean current circulation

Huang Chenjun[1*]
1. Research Center of Northwest China, Petroleum Exploration and Production Research Institute, SINOPEC, Beijing, CHINA
E-mail: hcj.syky@sinopec.com

Keywords: Anoxic environments, Dissolved oxygen, Temperature gradients, Current circulation, Transport dynamics, Global ocean

It is of great significance to understand the distribution of ocean anoxic environments and its formation mechanism for predicting organic carbon and other mineral enrichment in ocean sediment. Nowdays, there has been only formed a conceptual model of global ocean current circulation, since few data are available on the global ocean deep currents. Therefore, there is still a lack of sufficient ocean current data to reflect the replenishing detail of dissolved oxygen in deep ocean. In this study, the plane and profile concentrations of dissolved oxygen in the global oceans, have been found to match well with seawater temperature gradient, indicating that the later indirectly controls the supply and diffusion of dissolved oxygen by driving ocean current circulation. Meanwhile, the seafloor topographical tendency and the earth's rotation also have impacts on deep ocean currents. These can also be revealed by the diffusion paths of dissolved oxygen. This study might have further clarified the dynamics of global ocean deep currents, and uncovered the formation mechanism of ocean anoxic environments.

Influence of Quaternary MTDs on hydrate system in Qiongdongnan Basin, South China Sea

Hao Du[1*]
1. School of Earth Resources, China University of Geosciences, WuHan, Hubei, CHINA
E-mail: 1228910014@qq.com

Keywords: Gas hydrate, mass transport deposits, Qiongdongnan Basin, global carbon cycle

The hydrate system discovered in recent years are spatially related to mass transport deposits (MTDs), which are common gravity flow deposits in deep-water basins on the continental margin(Brooks, 2020; Festa et al., 2018; León et al., 2019). However, the hydrate system affected by MTDs is still unconstrained. In this study, the analysis of integrated cores, well logs and seismic data were used to study the influence mechanism of MTDs on hydrate system. Results show that hydrates reduce sediment permeability and cause build-up of overpressure at the base of the gas hydrate stability zone. Resulting hydro-fracturing forms pathways for overpressured fluids to migrate upward (so-called pipe structures)(Elger et al., 2018). However, seismic data and logging data show that the pipeline structure terminates in the underlying strata of the MTDs. The MTDs have lower porosity and permeability and higher density than in-situ seafloor sediments, and MTDs compress and shear the underlying strata during transportation. The MTDs leads to the inversion of porosity gradient of underlying sediments, and prevents the further migration of overpressured natural gas. The capping effect of Quaternary MTDs on natural gas contributes to the formation of high saturation hydrate, and limits the escape of natural gas to the ocean and even the atmosphere, especially in the hydrate system with active fluid activity. Given the wide distribution of MTDs, we believe that the impact of MTDs on carbon release in the marine environment and the global carbon cycle is underestimated.

Evaluation Method of Cobalt-rich Crusts Thickness in Seamount

E-mail: dwendu@fio.org.cn

Keywords: ME Seamount, Cobalt-rich Crusts, Thickness, comprehensive assessment method

Seamount crusts are rich in cobalt resources and have attracted worldwide attention. The thickness of crusts is an important parameter for the resource assessment of cobalt-rich crusts in seamounts. There are two major problems in the evaluation of crust thickness. First, the most effective geological sampling method in seamount exploration is used to obtain data, which is expensive, sparse and insufficient. Second, the use of a single thickness assessment method, such as Inverse Distance Weighted (IDW) and Kriging statistical method, has its own advantages and disadvantages, which cannot make full use of their advantages to give the most appropriate assessment under the current exploration and research level, resulting in the estimation results cannot express the thickness distribution more precisely. For example, the most accurate thickness data can be obtained according to station survey, but due to limited conditions and sparse conditions, it is difficult to comprehensively estimate the thickness of the whole research area. The “Distance-Slope” Kriging interpolation method (Dewen Du,et al.,2017) estimates the crust thickness according to the terrain Slope and the Distance between stations, which provides a larger prediction range, however, in the case of insufficient stations, the estimation accuracy is limited, and the farther away from the known information point, the lower the accuracy is. According to the restrictive mechanism of Cobalt-rich crust deposition and mineralization (Dewen Du, et al., 2020), the expected value of thickness data of stations collected in different topographic classification features has statistical significance for the estimation of crust thickness in the study area, but the local specificity of crust distribution cannot be reflected, so it is suitable for use in large-scale studies. In this paper, the evaluation scheme of crust thickness is developed comprehensively based on several methods of station survey thickness, mathematical statistical calculation of crust thickness expectation of terrain classification, and Kriging interpolation statistics. Firstly, the station buffer method was used to calculate the crust thickness in the 1km area around the station, and then the Thiessen polygon method was used to calculate the crust thickness covering the whole research area according to the station position, and then the optimal crust thickness within 1km was estimated by combining the two methods. Secondly, the “Slope-Distance” Kriging interpolation method is used to calculate the estimation of the crust thickness in the study area, and the optimal crust thickness within the effective radius is given to make up for the gap in the previous estimation results. Thirdly, the mathematical expectation method mentioned above is used to estimate crust thickness of the remaining unassigned regional. This method has been applied to the evaluation of ME seamount crusts thickness and achieved good results. It shows that this method is suitable for the evaluation of seamount crusts thickness under the condition of incomplete investigation.

E-mail: yanshijuan@fio.org.cn

Keywords: volcanogenic massive sulphide ore deposits, near-bottom camera, topographic profile matching, location and correction method

The submarine camera system is one of the most effective detection methods for the detection of volcanogenic massive sulphide ore deposits. The positioning of camera equipment is generally achieved by ultra-short baseline(USBL) positioning systems. Affected by the dynamic changes in the marine environment and the loss of acoustic signals, there are a large number of abnormal points in the USBL positioning data. The existing technical means cannot perform positioning correction for USBL positioning data with a large number of scattered abnormal points, which affects the accurate positioning of the camera data. In this paper, Dynamic Time Warping algorithm (DTW) is used to match the water depth profile of the camera to the high-precision terrain profile in the target area to solve this problem. Therefore, the location of the topographic profile with the greatest similarity to the camera's water depth profile can realize the positioning correction of the camera data, which is convenient to find the exact location of the volcanogenic massive sulphide ore deposits. The experimental research area of this paper is located in the Xunmei hydrothermal field, Southern Atlantic Ridge. In the near-bottom survey operation in this area, the Submarine camera is used to carry out the near-bottom tow-type operation. At the same time, the submarine camera is bound with a pressure sensor, so we can obtain a high-precision water depth profile of the camera. Using the seabed high-precision terrain data with a resolution of 1m * 1m obtained by the "Qianlong No.3" Autonomous Underwater Vehicle (AUV), by matching the water depth profile of the camera with the profiles extracted from the high-precision terrain data, we can finally find the location of the terrain profile that is the most similar to the water depth profile of the camera, to locate and correct the location and data of the submarine camera. Based on the Python language and ArcGIS technical environment, this paper extracts a total of 97469 topographic profiles in the target area, matches a terrain profile with a similarity of 95.9% to the water depth profile of the camera in the target area, and proves the reliability of the positioning correction results was verified through the record report of this voyage. The test results of the algorithm application show that this algorithm is fast and effective, and can solve the problem of the inability to accurately locate the underwater detection equipment when the USBL data is abnormal. It is expected to provide services for the accurate positioning of the underwater equipment in the international seabed resources survey.

The role of clay minerals in enriching rare earth elements (REYs) in deep-sea sediments from the Wharton Basin, Indian Ocean

Jia Li[1,2,3], Mu Huang[2,3], Miao Yu[2,3], Dongjie Bi[2,3], Xuefa Shi[2,3*]
1. College of Earth Science and Engineering, Shandong University of Science and Technology, Qingdao, Shandong , CHINA

3. Laboratory for Marine Geology, Pilot National Laboratory for Marine Science and Technology, Qingdao, Shandong, CHINA
E-mail: xfshi@fio.org.cn

Keywords: Rare-earth elements, enrichment mechanism, clay minerals, Wharton Basin

Recently, as the pelagic sediments enriched in rare-earth elements (REYs: including La-Lu and Y) being found in the Pacific and Indian oceans (Kato et al., 2011; Shi et al., 2021), the REYs in deep-sea sediments has been widely regarded as a potential mineral resource. However, their enrichment mechanism remains uncertain, and the role of clay minerals was remains controversial. In this study, we selected one sediment core (core S035GC26, 258 cm in length) obtained at a water depth of 4307 m in the Wharton basin of the Indian Ocean. The major and trace elements and clay minerals compositions of the bulk sediments and the clay components (< 2 μm) were analyzed, and the role of clay minerals played in the enrichment process of REYs was furthermore assessed.

The total concentration of REYs (∑REY) in the deep-sea sediments of core S035GC26 ranged from 86.1 ppm to 1036.8 ppm, with an average of 717.4 ppm. The good positive correlations between REY and Al_2O_3 (R^2=0.97) and between $REY_{bulk\text{-}sediment}$ and REY_{clay} (R^2=0.56) indicate that the enrichment of REYs in these deep-sea sediments is related to clay components. Our results show that montmorillonite and illite are the main clay minerals in these sediments, followed by chlorite and kaolinite. The ∑REY of these sediments gradually increase with the increase of montmorillonite content. Piper (1974) believed that the montmorillonite in deep-sea sediments played a positive role in the enrichment of REYs. Previous studies have confirmed that REYs are mainly hosted in bioapatite and micronodule, clay minerals are not the main REY-host minerals in deep-sea sediments (Yu et al., 2021; Zhou et al., 2021; Bi et al., 2021). However, the clay minerals may as a kind of "pre-carrier" in the enrichment process of REYs, due to their strong adsorption capacity. We speculate that the clay minerals may adsorbed the REYs in seawater at first, then the adsorbed REYs were released and transferred into the final REY-host minerals (e.g., bioapatite and micronodule) during the diagenetic process, although further studies are needed.

SEM and coupled systems: A powerful tool to characterize REE minerals

Huahua Lv[1,2*], Xuefa Shi[1,2], Yingqiu Zhang[1,2]
1. Marine geology and geophysics, First Institute of Oceanography, Ministry of natural Resources, Qingdao, Shandong, CHINA
2. Laboratory for Marine Geology, Pilot National Laboratory for Marine Science and Technology, Qingdao, Shandong, CHINA
E-mail: lhhyg@fio.org.cn

Keywords: REE mineral, Scanning Electron Microscopy, Energy Dispersive X-ray Spectrometer, microstructure and micromorphology, chemical composition, crystal structure

Scanning Electron Microscopy (SEM) and related analyses are particularly suited to the complexity and very fine grained nature of the rare earth element (REE) mineral assemblages.

1. Microscopic morphological characteristics

Imaging with secondary electrons provides information about morphology and surface topography of REE minerals, especially of those tiny particles, which are difficulty to characterize under ordinary optical microscope. Results from this analysis include micro-inclusions, growth rings, exsolution structures, reactive boundaries, metasomatic textures, alteration edges, etc., reflect the environments and conditions of REE mineral formation and transformation.

2. Rare earth elements mineral phases

Back-scattered electron imaging quickly groups the REE minerals and non- REE minerals, and gives out the shape, size, location, and distribution of REE minerals, also relative content under a corresponding image analysis software, thus, REE-bearing situations, such as main mineral form, REE mineral assemblages, close associations, growing matrix, host complexes, filling constituents, precipitation periods, etc., are exhibited in details.

3. Elements distribution patterns

X-ray Energy Dispersive Spectrometer (EDS) mounted on the SEM is a useful method to assess the chemical composition of minerals. There are three ways of EDS analysis: point spectrum, line scanning and area mapping, provide effective solutions for relative elemental contents in or between particles, then direct the different stages of REE mineralization and segregation degrees of ore-forming fluid according to the abundance variation.

4. Crystal structure parameters

Electron Back-Scattered Diffraction(EBSD) or Cathodoluminescence (CL) in the SEM can be used to obtain crystallographic data of REE minerals, with which we can learn the mineral internal structures, lattice defects and impurity contents, deduce the physical chemistry environment conditions when the lattices were formed, and establish genetic relations between REE minerals and their sources and the types of hosting deposits.

5. Automated identification and characterization

Configured with automated quantitative software such as MLA, TIMA, AMICS, BPMA, SEM can finish the scan and analysis of samples automatically, quickly show the mineral composition and content, particle size, dissociation, particle morphology, embedding levels, and other structural characteristics of REE minerals, indicate the occurrences, developments, associations, aggregations and alterations of them.

In a word, the SEM and combined analyses provide important evidences to test, support, and constrain various theories and processes proposed for the origin of the REE mineralization in the earth.

E-mail: xfshi@fio.org.cn

Keywords: deep-sea sediment, REY resource, parameter

As a great-potential rare earth elements (REY) resource, deep-sea sediments have attracted extensive attention. Component of deep-sea sediment is complex, including authigenic minerals, terrigenous detrital and volcanic materials. Authigenic bioapatite and Fe-Mn micronodules are the REY hosts in deep-sea sediments. Finding effective parameters to distinguishing them from the other components is critical for revealing mechanism of REY enrichment in deep-sea sediment. To search parameters of REY enrichment, we recompiled the published data of deep-sea sediments surrounding Minamitorishima Island in western North Pacific Ocean. We find that Fe/Mn ratios of sediments show good performance in indicating sediment REY enrichment. In the diagram of REY vs. Fe/Mn, REY contents of deep-sea sediments are higher than 500 ppm in the range of Fe/Mn < 5.0; by contrast, if Fe/Mn ratios are greater than 5.0, REY contents are rarely higher than 600 ppm. According to simulation with different endmembers, the results suggest that Fe-Mn micronodules control the sediment Fe/Mn. The simulation also shows that in the range of sediment REY contents < 3000 ppm, less than 20% of bioapatite are in the deep-sea sediments; while, more than 50% of bioapatite can exist in the deep-sea sediment when the bulk REY contents are extremely high, > 8000 ppm. Thus, the Fe/Mn ratio is an effective parameter in indicating the REY enrichment of the deep-sea sediment and may have potential in studying the enrichment mechanism.

Deep-sea REY resource: global distribution, metallogenesis, and exploitation perspective

Xuefa Shi[1,2*], Mu Huang[1,2], Miao Yu[1,2], Dongjie Bi[1,2], Tiancheng Zhou[1,2], Jihua Liu[1,2], Xiangwen Ren[1,2]
1. Key Laboratory of Marine Geology and Metallogeny, First Institute of Oceanography,MNR, Qingdao, Shandong, CHINA
2. Laboratory for Marine Geology, Pilot National Laboratory for Marine Science and Technology (Qingdao), Qingdao, Shandong, CHINA
E-mail: xfshi@fio.org.cn

Keywords: deep-sea REY-rich resource, metallogenic belts, metallogenesis, exploitation perspective

In recent years, the REY-rich (rare earth elements (REE) and Yttrium (Y)) sediment discovered in the deep-sea is a new type of marine mineral resources, which is characterized by considerably higher concentrations of middle and heavy rare-earth elements. The quantity of deep-sea REY resource is far more than the land reserves, which makes it highly important as a potential resource for future usage. Since 2011, large areas of REY-rich sediments have been discovered by Chinese scientists in the central India Basin, the southeastern and western Pacific Basins. Overall, four metallogenic belts are preliminarily identified in the Open Ocean: the western Pacific Ocean metallogenic belt, the central and eastern Pacific Ocean metallogenic belt, the southeastern Pacific Ocean metallogenic belt, and the central Indian Ocean-Wharton basin metallogenic belt. The REY-rich sediments are mainly zeolite clay and pelagic clay developed in the deep-sea basin, which is autogenetic, and some of them are developed near the mid-ocean ridge and affected by the hydrothermal processes. The research shows that bioapatite is the most important host phase of REY in the deep-sea sediments, which takes up the REY from ambient seawater and porewater. The REY is transferred from its original binding phase and eventually redistributed into the bioapatite. It is suggested that the deep (beneath the Carbonate Compensation Depth) water depth, low sedimentation rate, and strong bottom currents are principal controlling factors leading to large-scale enrichment of the REY in deep-sea sediments. Considering the similar water depth and ecological environment during mining, deep-sea REY-rich sediments would be mined together with polymetallic nodules as the first commercially-exploited deep sea minerals.

International Legal Regime for the Mining in the International Seabed Area

Xiangxin Xu[1*]
1. KoGuan School of Law, Center for Polar and Deep Ocean Development, Shanghai, CHINA
E-mail: lily.xiangxin.xu@sjtu.edu.cn

Keywords: the Area, Deep Seabed Mining Regime, International Seabed Authority

The discovery of strategic metals (such as cobalt) and metals used in clean energy infrastructure and technologies in the deep seabed (such as manganese, nickel and copper) has led to a surge of interest in mining in the area in the past decade. Unlike mineral resources on land or nearshore that are under the control of a State, mineral resources in the international seabed area (the Area) are designated as the common heritage of mankind, which means no State may claim or exercise sovereignty or sovereign rights over the Area or its resources which are vested in mankind as a whole and the rights of those resources may not be alienated. That being said, marine scientific research and exploration or exploitation of the mineral resources in the Area are subject to international law, inter alia, the United Nations Convention on the Law of the Sea (UNCLOS). UNCLOS establishes a comprehensive and complicated regime for activities in the Area and an international organization, namely, the International Seabed Authority (ISA), to control and manage activities in the Area on behalf of human beings as a whole. There exists a threshold of financial, technological, and environmental capabilities of the applicants accessing to mineral resources in the Area. Persons and entities who are willing to conduct activities in the Area must be assessed by the ISA. After getting permission from the ISA, persons and entities are legally allowed to do so. Moreover, the UNCLOS stipulates an array of obligations for the operators of different activities, breaches of which may incur individual liability, and even state responsibility. This lecture aims to provide a whole picture of the deep seabed mining regime and introduce the requirements, obligations, and liabilities for activities in the Area.

In situ geochemical characteristics in the microlayers of the polymetallic nodules from the Clarion-Clipperton Zone (CCZ) in the Eastern Pacific Ocean: implication for its genetic types

Cong Zhang[1], Xiaohu Li[1*], Xingwei Meng[1], Jihao Zhu[1], Fengyou Chu[1]

Keywords: Polymetallic nodules, Microlayers, Genetic type, In situ geochemical analysis, East Pacific Ocean

Polymetallic nodules enriched in metals of economic interest (e.g., Mn, Co, Ni, and Cu) from the Clarion-Clipperton Zone (CCZ) in the Eastern Pacific Ocean is one of the most important potential mineral resources on the seabed. We present in-situ elements distribution and correlation in microlayers of polymetallic nodules using X-ray diffraction, electron microprobe, and laser ablation inductively coupled plasma mass spectrometry to clarify the genetic types and element enrichment mechanism of nodules. The results show that nodules are characterized by significant rhythmic microlayers varying different geochemical characteristics. The inner microlayers of the nodule are mainly composed of vernadite and present columnar and laminated microstructure and dense microlayers, which features high Fe and Co contents, low Mn/Fe values, and positive δCe anomaly. Whereas the outer microlayers are mainly composed of 10 Å manganese with dendritic microstructure and loose microlayers, which presents high Mn, Ni, Cu, and Mn/Fe values and negative δCe anomaly. According to Mn-Fe-(Ni+Cu+Co) × 10 triangle diagram and rare earth element covariance discrimination diagram, the inner microlayers of the nodules are of hydrogenic origin, while the outer microlayers are of diagenetic origin. Element correlation analysis shows that Mn phase minerals have a high capacity for Ni and Cu, but Fe would inhibit Ni and Cu enrichment. Both Mn and Fe phase minerals are enriched in Co.

The CCZ is located near the equator and its high level of surface biological productivity favors the decomposition of marine surface organisms and producing abundant metals for nodules growth. The Antarctic Bottom Water (AABW) that enriched oxygen and flows through the CCZ is likely to be the reason for the difference in the genetic types of the inner and outer microlayers of the nodule. The strong AABW creates an oxidation environment conducive to the formation and growth of nodule water, while the weak oxidation environment caused by the decline of AABW leads to the transformation of nodules into diagenetic growth. The Mn phase minerals adsorb Ni, Cu, and Co through surface electrostatic force, of which Ni and Cu are further substituted by Mn^{2+} ions. The combination of Fe and Mn phase minerals occupies a certain amount of negative charge, which inhibits the Ni and Cu enrichment, while Co^{3+} replaces part of Fe^{3+} in the Fe phase minerals. The "dark" mineral microlayers indicate that the specific internal microenvironment formed by the infiltration of seawater into the pores of nodules may lead to the secondary metasomatism of minerals in nodules.

E-mail: taochunhuimail@163.com

Keywords: Northwest Pacific, deep-sea sediments, material source,sedimentary environment, REY enrichments

Recently lots of rare earth elements and yttrium (REY)-rich sediments were discovered in the sea area of Minamitorishima Island, Northwest Pacific. In order to understand the material source and REY enrichments of sediments in this area. Clay minerals and Sr-Nd isotopes analyses on gravity core GC1601 gained in the Southeast Sea area of Minamitorishima Island were performed. The results show clay mineral compositions of the core is very similar to that of terrigenous materials, and its montmorillonite/illite (M/I) ratio ranges from 0.09 to 0.20 with an average of 0.15, suggesting that the sediments in the study area should be mainly dominated by terrestrial sources, which corresponds to the results of Sr-Nd isotope study. Considering that the study area is far away from the mainland and in the downwind direction of the East Asian monsoon, it is proposed that the terrigenous material of the sediments in the study area is likely East Asian dust. The εNd values of GC1601 show a positive correlation with P2O5, Co, Ni, and Cu, and have an increasing trend with increasing depth, approaching that of the seawater, indicating that the sedimentary environment in the area is relatively stable. Unlike the sediments in the South Sea area of Minamitorishima Island, the sediments in study area receive small influence of Lower Circumpolar Deep Water (LCDW), combining with the large supply of terrigenous materials for the sediments, it is difficult for the study area to form high-grade REY-rich muds.

Keywords: Ultra-slow spreading, Southwest Indian ridge, Hydrothermal circulation model, Driving mechanism, Ore-controlling mechanism

The ultra-slow spreading mid-ocean ridge has unique magmatic-tectonic activity characteristics, which leads to its hydrothermal circulation model is different from other types of ridges. Its hydrothermal system may circulate deeper, last longer and have a greater probability of producing Cu-Au-rich deposits. Due to the limitation of regional location and investigation degree, the hydrothermal circulation mechanism of ultra-slow spreading ridge is still unclear, which limits the understanding of the distribution mechanism of sulfide resources at the southwest Indian ridge. Relying on China's self-developed deep-sea manned / unmanned carrier and exploration platform and the 10000 km2 sulfide exploration contract area in the southwest Indian Ocean, the research team studies the hydrothermal circulation system of ultra-slow spreading from four aspects: the spatial structure of hydrothermal channel and heat source driving mechanism, the deep process of local magma supply and its metallogenic effect, the evolution process of detachment fault and its control mechanism on hydrothermal circulation system, and the biomineralization effect of thermal radiation light from hydrothermal vents. This study reveals the hydrothermal channel structure of the ultra-slow spreading ridge and establishes the driving model of mantle heat conduction; A new causal model of ultra-slow spreading ridge and ultra-thick oceanic crust is proposed, which reveals the deep magmatic process of tectonic and magmatic ridge; The development and evolution mechanism of detachment faults with different spreading rates and magma supply conditions are clarified, and the ore-controlling geological model of detachment faults of ultra-slow expansion ridge is established. Through this study, the hydrothermal cycle model of ultra-slow spreading ridge is finally established, which improves the understanding of the hydrothermal circulation mechanism of ultra-slow spreading ridge. The research results provide key support for sulfide contract exploration in the southwest Indian Ocean of China.

Contribution of microbial processes to the enrichment of Middle Permian manganese deposits in northern Guizhou, South China

Wenchao Yu[1*]
1. School of Earth Sciences, China University of Geosciences (Wuhan), Wuhan, Hubei, CHINA
E-mail: yuwenchaocug@163.com

Keywords: Geomicrobiology, Maokou Formation, Mn-metasomatism

Economically important manganese deposits are hosted in the Middle Permian Maokou Formation of Zunyi, northern Guizhou, South China. During the Middle Permian, the intense rifting related to the initial stage of the Emeishan Large Igneous Province (ELIP) led to the development of carbonate platforms and inter-platform troughs. The manganese deposits occur in the transitional zone between carbonate platforms and troughs. Previous studies emphasized that the hydrothermal activities at the bottom of the trough basin controlled the formation of manganese deposits. In this study, new sedimentary, mineralogical, and stable isotope evidence are acquired from this manganese deposit, indicating that the microbially-mediated metallogenic mechanism also made an important contribution for the Middle Permian manganese deposition. The metallogenesis of this manganese deposit is highly like the combination of hydrothermal and microbial processes. Manganese ores in Zunyi are manganese carbonate, showing massive and clastic structures, no macroscopic nor microscopic lamination are found, samples are coarse-grained, diagenetically recrystallized with abundant mineralized microbial and microfossil biosignatures. FTIR, EPMA, and Raman analyses recognize micrometer-scale cyclic mineralogical assembly and help reconstruct the proposed new model of microbial manganese metallogenesis. Hydrothermal activity in the basin provided dissolved Mn2+ ions into the anoxic basal watermass. In the syngenetic stage, microbial systems could be subdivided into three categories: (1) cyanobacterial system, (2) Mn-biomat system and (3) Fe-biomat system. Cyanobacterial activity led to the precipitation of calcite, and it could be partially affected by Mn-metasomatism and transformed to Mn-bearing calcite. Mn-oxidizing microbes led to the precipitation of manganese bio-oxide (δ-MnO2) near the redoxcline of the basin. Fe-biomat system was responsible for the precipitation of Fe-oxides (hematite) and Fe-hydroxides (ferrihydrite and lepidocrocite). After burial, manganese oxides reacted with the organic matter in the sediments through the microbially-mediated processes during the early diagenesis and the Mn-metasomatism of the cyanobacterial carbonate jointly contributed to formation of early diagenetic manganese carbonate ore. The redox fluctuations between oxic/suboxic and anoxic zones led to the re-oxidation process and resulted in cyclic marcasite. Anatase cycles observed in samples were interpreted as the diagenetic product of Fe-biomat system.

Origin and evolution of carbonates and clay minerals in the Bakchar marine ironstone deposit (Western Siberia)

Maxim Rudmin[1,2*], Natalia Kalinina[1]
1. Division for Geology, Tomsk Polytechnic University, Tomsk, RUSSIA
2. Laboratory of Sedimentology and Paleobiosphere Evolution, University of Tyumen, Tyumen, RUSSIA
E-mail: rudminma@tpu.ru

Keywords: Siderite, clay minerals, ooidal ironstones, marine deposit, iron ores

The metal source and processes of iron mobilization in Phanerozoic ooidal ironstone deposits remain controversial (Kimberley, 1994). In Phanerozoic ooidal ironstones, siderite is the main cement in association with a clay matrix. The genesis of siderite is poorly examined for tracking sources of carbon and metals and for understanding processes of mobilization and transportation. Clay minerals are an essential component of ooidal ironstones, occurring forming various mineral phases and associations. However, little is known about their modification, evolution and/or transformation during the formation of marine iron-rich deposits.

A detailed study of the cement and matrix of ooidal ironstones of the Bakchar deposit (Western Siberia) was carried out to assess the factors influencing ore-forming processes within the sedimentary sequence. Siderite is one of the main cementing minerals in ironstones, which is of two varieties that differ in morphology, chemical and isotopic composition, and fluid inclusions. The first variety of siderite appears either veinlet or anhedral cement with the following stable isotopes composition: $\delta^{13}C$ from -39.5 to -29.7‰ and $\delta^{18}O$ from -15.2 to -5.1‰. Fluid inclusions of the first variety of siderite show a relatively high homogenization temperature (170–320°C) and methane in the gas phase suggesting formation by methane-bearing hydrothermal fluids. The second variety of siderite occurs as individual grains or concretions in the ironstone matrix and is relatively enriched in ^{13}C and ^{18}O ($\delta^{13}C$ from -28.1 to -12.2‰ and $\delta^{18}O$ from -28.4 to -2.1‰), suggesting its formation on the seafloor under the combined influence of methane flux and seawater. The authigenic mineral associations of ooidal ironstones reflect the transition from methanic (sulfate-methane transition zone) to ferruginous (iron reduction zone) through sulfidic zone across thin intervals. Such intervals are accompanied by the different mineral association. The proximal zone of the ore deposit is marked by the first variety of siderite, with rare authigenic minerals, and a low clay content (kaolinite, chlorite, nontronite) within ooidal ironstones deposit. This zone is an area of intense diffusion of metals- and carbon-bearing fluids through marine sediments. The clay in the proximal zone of this ore-forming process characteristically shows an increase in kaolinite and Fe contents of the smectites. The intermediate zone is montmorillonite-illite-saponite-nontronite with the second variety of siderite, and the distal zone is illite-montmorillonite (illite-smectite) with rare inclusions of siderite of the second variety. The ratio of 1M phyllosilicates (kaolinite) to the main swelling 2M phyllosilicates in the clay fraction (K/M mineral index) varies within the spatial zones. A coastal-marine environment possibly contributed to the accumulation of montmorillonite and illite contents within sediments, which was transformed into nontronite and saponite during diffusion of methanic fluid solutions through marine deposits.

The study was funded by the Russian Science Foundation (21-17-00019).

Periodic enrichment of critical metal elements in Late Permian coal-bearing series in western Guizhou —the astronomical forcing of volcanic activity

Tianyang Yang[1], Yulin Shen[1*]
1. School of Resources and Geosciences, China University of Mining and Technology, Xuzhou, Jiangsu, CHINA
E-mail: yulinsh@163.com

Keywords: Critical metal elements, Volcanic activity, Long eccentricity cycle, Mineralization, Development regularity, Late Permian

A series of critical metal elements enrichment layers are distributed in the Late Permian coal-bearing strata in western Guizhou and eastern Yunnan, and the content of some layers reached the exploitable content[1-8]. The distribution of these critical metal elements enrichment layers in the sequence framework has obvious regularity. According to the distribution in the vertical direction, both the sequence stratigraphic framework and the development regularity of critical metal elements enrichment layers are discussed. The results show that the critical metal enrichment layer is well related to the astronomical orbit period changes. The Lopingian has well-preserved astronomical orbital cycles[9-10]. Among them, 11 long eccentricity cycles were preserved in the Longtan Formation, and 5 were preserved in the Changxing Formation. According to the calculation results of geochemical data, the weathering parameters have obvious periodic variation in the vertical direction, which are well related to long eccentricity cycles and the critical metal enrichment layers. The ages of critical metal element enrichment layers in the sequence framework were roughly similar, which may indicate the periodicity of volcanic activity during the period of the Later Permian. It is likely that volcanic activity is affected by the period of the astronomical orbit. Periodic orbital changes forced volcanic activity and formed rhythmic distribution characteristics. Therefore, a variety of parameters reflecting periodic changes is related. The preservation of critical metal elements is affected by the sedimentary environment. Hydrostatic and sealing conditions can better preserve critical metals and mineralization.

Keywords: Neoproterozoic, Metallogenesis, Manganese deposits, Paloclimate, Redox

The Neoproterozoic Era witnessed two global glaciations, i.e., the Sturtian Glaciation (~ 720-663 Ma) and the Marinoan Glaciation (~ 654-635 Ma)(Kennedy et al., 1998; Macdonald et al., 2010; Shields-Zhou et al., 2012; Lan et al., 2014; Rooney et al., 2015) in the Earth history. Large amounts of Mn-carbonates precipitated in the post-Sturtian Datangpo Formation of the Nanhua Basin, South China, which are known as “Datangpo-type” manganese deposits. The metallogenic process of the sedimentary manganese deposits in the Nanhua Basin consists of two stages. Firstly, the dissolved Mn^{2+} was oxidized to Mn oxides/oxyhydroxides and then precipitated in the sediments. Secondly, Mn oxides/oxyhydroxides were reduced by organic matter and then preserved as Mn-carbonates. The evidences of Fe speciations, Fe isotope compositions and Corg:P (Feng et al., 2010; Li et al., 2012; Zhang et al., 2013, 2015; Yu et al., 2016; Ma et al., 2019) indicate that deep Nanhua Basin was mainly in anoxic conditions, but interrupted by episodic oxic intervals, which can provide oxygen for the Mn^{2+} oxidation. In this study, we report high-resolution chemical index of alteration (CIA) values to reconstruct paleoclimate variation from the syn-Sturtian Tiesi’ao Foramtion to the postglacial Datangpo Formation. The CIA profile of drillcore ZK2115, which shows no relationship to core lithology, exhibits a progressive upsection increase, from values of 45-67 (mean 58) in the upper Tiesi’ao Formation to 60-72 (mean 67) in the Mn-carbonate unit and to 64-70 (mean 68) in the overlying black shale unit of the Datangpo Formation. This pattern reflects a slowly warming climate during the final stage of the Sturtian Glaciation and the subsequent deglacial/early interglacial intervals. Co-fluctuations in CIA and Mn-carbonate precipitation during the deglacial interval can be interpreted as evidence of stepwise disintegration of the Sturtian icesheet, releasing pulses of cold, dense, well-oxygenated waters that episodically ventilated the deeper parts of the Nanhua Basin. The episodic ventilation promoted the Mn-carbonates precipitation through the redox variations in the deep basin. This model explains the influences of paleoclimate and redox factors on the metallogenetic process of the “Datangpo-type” manganese deposits. The episodic high-density flows caused by slowly warming paleoclimate transferred oxygen to the deep basin resulting in the redox condition variations. Then the dissolved Mn^{2+} was oxidized to form Mn oxides/oxyhydroxides which can facilitate the metallogenesis in the Cryogenian Nanhua Basin. This study explains the relationship between environmental factors and the metallogenesis of the “Datangpo-type” manganese deposits.

Sediment-hosted High-grade Iron Ore Deposits

Joydip Mukhopadhyay[1*]
1. Geology, Presidency University, Kolkata, Kolkata, West Bengal, INDIA
E-mail: Joydip17@gmail.com

Keywords: Iron ore, Sedimentary, BIF, Hypogene, Supergene

Iron ore deposits with Fe-wt% >45% are in general mined for the iron and steel industry. The deposits can be associated with magmatic processes or more commonly within sedimentary host successions with Fe-enrichment either by hypogene hydrothermal or by supergene weathering processes or a combination of both (Barley et al., 1999; Beukes et al., 2003, Dalstra et al., 2004). The most important sedimentary Fe-ore deposits are mostly restricted to the BIF host rock in the Archean-Proterozoic sedimentary/volcano-sedimentary successions. Besides these BIF-hosted Fe-mineralization, detrital channel iron ore deposits also constitute important resources. The BIF-hosted deposits supply over 95% of the world's production. These deposits are commonly high-grade with Fe-wt % reaching >65% in many world-class deposits of Brazil, Australia, India and South Africa. Mineralogically the high-grade Fe-ore deposits are overwhelmingly enriched in hematite with martite, magnetite and goethite constituting subordinate components. The hypogene hydrothermal deposits replacing the host BIF mother rock might include magnetite/martite-rich orebodies at depth and profuse carbonate alteration. The best candidates for the hypogene hydrothermal orebodies from the Kaapvaal, Pilbara cratons of South Africa and Australia, respectively, and the Iron Quadrangle of Brazil, where iron formations developed on top of or within carbonate platforms and the orebodies show profuse carbonate alteration at depth. Similar carbonate alterations are yet to be described from the Indian high-grade ore deposits. The supergene ores on the other hand are monotonously hematitic. The grade of ore in supergene deposits decreases with depth. The hypogene orebodies with martite-magnetite components at a deeper profile, when exposed to the surface, undergo extensive supergene alteration. The supergene alteration leads to dissolution and porosity development in the hypogene orebodies. Such alteration leads to the development of porous to dusty ores (Beukes et al., 2008, Mukhopadhyay et al., 2008). The Mineralogical, textural, and chemical compositions provide important clues for the genesis of BIF-hosted high-grade iron ore deposits.

Development of a methodological approach to better assess the aquifer potential of a glacial deposit environment

Lévesque Yan[1*]
1. Département des sciences appliquées, Université du Québec à Chicoutimi, Rimouski, Québec, CANADA
E-mail: yan.levesque1@uqac.ca

Keywords: Saint-Narcisse Moraine, stratigraphy, TEM, sediments, aquifer, regional piezometry

Geological contexts that lack minimal stratigraphic and piezometric information can be challenging to produce an initial hydrogeological map in remote territories. This study proposes an approach to characterize a regional aquifer using transient electromagnetic (TEM) surveys. Given the presence of randomly dispersed boreholes, the Saint-Narcisse moraine in the Mauricie region of Quebec (Canada) is an appropriate site for collecting the required geophysical data, correlating the stratigraphic and piezometric information, and characterizing regional granular aquifers in terms of stratigraphy, geometry, thickness, and extent. In order to use all TEM results (i.e., 47 stations) acquired in the moraine area, we also correlated 13 TEM stations, 7 boreholes, and 6 stratigraphic cross-sections to derive an empirical and local petrophysical relationship and to establish a calibration chart of the sediments. Our TEM data, combined with piezometric mapping and the sedimentary records from boreholes and stratigraphic cross-sections, revealed the compartmentalization of a multi-kilometer morainic system and indicated the presence of two large unconfined granular aquifers overlying the bedrock. These aquifers extend more than 12 km east to west across the study area and are between 25 and >94 m thick. The TEM method provides critical information on groundwater at a regional scale by acquiring information from multiple stations within a short time span to a degree not possible with other existing methodologies.

Single sandbody architecture of sublacustrine fan in middle sub-member of 3rd member, Shahejie Formation in Shishen 100 area of Dongying Depression

Zijie Gao[1*]
1. College of Geosciences, China University of Petroleum (Beijing), Beijing, CHINA
E-mail: 304766059@qq.com

Keywords: Dongying Depression, Shahejie Formation, Sublacustrine fan, Quantitive scale, Three-dimensional architecture model

Sublacustrine fan deposition is one of the hot research directions of lacustrine deep-water gravity flow in China. This kind of tight reservoir usually has the characteristics of rapid planar changes and high heterogeneity. There are few studies on the single sandbody architecture of sublacustrine fan in lacustrine rift basin. As a result, a reasonable and unified architecture model has not been established. Taking the turbidite sandstone reservoirs in the middle sub-member of 3rd member of Shahejie Formation in Shishen 100 area of Dongying Depression as an example, based on the integrated analysis of the core, seismic, logging and dynamic production data, the analysis of architecture was investigated, and the geometric characteristics and spatial superposition relationship of single sandbody in each layer were determined. This study indicates that the sublacustrine fan deposits with feeder channels are developed in the target section, which includes channel system and lobe system. 7 different sedimentary microfacies were identified in sublacustrine fan, including main channel, branch channel, overbank lobe, lobe edge, slip block, semi-deep and deep lacustrine. For a single channel, the average thickness is 8.3 meters, the width ranges from 215 meters to 1040 meters, and the aspect ratio ranges from 37 to 99. The main channel in the shape of wide strip is near the provenance, which bifurcates continuously and becomes smaller scale along the provenance direction. At the end of main channel eventually evolve into branch channel and lobe. The branch channels are narrow stripe-shaped, and located at the upper part of the lobe, downcutting the lobe sandbodies. The lobe composite sandbody in the shape of lobe and fan is composed by multiple tongue-shaped lobes, and narrower in the proximal region while wider in the distal region. The lobes are mainly as the laterally compensational superposition pattern across the provenance direction. While along the provenance direction, they are progradational or retrogradational. The compensational superposition pattern is related to the ultra-short term base-level changing. For the single lobe with convex top and flat bottom vertically, the maximum width ranges from 355 meters to 1260 meters, the maximum thickness ranges from 3.3 meters to 10.2 meters, and the aspect ratio ranges from 84 to 152. The composite sandbodies dominated by channel deposits develop small-scale lobes, and are mostly isolated. For this kind of sandbody, the maximum width is 592 meters and average aspect ratio is 85. In comparison, the scale of composite sandbodies dominated by lobe deposits are larger and they develop more continuously. For this kind of sandbody, the maximum width is 895 meters and average aspect ratio is 145. Moreover, the slip blocks are isolated lenticular in front of the lobes. Ultimately, according to the results, the three-dimensional architecture model of sublacustrine fan in the study area was established. Meanwhile, these results seek to enrich the reservoir architecture theory of sublacustrine fan in lacustrine rift basin, and provide geological bases for the deployment of well pattern and optimization of injection-production parameters.

Sedimentary Model-constrained Prediction of Sandy Conglomerates Distribution in Provenance Area

Dakun Xiao[1*]
1. Oil Development Department, CNOOC Research Institute, Beijing, CHINA
E-mail: xiaodk3@cnooc.com.cn

Keywords: provenance area, sandy conglomerates, prototype sedimentary model, paleogeomorphology, reservoir prediction

The sedimentary regularity of sandy conglomerates in buried hill provenance area is complex, and predicting its distribution is of great significance to the development of buried hill reservoirs. Based on the prediction idea of medium-deep sandy conglomerates in offshore oil and gas fields and guided by the prototype sedimentary model, the technical process of sandy conglomerates reservoir prediction in provenance area is established and applied to the Archaean buried hill of Bohai A Oilfield. The following understandings are obtained: Through the investigation of modern deposition in the western mountainous area of Karamay City, Junggar Basin, 3 prototype sedimentary models of sandy conglomerates in provenance area are established according to the geomorphic background mainly controlling deposition. Using impressing method and differential amplification technology based on slope attribute to restore the paleogeomorphology of buried hill in oilfield A, its sandy conglomerates deposition conforms to the type of ‘intermountain erosion channel–piedmont alluvial fan’. Based on the principle of seismic sedimentology, the low-frequency seismic data are optimized to predict sandy conglomerates distribution in provenance area of oilfield A. The sandy conglomerates thickness in the geomorphic unit of intermountain gully is large and is distributed in continuous strips. The sandy conglomerates development degree in the ridge area of mountain peak is low and is distributed in discontinuous patches. The sandy conglomerates thickness in the geomorphic unit of piedmont slope changes greatly and is distributed in contiguous areas.

Reservoir Classification and Evaluation Based on Fractal Theory and Factor Analysis

Hao Cheng[1,2], Zhenkui Jin[1*], Rukai Zhu[2]
1. College of Geosciences, China University of Petroleum (Beijing), Beijing, CHINA
2. State Key Laboratoty of Enhanced Oil Recovery, Research Institude of Petroleum Exploration&Development, Beijing, CHINA
E-mail: chenghao12134@163.com

Keywords: Fractal Theory,Factor Analysis,High-pressure Mercury Injection Test,Reservoir Classification and Evaluation

With the development of exploration and development of oil and gas resources, the early reservoir description methods based on physical parameters can no longer meet the requirements of guiding the development and production of modern oil and gas fields. The pore structure of the reservoir is an important factor affecting reservoir properties and seepage properties, and its fine characterization has gradually become an important content of reservoir description. The reservoir pore structure is complex and affected by many factors, so it is difficult to describe quantitatively. Katz, Wong, and Pfeifer later discovered and confirmed that the pore structure of sedimentary rocks has fractal characteristics, which can be used as an effective means to characterize reservoir physical properties, pore structure, and heterogeneity.

The concept of fractal was put forward by Mandelbrot in 1977, which is a mathematical-statistical theory to study the self-similarity of objects. It is a more accurate quantitative representation of the inhomogeneity of the distribution of the basic properties of the stratum in three-dimensional space. The theory has been mature and widely used in architecture, physics, geology, and other industries. In geology, it is mainly used in the quantitative characterization of reservoir pore structure, joint or fracture, microscopic image observation, etc., and is mostly used to describe geological body structure. It can also be used as a measure of the irregularity of complex geologic bodies at the microscopic scale, reflecting the order and complexity of geologic body microscopic morphology.

1. Fractal Theory

In this paper, the fractal dimension of the reservoir is obtained by calculating the experimental data of high-pressure mercury injection of rock samples. The fractal formula of the capillary bundle was used to process the experimental data.

2. Factor Analysis

Factor analysis combined R-type analysis of variable correlation analysis with Q-type analysis of sample correlation analysis. The R-type and Q-type factor matrices were calculated respectively, and then the R-type factor load of the variable and the sample was formed. On this basis, the correlation statistics and analysis between variables, samples, and samples were carried out to obtain the objective classification results of samples.

3. Comprehensive Analysis

Based on the principal factor analysis of reservoir parameters, the correlation between the fractal dimension and the key parameters in the principal factor analysis is further verified to clarify the accuracy of the fractal dimension in the characterization of the overall reservoir properties. By comparing the fractal dimension with the physical property and pore structure of the strata, the relationship between the fractal dimension of different types of rocks and the influence of rock properties on the fractal dimension are discussed. It provides

a reference for quantitative characterization of rock mass structure and rock type discrimination in the study area.

Pore-throat characteristic response of different sedimentary microfacies of shallow-water braided river delta reservoirs in Guantao Formation, Bohai Bay Basin, China

Zhao Wang[1*], Hongming Tang[1]

1. School of Geoscience and Technology, Southwest Petroleum University, Chengdu, Sichuan, CHINA

E-mail: wangzhao_528@163.com

Keywords: Pore structure, Sedimentary microfacies, Loose sandstone,Bohai Bay

Abstract: The Guantao Formation Reservoir in the Penglai Oilfield is a loose sandstone with high porosity and high permeability. The reservoir diagenesis is weak and is dominated by compaction diagenesis. However, insufficient research into the relationship relationship between sedimentary microfacies and pore structure characteristics, which restricts the prediction of favorable reservoir distribution and the scientific implementation of development plans. In this paper, the loose sandstone reservoir of Neogene Guantao Formation in Penglai Oilfield are targeted to clarify and estimate the sensitivity of pore structure characteristics to sedimentary microfacies and the main controlling factors affecting the microscopic pore structure of the reservoir are quantitatively analyzed by grey correlation analysis. Firstly, the main sedimentary microfacies types of Guantao formation reservoir are identified based on core and logging data. Then, the reservoir characteristics of different sedimentary microfacies, such as reservoir space types, pore size distribution, fractal dimension, grain size characteristics and mineral distribution were revealed by means of high-pressure mercury injection, laser grain size analysis, core analysis and scanning electron microscopy. Finally, after the above parameters are extracted, grey correlation analysis is applied to quantitatively analyze the main controlling factors affecting the pore structure characteristics. The results show that the pore structure of various sedimentary microfacies is comprehensively influenced by the sedimentary texture and differences in mineral distribution. Characterized by more abundant hard siliceous minerals, positive skewness, and lower pore sorting coefficients, the arenaceous microfacies possess larger pore-throat radius and lower pore fractal dimensions than argillaceous microfacies. Using the grey correlation method, it is clarified that the order of importance affecting the pore structure characteristics is the mean grain size> median grain size> potassium feldspar> plagioclase> kaolinite> sorting> mix-layer illite/smectite > skewness> quartz> chlorite >illite. These results provide new insights for studying the control mechanism of microfacies controls on reservoir quality.

Multiple-point geostatistical simulation of outcrop based on UAV oblique photographic data:A case study of Shihezi Formation in Pingtou Township, Lüliang City, Shanxi

Senlin Yin[1*], Gongyang Chen[1]

1. Research Institute of Mud Logging Technology and Engineering, Yangtze University, Yangtze University, Jingzhou , Hubei, CHINA

E-mail: yinxiang_love@126.com

Keywords: UAV,oblique photography, digital outcrop,three-dimensional outcrop modeling,multiple-point geostatistics,training image

Aiming at shortcomings in the traditional research methods of outcrops, using the agility, overall perspective and high-degree quantification of UAV oblique photography, the authors have completed the collection, processing and geological interpretation of delta outcrops, and established the three-dimensional digitized outcrop model and quantitative geological knowledge database of reservoirs. Through the fine analysis and comparative study of multiple outcrop sections, and the use of such methods as lithofacies combination, hierarchical interface , interaction of plane and section, sequential indicator stochastic simulation and multiple-point geostatistical simulation, this study establishes the three-dimensional multiple-point statistical model of the outcrop area. The study shows that: (1) The three-dimensional coordinate system of the oblique photographic data collected by UAV after processing is fully coupled with the information of high-precision images, realizing the three-dimensional digitalization, visualization and quantification of the geological information of outcrops. Under the setting of well points, in combination with the lithofacies constraints of well point, this paper carries out a comparison of outcrops with cross-well base-level cycles and the tracking of substrata, and establishes the spatial stratigraphic framework and quantitative reservoir geological knowledge database of the outcrop area. (2) Combining the analysis of traditional outcrop sections and the quantitative reservoir geological knowledge database of modern UAV oblique photography is a complementary means of establishing the spatial distribution of geological attributes and geological models in the study area, which improves the rationality of research results. Three types of genetic sandbodies with great differences in architecture is developed from bottom to top in the outcrop area, i.e., crossed-superimposed distributary channels, distributary channels superimposed with sheet sand bars, and skeletal sandbodies such as thin sheet sandbody or isolated distributary channels. (3) UAV oblique photography model expands the study of two-dimensional irregular outcrop sections into three-dimensional space, and establishes a three-dimensional sequential indicator stochastic simulation model, which not only enhances the correlation between the sections, but also provides strong support for studying the plane sedimentary microfacies of outcrops, and finely describing the distribution of sandbody architecture by the interaction of plane and section. (4) Based on the interaction of plane and section, as well as data from the quantitative reservoir geological knowledge database, this paper determines the structure model of three-dimensional training images, finally conducts three-dimensional multiple-point statistical simulation, and explores the facies-controlling porosity parameters and "sweet spot" distribution rules. The results show that there are small differences in the realization of the multiple-point model, the distribution of sand bodies in each layer, the quantitative reservoir geological knowledge database, and also the statistical data values of various models; the model achieved by multiple-point 3D simulation is highly reliable.

Effects of basinal water depth on bar finger architecture in the deltaic environment

Zhenhua Xu[1*], Shenghe Wu[2], Changmin Zhang[1]
1. School of Geosciences, Yangtze University, Wuhan, Hubei, CHINA
2. College of Geoscience, China Univeristy of Petroleum Beijing, Beijing, CHINA
E-mail: xuzhenhua@yangtzeu.edu.cn

Keywords: Bar finger, Basinal water depth, Architecture, Delft3D simulation

Bar finger is the significant sand body in the digitate delta, consisting of mouth bar, distributary channel and levee deposits. It is common seen in modern deposits, as well as ancient hydrocarbon reservoirs, formed by fine-grained, cohesive river. Bar finger could be developed in both shallow-water and deep-water deltas, which exhibits distinctive architectures. Basinal water depth play critical roles on their architecture. However, it is still unclear that effects of basinal water depth. We utilize Delft3D simulations and model deposits to quantify the effects of basinal water depth on bar finger geometric and internal architectures, and recognize criteria for shallow-water and deep-water deltas. The results show that (1) bar finger is almost straight if basinal water depth is larger than distributary channel depth, otherwise, bar finger is sinuous, and the sinuosity of bar finger positively scales to the basinal water depth; (2) bar finger width and length is negatively related to the basinal water depth; (3) basinal water depth determines distributaries-mouth bar combination style, high basinal water depth accompanies with thin mouth bars and relatively deep distributaries, low basinal water depth accompanies with thick mouth bars and relatively shallow distributaries with many avulsed distributaries; (4) basinal water depth influence the existence of point bar, if basinal water depth is smaller than distributary channel depth, sinuous bar finger could develop point bars at inner bank of distributary channel, resulting in distinct internal archtecture with straight bar finger. As results, the ratio of basinal water depth to distributary channel depth is a crucial parameter to determine whether shallow-water or deep-water delta. And three morphologic criteria for digitate shallow-water and deep-water delta is recognized: Sinuosity, the ratio of distributary channel depth to mouth bar thickness, the existence of avulsed distributaries, the existence of point bars. This work provides insights into natural and artificial digitate delta growth and provides new quantitative facies models for shallow-water digitate delta reservoirs.

Characteristics and Origin of Conglomerate Diagenetic Traps in the Junggar Basin

Wang Guo Dong[1*], Pan Jian Guo[1], Qu Yong Qiang[1], Qi Wen[1]
1. Western Exploration Institute, Research Institute of Petroleum Exploration & Development - Northwest (NWGI), Petrochina, Lanzhou, Gansu, CHINA
E-mail: wang_gd@petrochina.com.cn

Keywords: Diagenetic trap, Conglomerate, Baikouquan Formation, Junggar Basin

The reservoir lithology of Trassic Baikouquan Formation is primarily fan delta conglomerate with low porosity, permeability, and compositional and structural maturity. The properties of the distributary channel conglomerate of the fan delta front are better than those of the distributary channel of the fan delta plain, and reserviors in delta front have strong heterogeneity. So far, there is still controversy over the types of hydrocarbon trap in the fan delta front, which has led to the different understanding of hydrocarbon accumulation[Lei et al., 2015; Zhi, 2017]. In this study, 225 samples were collected from 31 wells for reservoir characteristics and diagenetic research. Based on reservoir characteristics and diagenesis of reservoirs and dense layers at different burial depths, the relationship between every single factor and secondary pore development was analyzed according to differences in sedimentary facies, detrital feldspar content, formation temperature, and formation water characteristics. These parameters define the formation mechanism of the traps. The reservoirs underwent a series of diagenetic events during the burial process, accompanied by changes in reservoir structures and properties. Influencing factors, including rock composition, structure, and diagenetic environment, i.e., temperature, pressure, fluid, and tectonics, created strong heterogeneities during the processes changing reservoir quality. Microscopic observations of the Baikouquan Formation reservoirs in the Mahu sag show that the reservoir qualities are mainly related to diagenesis. Diagenetic differences are primarily due to rock composition, paleogeothermal environment, and formation fluids during burial. Reservoir qualities of the Baikouquan Formation were improved during deep burial due to the formation of secondary pores from feldspar dissolution. The detrital feldspar in the front reservoirs dissolved and secondary pores formed when the formation temperature was in the correct range for a weakly acidic fluid environment. Feldspar dissolution mainly depends on feldspar concentrations, weak acid formation, and paleo-temperatures. When all three conditions are not satisfied, i.e., low feldspar concentrations, non-acidic water, or inappropriate paleo-temperatures, the reservoir quality cannot be effectively improved and instead becomes a diagenetic dense layer that acts as a barrier to oil and gas.

A Study on the Single Sand Body Architecture Model of Gravity Flow Channel in Ban 1 Oil Formation in Banqiao Oilfield

Lei Bao[1], Jiagen Hou[1*], Yumin Liu[1], Peipei Liu[1]
1. College of Geosciences, China University of Petroleum(Beijing), Beijing, CHINA
E-mail: houjg63@cup.edu.cn

Keywords: Banqiao Oilfield, Shahejie Formation, Gravity Flow, Single sand body; Architecture Model

The Ban 1 oil group is the main oil-bearing of the second member of the Shahejie Formation in Banqiao Oilfield. This layer is a lacustrine gravity flow deposition, and is mainly composed of channel deposition. In this paper, through the in-depth study of the gravity flow channel in the Ban 1 oil group, the sedimentary architecture characteristics of the gravity flow channel under different influencing factors such as channel stage, scale and swing stability are analyzed, and different channel architecture patterns are summarized, which provides model guidance for the subsequent development of reservoirs in the area. Combined with coring data, the sedimentary background and sand body distribution characteristics of the study area were analyzed, and it was determined that the study area developed lake bottom gravity flow channel deposits. In this paper, by selecting key blocks with dense well net and high development level, combined with dynamic information such as tracers and injection-production relationship, the channel architecture boundary is determined, and the results of the thin layer-level single water channel division are obtained, and finally the scale of the waterway is quantitatively analyzed. The research results show that there are two complex channels in the study area, and there are multiple single water channels in each complex. The water channel complex is mainly developed in the north area of Banqiao, and the water channel gradually bifurcates into the lobe in the middle area of Banqiao. The average thickness of a single channel is 7.2m, the plane width of the channel is 664m, and the width-thickness ratio is between 120:1 and 172:1. Statistical analysis of the size of a single sand body shows that the width and thickness are positively correlated (w = 182.79hmax-237.7). On the basis of studying the single sand body configuration and geometric characteristics of the gravity flow channel in the study area, the three-dimensional architecture of the gravity flow channel in this area is summarized according to the channel stage, channel size and swing stability. The model provides a geological basis for the subsequent determination of the remaining oil distribution and well location deployment.

Characterization of pore structure of deep shale based on shape coefficient

Boyuan Zhu[1], Renfang Pan[1*], Jianghui Meng[1]
1. School of Earth Sciences, Yangtze University, Wuhan, Hubei Province, CHINA
E-mail: pan@yangtzeu.edu.cn

Keywords: Sichuan Basin, Longmaxi formation, deep shale, scanning electron microscope, shape coefficient, pore structure

Abstract: Deep shale gas is gradually becoming the key exploration and development object in Sichuan Basin, China. The corresponding nano pore characterization technology and method of deep shale gas also need to be further developed and innovated. Field emission scanning electron microscope was used to observe and extract the minimum ferite diameter of micropores, mesopores and macropores. The elliptical shape coefficient of organic pores was obtained through calculation. The pore structure of deep organic-rich siliceous shales of the Longmaxi Formation in the Luzhou area of the southern Sichuan Basin was characterised quantitatively by shape factors. According to the ideal (oval) organic pore shape coefficient, micropores (0.93) are the least affected by compaction, followed by mesopores (0.85), while macropores are the largest (0.61). Their shape gradually tends to be flat from circle. According to the true shape coefficient of organic pores, in the deep shale section with organic pores of about 4000 m, the shape of macropores was the worst preserved, common complex irregular ellipses are densely and disorderly distributed in organic matter, and the true shape coefficient was about 0.3~0.6; The mesoporous shape was well preserved, the common approximate regular ellipse is sparse and disorderly distributed in organic matter, and its true shape coefficient was about 0.6~0.9; The shape of micropores was the best preserved. They are usually approximately regular circles, which are densely and evenly distributed in organic matter, and their true shape coefficient was about 0.9~1.0. The preservation and distribution of full pore organic pores are characterized by shape coefficient, and the heterogeneity of pore structure decreases from macropores to micropores. Therefore, micropores and mesopores are the main enrichment sites of adsorbed gas and free gas.

Sandbody Architecture and Reservoir Heterogeneity of Sandy Braided River: An Insight from Outcrop and Subsurface Data

BINTAO CHEN[1*], ZHONGSHENG SHI[1], LUO XUE[1], LUN MA[1], LEI WANG[1]

1. Oil Reservoir Description Department, Research Institute of Petroleum Exploration & Development-Northwest (NWGI), Petrochina, Lanzhou, Gansu, CHINA

E-mail: tobychencugb@foxmail.com

Keywords: Sandy Braided River, Sandbody Architecture, Remaining Oil Distribution, Sedimentologic Genesis-based Mudstone Types, Crude Oil Distribution

As an important oil/gas reservoir, sandy braided river sandstone is characterized by thick thickness, well continuity and good physical properties. However, muddy barrier-intercalation is developed inside the sandy braided river, there are few systematical study have been carried out on reservoir heterogeneity of this type of reservoir. On the basis of outcrops in Yungang Formation of Datong Basin, Shanxi and study in sandy braided river in Jimidi Formation of Melut Basin, according to fine observation of outcrops and cores, measurement for outcrops, inter-well correlation, experimental analysis, and logging interpretation, the results show that sandy braided river deposit is dominated by seven typical litho-facies and five litho-facies assemblages, where three types of muddy barrier-intercalations with different sedimentologic genesis were recognized, flooding mud (Fm) with large thickness and wide distribution, and lateral accretion draping mud (Lm) and abandoned-channel filling mud (Am and Em) with restricted distribution inside single channel. Four typical sandbody architecture units are common to be found, including channel (CH), Channel bar (CB), Point bar (PB) and overfall deposits (OF), where distribution frequency of channel and channel bar is the highest and reservoir quality of channel bar is the best. According to the case study in Jimidi Formation in Ruman area of Melut Basin, channel and channel bar architecture units that are characterized with high porosity and permeability controlled the enrichment of heavy oil, especially the channel bar architecture units, with higher charging of heavy oil, is the major reservoir type for remaining oil.

3 Shenzhen Branch，CNOOC China Limited，Shenzhen Guangdong, PR China

E-mail: liangxu@cnooc.com.cn

Keywords: Shallow water braided river delta, composite sand body, seismic sedimentology,seismic edge detection, channelization characteristics

Braided river delta sand bodies are widely developed in Enping formation of Eocene in Lufeng sag, Pearl River Mouth Basin, which is the key target area for CNOOC's 14th Five-Year Plan.The unclear relationship between reservoirs and the complex internal structure are the bottlenecks restricting the planning of such oilfields. Combining well-seismic and carrying out the anatomy of composite sand body is the key to solving the problem. Taking the Enping 420 Oil Group in Lufeng A Oilfield as an example, under the guidance of the theory of sequence stratigraphy, seismic sedimentology and regional big data pattern, combined with core-logging facies, paleogeomorphology analysis and seismic inversion volume edge detection technology , clarified the internal structural characteristics of the sand body. The results show that: (1) the geomorphology of the Enping 420 oil group was relatively flat during the depositional period, but there were structural slope breaks in some parts, which was the shallow-water braided river delta deposition dominated by the channel; (2) it was subdivided into three periods vertically, among which the early sand The sand body is small in scale, poor in physical properties, and limited in distribution; in the middle stage, the sand body is large in scale and is the concentrated section of the main oil layer; in the late stage, the sand body is in limited distribution. (3) On the plane, it is characterized by divergent interweaving channels, the width of the main channel is 300m~600m, with good connectivity. The above achievements have effectively guided the well pattern deployment and well type selection of Lufeng A Oilfield, and promoted the rapid production of the oilfield.

Configuration characterization of underground deep-sea channel reservoir driven by geological model

xiaoming Zhao[1*], Liu Fei[1]
1. School of Geoscience and Technology, Southwest Petroleum University, Chengdu, Sichuan, CHINA
E-mail: zhxim98@163.com

Keywords: deep-sea channel, Sedimentary configuration, Configuration characterization, Well-seismic combination

Deep sea channel is the migration channel of terrigenous debris to deep-sea plain. It is also one of the main oil and gas reservoir units in deep-sea sedimentary environment. It has important value and significance of oil and gas resources exploration and development. Studies have confirmed that although the deep-sea channel reservoir often has high porosity and permeability, its plane flow path and internal building structure are complex and changeable. Even in a very short lateral distance, the reservoir thickness and connectivity will change greatly, which greatly increases the drilling risk and reduces the design quality of development scheme. In addition, due to the limitation of marine sedimentary environment and operation cost, deep-sea oil and gas fields often have "few wells, large well spacing and thin well pattern". The traditional reservoir configuration characterization method suitable for onshore dense well pattern is difficult to adapt to deep-sea oil and gas fields. In addition, the complex superposition relationship of channel reservoir itself brings challenges to the high-precision prediction of underground deep-sea channel reservoir, which affects the efficient development of deep-sea channel reservoir. Therefore, this paper proposes a geological model driven characterization method of underground deep-sea channel reservoir configuration. The specific process is as follows:

Construction of development scale channel configuration mode: on the development scale, the deep-sea channel is divided into four levels: channel system, complex channel set, complex channel and single channel. Then, based on the shallow high-frequency 3D seismic data, the vertical superposition mode and plane migration mode of four levels of deep-sea channel are established.

Analysis of core-logging-seismic response characteristics of interfaces with different orders of architecture: According to the characteristics of small scour or lithofacies abrupt change in the bottom interface of a single channel, the structural interface of a single channel order is identified on the core; The interface characteristics of a single channel level structure are determined on the logging curve, and the logging response characteristics of the interface of a compound channel level structure are identified through the combination of a single channel, medium-sized scour surface and lithofacies change characteristics; Through the analysis of profile shape and style, the seismic response characteristics of the interface of single channel and complex channel structure are determined, and the well-seismic response characteristics of the interface of the complex channel series and the hierarchical structure of the channel system are identified through the complex channel combination and seismic profile structure analysis.

The above method completes the fine characterization of channel sedimentary bodies of different sedimentary scales through step-by-step constraints. While proving the sedimentary characteristics of large-scale underground channel reservoir sand bodies, it can also clarify the sedimentary distribution characteristics of impermeable geological bodies such as small-scale sand-mud interlayers. , has important geological significance for the exploration and efficient development of deep channel type reservoirs.

Quantitative characterization of clastic reservoir architecture based on envelope surface: a case study of P oilfield in Bohai Sea

Xiaoming Ye[1*], Xiaohong Liu[1], Shaopeng Wang[1], Lan Zhang[1], Chunliang Huo[1]
1. Bohai Oilfield Research Institute, Cnooc China LimitedTianjin Branch, Tianjin, CHINA
E-mail: yexm@cnooc.com.cn

Keywords: reservoir architecture, geological modeling,envelope surface ,equivalent characterization, bohai oilfield

In order to solve the problems existing in conventional grid-based clastic reservoir architecture modeling methods, such as low model accuracy and non-convergence of reservoir numerical simulation, a quantitative characterization method of clastic reservoir architecture based on envelope surface was proposed. This method achieves the fine geology modeling and reservoir numerical simulation of clastic reservoir architecture through the prototype modeling of reservoir architecture envelope surface, envelope surface reconstruction based on discrete architecture data and equivalent characterization of envelope surface. In P oilfield of Bohai Sea, this method was applied to quantitatively characterize the braided river reservoir architecture units.Firstly, the 3D surface-based prototype model of braided river architecture units was established based on the geological knowledge base. Then, under the constraints of the prototype model, the envelope surfaces of each level architecture units were constructed by using the reservoir architecture data of different dimensions,such as 1D well point data,2D boundary data, etc. Finally, an equivalent characterization method based on the conductivity of grid interface was used to realize the quantitative characterization of the envelope surface in conventional grid-based reservoir numerical simulation, which provided a model basis for fine remaining oil prediction and potential exploitation in the middle and late stage of oilfield development. Reservoir numerical simulation results of P oilfield show that the historical fitting coincidence rate of the new model based on the proposed method is 12 percent higher than that of the old model, and the overall prediction accuracy of remaining oil is more than 85%.In addition, this method has been successfully applied in many meandering river and delta oilfields in Bohai Sea, showing a good application prospect.

A Multi-point Stochastic Based Turbidite Lobe Architecture Modeling of L Oilfield, Lower Congo Basin, West Africa

Rui Xu[1*], Wenbiao Zhang[1], Wenming Lu[1], Meng Li[1]
1. Overseas Key Project Supporting Center, Petroleum Exploration and Production Research Institute, SINOPEC, Beijing, CHINA
E-mail: xurui.syky@sinopec.com

Keywords: Deep-water Turbidites, Lobe Reservoir Architecture, Multi-point Stochastic Modeling

Deep-water turbidite is a specific field of current exploration and development because of its considerable petroleum potential. As a significant composite of turbidite deposition system, internal architectural and 3D characterization of turbidite lobe has been technical tacking difficulty as consequence of its complex depositional environment and strong heterogeneity. Based on a large number of cores, logging, field outcrop and high-frequency three-dimensional seismic data, using the research ideas of well-seismic combination and progressive constraint, taking Miocene reservoir developed turbidite lobe of L Oilfield in the Lower Congo Basin of West Africa as an example, detailed architecture analysis and three-dimensional geological modeling were carried out. Firstly, the standard of lobe architecture level was clarified and the three-dimensional architecture model was established based on multi-dimensional and multi-scale data. Secondly, according to the middle-high frequency seismic data of the target layer in the study area and the high frequency seismic data of shallow layer, seismic RMS attribute slices were used to obtain the lobe deposition samples. The length, width and thickness of the turbidite lobe system were quantitatively analyzed to establish empirical function of geometric parameters and as a quantitative knowledge base to provide parameter guidance for multi-point statistical simulation. Lastly, the lobe training image is established by means of seismic multi-attribute and seismic volume carving technology, and 3D architecture model of turbidite lobe in the target layer M8 sand group is established by multi-point geostatistics method. The simulation results generally followed the lobe architecture model and were highly consistent with the actual drilling inspection well. This study has formed a set of detailed modeling technology for deep-water turbidite lobes, and enriched the geological knowledge base of deep-water turbidite lobes, which has practical significance for efficient development of lobe reservoirs.

Sedimentary Architecture Models of Fluvial Successions in Responsible for Variable Accommodation to Sediment Supply Ratio

Wei Li[1*], Dali Yue[1], Shenghe Wu[1]
1. College of Geosciences, China University of Petroleum (Beijing), Beijing, CHINA
E-mail: wei_li_geologist@qq.com

Keywords: Accommodation, Sediment supply, Sedimentary architecture; Fluvial succession, Datong basin

Fluvial rivers are common landforms of continental environments, and sedimentary architecture models of their successions are variable with the change of accommodation to sediment supply ratio (A/S ratio). However, few published research documents proposed variable sedimentary architecture models of fluvial successions in responsible for conditions of A/S ratio. Therefore, this work aims to establish variable sedimentary architecture models of fluvial successions that are responsible for the conditions of A/S ratio, based on the outcropping fluvial successions located in the Datong Basin, China. The used fluvial outcrop is composed of 8 outcrop sections, and the used dataset mainly includes (i) outcrop photomosaics, (ii) data obtained from analyses of rock samples, consisting of measurements of grain size, porosity, and bulk and skeletal density, (iii) impregnated thin sections. Outcrop fluvial strata is divided into 9 short-term and 2 medium-term depositional (A/S ratio) cycles based on mudstone (sandstone) percent, paleosol maturity, and ancient river depth. The results indicate that fluvial rivers transit between different patterns following the sequence, i.e., braided rivers, wandering rivers, transiting rivers between braiding and meandering, and to meandering rivers. Sedimentary architecture models are different significantly for their succession in different river pattern or conditions of A/S ratio. For example, erosion/incise surfaces and chutes show a heavy density in braided river successions whereas decrease sharply in wandering river successions. Also, mid-channel bars in wandering rivers are commonly composed of a set of vertical accretion sandbodies, which are separated by thin silt layers. Generally, variable sedimentary architecture models that are responsible for different conditions of A/S ratios are proposed in this work.

Depositional architectures of tectonically forced deep marine channel bends: Niger Delta offshore

Massine Bouchakour[1], Xiaoming Zhao[1*]
1. School of Geoscience and Technology, Southwest Petroleum University, Chengdu, Sichuan, CHINA
E-mail: zhxim98@163.com

Keywords: submarine channel, depositional architectures, deflected bend, tectonic forcing, autogenic processes, Niger Delta

Throughout the past decades, submarine channels have been one of the most relevant hydrocarbon prospects in continental slopes. The detailed descriptions of channel architectures and the connectivity of sand bodies have aided hydrocarbon production in terms of reservoir heterogeneity and connected oil. Nevertheless, the ranges of these stacked channels within tectonically complex slopes remain poorly understood, in part because their sedimentary records diverge. Two submarine channel systems have been investigated in the Agbada formation, within the southern Niger Delta offshore, to help understand and depict the distribution of submarine channel architectures around growing structures. A critical examination of these channels including stratigraphic subdivision has led to the identification of several vertically-stacked channel complexes, revealing a number of channel bends around structural reliefs. These latter have been mapped using seismic attributes, including variance, RMS, and spectral decomposition. The cross sections analysed along these bends, have permitted the characterization of channel stacking patterns, consisting of lateral offsets, vertical amalgamations, and oblique amalgamations. The integrated seismic profiles and planforms, have been further used to assess several parameters around the bends, such as channel TWT-thickness, width, sinuosity, bend amplitudes, and channel shift distances. This has allowed the classification of the deflected bends throughout the opposition of tectonic forcing against channel autogenic processes.

The tectonic forcing reflects the high amplitude bends growing with dominantly lateral offsets. In addition, the seismically-defined channel chute cut-offs are as well believed to form on stepwise tilting of channel floor. Where the channel encounters orthogonal ridge, the deflected bend has been associated to overwhelming sands 'swept' into structural lows making up 'ladle-shaped' architectures with bars and channel cuts, and significant amounts of upstream sediment reflections. While, the opposite autogenic influence is shown by levee confinements, which dramatically restricted the bend growth and were favorable to downstream translation of channel pathways. These channel relief constrictions have comprehensively resulted oblique and vertical channel trajectories within bend apices. Besides, where channel sedimentation is dominantly mud-rich debrites, the deflected bends were particularly kinked, showing up a poor development of channel lateral shifting. Such architecture is believed to emerge under the influence of downstream surge flows surpassing the tectonic drift. These observations demonstrate the pivotal role of channel sedimentary processes altering the architectures of tectonically influenced bends, establishing a new outlook for future investigations on structurally controlled submarine channels.

Keywords: architecture, flow unit, carbonaceous debris; outcrop modeling; Ordos Basin

The spatial distribution of flow units and reductant within a sandstone uranium reservoir is very beneficial for exploring the uranium mineralization mechanism; however, such studies have been almost neglected. As such, this paper aims to provide the sedimentological interpretation and heterogeneity models of the sandstone of the Middle Jurassic Zhiluo Formation at Shiwan outcrop area, in the eastern Ordos Basin. The outcrops are sandstone-dominated subaqueous distributary channel successions, in which five distinct architectural elements are identified and interpreted: channel units (CU), downstream accretion elements (DA), lateral accretion elements (LA), sandy bedforms (SB) and no-channelized fine-grained sediments (NFS). Within the sandstone succession, six flow units are present in the middle and lower parts of CU, or the lower parts of DA and SB elements, with their geometry to be controlled by the fourth- or third-order bounding surfaces. Moreover, the carbonaceous debris-rich zones (CDZ) are places with the highest abundance of reductant and preserve exclusively upon the basal erosional surfaces of CU and DA elements. Based on those results, a prediction model is established and shows that the formation of interlayer oxidation zone is strongly selective and confined within the CU and DA elements. The favorable sites of uranium mineralization are preferentially distributed in the transition zone between the front of flow unit and the CDZ.

Architecture of deep marine and deep lacustrine turbidite lobe deposits

Leifu Zhang[1*], Wenqi Zhang[1], Jiacheng Xu[1], Ya Deng[1], Dawang Liu[1], Yuning Wang[1]
1. Middle East E&P, PetroChina Research Institute of Petroleum Exploration and Development, Beijing, CHINA
E-mail: leifu.zhang@pku.edu.cn

Keywords: turbidite lobe, deep-marine, deep-lacustrine, architecture, thickening-upward cycle

Deepwater (deep-marine and deep-lacustrine) turbidites are sedimentary sand-bodies with good physical properties, and their complex internal structures and heterogeneities directly control the distribution of residual oil. In recent years, significant progress has been made in the exploration and development of deep-marine turbidities, and a series of giant oil and gas fields have been discovered, making deepwater domain an important strategic replacement area for future global oil and gas resources. Architectural characteristics of deepwater turbidite channels have been extensively studied, whereas works on the architecture hierarchy and anatomy of the turbidite lobes are less. In this study, three turbidite lobe analogues are investigated and correlated: the deep-marine Carboniferous Ross Sandstone Formation outcrops in western Ireland, the deep-marine Silurian Longmaxi Formation cores in the Sichuan Basin, and the deep-lacustrine Triassic Yanchang Formation outcrops in southeast Ordos Basin. Based on detailed anatomy, deep-marine and deep-lacustrine turbidite lobes can be comparable in many aspects: 1) three genetic units are recognized: turbidite lobe, turbidite channel, and slump-slide; 2) turbidite lobes can be classified into a similar four-fold hierarchy from bed, lobe element, lobe, to lobe complex. The architecture units at each hierarchical level and the corresponding architecture interfaces have completely different characteristics, among which the lobes show characteristics of evident compensational stacking, and the lobe elements display a thickening-upward pattern; 3) typical thickening-upward cycles consist of, from bottom to top: laminated shales/shales with interbedded siltstone beds; interbedded sandstones/siltstones and mudstones; structureless massive sandstones with a strong degree of amalgamation and load structures at bases. In general, the turbidite lobe deposits appear as tabular, parallel/sub-parallel sandstone with mudstone interbeds. Turbidite lobe deposits transit from thick, massive sandstones with high net-to-gross ratio and high degree of amalgamation at the proximal region into thin sandstones interbedded with mudstones with low net-to-gross ratio and degree of amalgamation towards distal fringes both laterally and longitudinally. By detailed anatomy of hierarchy and lateral tracing of architectural units, this study suggests that, despite less extent and shallower water depth, deep-lacustrine turbidite lobes have similar features with deep-marine turbidite lobes, in terms of depositional mechanism, genetic units, architecture hierarchy, and lateral distribution of facies associations. This could benefit future exploration and development of deepwater turbidite lobe reservoirs.

Sedimentary characteristics and architecture model of river-dominated shallow water delta front

Qiongyuan Wu[1*], Shaopeng Wang[1], Guangyi Sun[1], Honglin Yue[1], Dalin Zhao[1]
1. Bohai Oilfield Research Institute, Tianjin Branch of CNOOC Ltd, Tianjin, CHINA
E-mail: wu_qy90@126.com

Keywords: Shallow water delta front,Sedimentary model,Lake-level fluctuation,Sandbody Architecture,Huanghekou Sag

Based on the comprehensive application of modern sedimentary, core, logging and dynamic data, the sequence stratigraphy and sedimentary characteristics of oilfield A in Huanghekou Sag are studied in detail, and the architecture model of distal fine-grained shallow water delta is established. The study shows that the lower Ming member of Neogene in A oilfield in the Huanghekou sag is divided into two complete third-order sequences and seven fourth-order sequences, that is, the bottom third-order sequences composed of IV and V oil groups are dominated by low-stand and transgression domains, and the top third-order sequences composed of I, II and III oil groups are dominated by low-stand and high-stand domains. Slow slope and far away from provenance are necessary conditions for the development of fine-grained shallow-water deltas. Fine sedimentary particle size, scale of sedimentary structure and small thickness of single genetic unit sand body are obvious sedimentary characteristics. The high frequency fluctuation of lake level controls the sedimentary model of distal fine-grained shallow water delta. Flake shallow water deltas are mostly developed in the lowstand period, with underwater distributary channel sand body as the main body, and channel migration and swing frequently. Dendritic shallow water deltas are developed in the early stage of transgression and highstand, and underwater distributary channels are striped and isolated. In the late high-level region, lobed shallow water deltas were developed, overbank deposits are mostly developed between single distributary channels and some distributary channels were transformed into bar and sheet sand by lake waves in the distal. The research results provide a basis for the exploration and development of shallow water delta in the Huanghekou Sag.

Sedimentary sequence and architecture analysis by integrating multi-discipline data – An example of a sandy conglomerate reservoir in Qie12 block, Qaidam Basin, NW China

Qingshun Gong[1*]
1. Experimental Research Institute, Petrochina Hangzhou Research Institute of Geology, Hangzhou , Zhejiang, CHINA
E-mail: gongqs_hz@petrochina.com.cn

Keywords: Sedimentary sequence, sedimentary architecture, sandy conglomerate reservoir, Qaidam Basin

Understanding the sedimentary sequence and architecture is important for planning the development strategy. We illustrate a case study of analyzing the sequence and architecture of a sandy conglomerate reservoir by integrating geology, petrophysics, seismic, and development data. The analysis indicates that the depostional environment of the target lower part of the Ganchaigou Formation is an alluvial fan. We defined eight lithofacies according to the core analysis and five sedimentary microfacies by integrating the core and petrophysical data. We next propose four sedimentary architectural models by integrating the lithofacies result, microfacies analysis, and high frequency sequence models. The four architecture models include the extensively connecting body sandwiched with intermittent channels, the composite channel formed by the overlapping and separation of stable channels, the lateral alternated braided channel and sheet flow sediment, and the runoff channel inlaid in flood plain mudstone. We finally build an architecture model for the alluvial fan. The model of the alluvial fan overall shows an upward-fining grain-size features and this feature indicates that the alluvial fan belongs to a retrograding sequence. The built model consists of six alluvial fan bodies that migrates from north.

Sedimentary architecture characteristics of submarine fan lobes under gravity flows and bottom currents ——Insights from a deep-water research in East Africa

Mei Chen[1,2], Shenghe Wu[1,2*], Jiajia Zhang[1,2]

1. State Key Laboratory of Petroleum Resources and Prospectin, China University of Petroleum (Beijing), Beijing, CHINA
2. College of Geosciences, China University of Petroleum (Beijing), Beijing, CHINA

E-mail: 1786307626@qq.com

Keywords: Gravity flows, Bottom currents, Submarine fan, Lobe, Reservoir architecture, Connectivity feature

Submarine fan deposits have great potential for oil and gas resources, and the study of their sedimentary architecture is essential for the development of deep-water reservoirs. At present, the influence of bottom currents on submarine fan channel architecture has been widely recognized. Whereas, for submarine fan lobes, the current study only found that bottom currents can modify the entire lobe system distribution and deposit architecture under gravity flows and bottom currents, and no research has been carried out on the effect of bottom currents on different hierarchical lobe architecture under this deep-water environment. In this paper, we study on a deep-water area in East Africa under gravity flows and bottom currents, including architecture of the submarine lobe, and different stacking patterns and connectivity features of different hierarchy lobes by using well core, logging and seismic data. Then, the sedimentary architecture pattern of submarine lobes under gravity flows and bottom currents is established. The main conclusions include: 1) the lobe complex and the single lobe show unidirectional southward stacking pattern, which is opposite to the direction of bottom currents, and the single lobe presents an asymmetric shape with thicker lobe margin on bottom currents; the mudstone between the lobe complex is thick and continuous, and the mudstone between the single lobe is thin and discontinuous. 2) The lobe layers in a single lobe display vertical accumulation, which shows no obvious relationship with bottom currents; there are few mudstone interlayers in a single lobe, and the mudstone interlayers gradually increase from the proximal the distal of the lobe. 3) The influence of the bottom currents on the lobes is mainly manifested in the fact that the single lobe in the early stage deposited thicker vertically of the lobe margin along the bottom currents side, so that the followed single lobe deposit on the lower position of the previous topography, showing the migration opposing bottom currents. For the effects of the bottom current on the channel, their migration directions are all opposite to bottom currents. For the submarine lobe, there is no obvious asymmetry with large-scope horizontal drift deposits on the bottom currents side. Instead, the single lobe margin is thicker vertically on the bottom currents side, which shows the asymmetry that the main body of the lobe is biased to the bottom currents side. The research is of great significance to improve the theory of deep-water sedimentary architecture and development of reservoir.

Densification of the Lower Cretaceous tight sandstones, Sandaoqiao area, western Tabei uplift in the Tarim Basin: implications for paleo-uplift evolution

Shuo Qin[1], Ren Wang[1*], Zhong Wan Shi[1]
1. School of Earth Rerources, China University of Geosciences (Wuhan), Wuhan, Hubei Province, CHINA
E-mail: rwang@cug.edu.cn

Keywords: Paleo-uplift evolution, Tight sandstone, Densification mechanism, Tarim Basin

Previous practices proved that sandstone reservoir of Lower Cretaceous is partial tight in the Tabei uplift. And the petroleum accumulation is related to the paleo-uplift distribution. At the aid of seismic, core and drilling data, three stratigraphic sequences and sedimentary facies are identified. And using porosity and permeability, thin section, cathode luminescence and pore structure data describe the reservoir characteristics. Based results above to clarify the relation between reservoir densification and paleo-uplift evolution. The target layers are Lower Cretaceous Yageliemu Formation (K1y), Shushanhe Formation (K1s) and Baxigai Formation (K1b). The K1y and lower K1s are regarded as the first stratigraphic sequence of Lower Cretaceous (K1SQ1). And the upper K1s and K1b are considered to be K1SQ2 and K1SQ3, respectively. The K1SQ1 in the study area develops braided-river delta. Then rising sea level submerges the uplift and the study area develops bar. The provenance of K1SQ1 and K1SQ2 comes from the weathering products of northwest denuded zone. The K1SQ3 develops meandering river delta derived from southeast area. The results show the reservoir has an averaged porosity of 7.8% and an averaged permeability of 9.7 mD, indicating a low porosity and medium permeability reservoir. However, the physical properties of reservoirs in different sequences are different. The reservoir in K1SQ3 has the maximum averaged porosity (10.3%) and permeability (34.6mD), followed by K1SQ1(7.2%, 2.1mD) and K1SQ2 (6.7%, 0.29mD). Meanwhile, the results of mercury injection indicates that the pore structure of K1SQ3 is more connected. Sedimentation and diagenesis are main factors that controlling the partial densification of reservoir, which is closely related to the uplift evolution. (1) When the uplift was submerged, it inherited to form a bar. The grain size of bar within K1SQ2 is smaller which makes the primary porosity is limited. (2) Cathode luminescence results show that the calcite cements within reservoir of K1SQ2 are much more developed than that of K1SQ1 and K1SQ3. The cements block the pores and throats which significantly decreases the physical properties of reservoir. These cements in bar are developed because the bar is far away from the Terrigenous clastic. The settings of shallow lacustrine makes it is favorable for calcite cements formation. In summary, uplift evolution makes the sedimentary facies and diagenesis environments change, then they will affect the reservoir quality.

Characterization of the single sandbody architecture in the sublacustrine fan reservoir of Triassic Yanchang Formation in Heshui Area, Ordos Basin, China

Wurong Wang[1,2], Dali Yue[1,2*], Xuefeng Qu[3], Shenghe Wu[1,2], Jian Liu[3]

1. College of Geosciences, China University of Petroleum (Beijing), Beijing, CHINA
2. State Key Laboratory of Petroleum Resources and Prospecting, China University of Petroleum (Beijing), Beijing, CHINA
3. Research Institute of Exploration and Development, PetroChina Changqing Oilfield Company, Xi'an, Shaanxi, CHINA

E-mail: yuedali@cup.edu.cn

Keywords: Sublacustrine fan, single sandbody, architecture model, Triassic Yanchang Formation, Ordos Basin

In recent years, the research on the deep-water gravity-flow deposits has become a hot and difficult topic in the field of international academic research and petroleum exploration and development. Compared with marine gravity-flow reservoirs, the distribution of lacustrine gravity-flow reservoirs is more complex, which leads to greater petroleum development difficulty and poorer economic benefits. Taking the lacustrine gravity-flow reservoirs in the Chang 6 oil-bearing interval of the Triassic Yanchang Formation in the Heshui area, Ordos Basin, Chian as the research object, the distribution of the single sandbody architecture and the semi-quantitative to quantitative sedimentary architectural model of the sublacustrine fan reservoir was investigated by integrating the core, well logging and production data in this research. Six architecture elements were identified in the sublacustrine fan, namely, main channel, branch channel, lobe, lobe edge, inter-channel and inter-lobe, among which the lobe sandbodies are the most widely distributed. Based on the single sandbody boundary identification mark of exploration wells and horizontal wells, the boundary of single sandbody was divided. The lobe complex is composed by multiple individual lobes through different compensational superimposition pattern, including lateral, deintegration or prointegration pattern, which is related to the base-level changing. The single lobe is tongue-shaped on the plane and is slightly narrower in the proximal region as well as slightly wider in the distal region. There is an obvious linear positive correlation between the maximum width and the maximum thickness, with the aspect ratio ranging from 100 to 160. Ultimately, according to the analysis results of the single sandbody architecture in study area, a three-dimensional architecture model of the sublacustrine fan in the depression lacustrine basin was established. The research results can provide reference for the architecture analysis of the similar oilfields, and can facilitate hydrocarbon exploration and production in similar lacustrine deep-water gravity-flow reservoirs.

Study on sedimentary characteristics and main controlling factors of fluvial-dominated shoal lake delta ——Taking Yongjin area in the Hinterland of Junggar Basin as an example

Yue Yang[1], Fan Song[1*]
1. School of Geoscience and technology, China University of Petroleum (East China), QINGDAO, SHANDONGSHENG, CHINA
E-mail: 110909319@qq.com

Keywords: Shoal water delta, Distributary channel, Sedimentary characteristics, Distribution characteristics, Qigu formation

Due to the great controversy over the influence of different main control factors such as water flow characteristics and provenance supply on the development and sedimentary characteristics of shoal water delta, in this paper studies the sedimentary characteristics of Jurassic Qigu formation in Yongjin area by comprehensively using core , well logging, seismic, experimental test and other data. It is found that the basin is mainly braided river delta in this period, which is different from that generally believed by predecessors, Typical fluvial-dominated shoal lake delta are developed in this area, and the sedimentary characteristics are quite different from braided river deltas. Combined with the characteristics of lithofacies, well logging facies, seismic facies, the sedimentary microfacies and water environment of shoal water delta are identified; The distribution characteristics of sand bodies are analyzed in combination with the changes of sea level rise and fal1, the distribution characteristics and evolution law of sedimentary microfacies, and the characteristics of seismic facies. The study shows that the sedimentary microfacies are mainly underwater distributary channels, lack of mouth bars, etc., and the phenomenon of scouring and cutting between channels in a single stage is obvious. The sediment is mainly fine sandstone with thin layer of mudstone, which often appears alternately in reddish brown and light gray, reflecting that the sedimentary water body is shal1ow and oscillatory. The shoal water delta in the study area extends far to the center of the lake basin. The vertical superposition mode of sand body can be divided into four types: thick at both ends, thin at the middle and thin at the lower part, thin at one end, thick at the middle and equal at one end, thin at both ends, thick at the middle and thick at the upper part, and nearly equal thickness; The stacking modes of sand bodies on the plane can be divided into three types: continuous type, cross cutting strip type and isolated strip type; The genesis is mainly controlled by six factors: gentle topographic conditions, changeable lake level fluctuation cycles, shallow water depth, sufficient material source supply, frequent climate change and stable basin tectonic activities.

Transport pathways of source to sink systems and Sand Controlling Mechanism of the Paleogene in Chengbei-Zhuanghai area.

Hao Gao[1], Jing Yuan[1*], Fan Song[1]
1. School of Geoscience and Techology, CHINA UNIVERSITY OF PETROLEUM(East China), QINGDAO, SHANDONG province, CHINA
E-mail: drjyuan@163.com

Keywords: source to sink system, palaeogeomorphology, Transport pathway, Chengdao-Zhuanghai area,

The source to sink system concerns with various components of sedimentary systemsfrom source areasthrough dispersal systemsthence to deposition in a number of potential sedimentary sinks. Chengbei-Zhuanghai area is taken as a whole source to sink system. utilizing logging,well logging,rock core and three-dimensional seismic data,we analayed the basement rock types of provenance transport system and sedimentary system types and features on the Chengbei-Zhuanghai area from the perspective of source to sink system,reconstructed the palaeogeomorphology,The palaeogeomorphology,and gully transport system, sedimentary results and distribution, the coupling relationship of source to sink system are clarified to guide the exploration and prediction of favorable zones in the study area and similar basins.The principle and method of high-precision paleogeomorphology restoration are adopted for paleogeomorphology restoration in Chengdao -Zhuanghai area. The analyzing processes include five steps:(1) correcting of apparent thickness;(2)recovering eroded thickness;(3)establishing of compaction equations;(4)restoring compaction of formations in each single drilling wel;(5)composing maps of thickness of original layer and paleo-geomorphology. Furthermore, the paleo-geomorphological maps of the EdIII1 Fomation and Es3 Fomation. When the Es3 Fomation time,One highland in the western and sag in the eastern in the Chengdao area , which is sandwiched between Chengbei low uplift and Chengbei 30 buried hill. One highland in the middle and two sags in the eastern and the western sides of the Zhuanghai area were recognized from the map.Three types of gully valleys (V-shape, U-shape, W- shape and composite shape), fault troughs (single fault trough and double fault trough) and structural transformation zones are usually developed by using the method of three-dimensional seismic data to identify the transport pathways. The sedimentary strata in the eastern depression of Chengdao low uplift in Chengdao area are well developed, and the uplift zone is overlain layer by layer. Multiple negative geomorphologic units can be seen in the uplift zone and the depression, and 25 transport channels are mainly developed, including 15 paleo-valleys and 10 fault troughs. Three types of sedimentary facies were observed in the main horizon of the catchment unit, namely, sublacustrine fan, nearshore subaqueous fan and fan delta. Sublacustrine fan and fan delta developed in gentle slope, semi-deep water or shallow water environment. The nearshore subaqueous fan is generally developed in the steep slope and deep water environment, which is featured with wide and continuous plane distribution and superimposed vertical distributionCoupling mode of the source-to-sink system suggests that effective source area controls the size of sedimentary system; sand transporting path controls sedimentary distribution direction and shape.

Influence of bottom currents on the hierarchical architecture of deep-water channels

Jiajia Zhang[1], Shenghe Wu[1*]
1. College of Geosciences, China University of Petroleum-Beijing, Beijing, CHINA
E-mail: reser@cup.edu.cn

Keywords: bottom current, deep-water channel, architecture

Deep-water channels are important reservoir element in deep-marine setting that preserve complex internal architectures governed by both sediment gravity flows and bottom currents. The existing models for bottom current-influenced channel architecture fail to consider the effects of channel hierarchy and sinuosity, leading to two contradictory interpretations: lateral channel migration upstream or downstream of bottom currents. This study intends to unravel the complexity of bottom current-influenced channel architecture through 3D seismic-based analysis on several channel samples from offshore Mozambique where interaction of sediment gravity flows with bottom currents is representative. Results reveal the hierarchical variations in channel stacking patterns, rather than the previously assumed unidirectional migration regardless of architectural hierarchy. The multiple channel systems from different sequences migrated bidirectionally in a compensational stacking pattern, with rare influence by bottom currents. The multiple channel complexes within a channel system show unidirectional migration upstream of bottom currents, which suggests dominant influence by bottom currents in agreement with previous findings. The multiple individual channels within a channel complex show diverse stacking patterns involving lateral migration upstream or downstream of bottom currents, and longitudinal migration downstream of sediment gravity flows. These patterns vary according to bend orientation and sinuosity due to the combined effects from sediment gravity flows and bottom currents. A hierarchical model for bottom current-influenced channel architecture is finally developed highlighting the hierarchically variable interaction between the two important deep-marine sediment transport processes. These findings prompt reevaluation of the existing models and deeper digging into the interacting process regimes.

E-mail: ly2021.syky@sinopec.com

Keywords: lacustrine carbonate, eletrofacies, facies model, reservoir heterogeneity

The fourth member of Shahejie (Es4) lacustrine carbonate in Dongying Depression is deeply concerned with the ultra-high production of about thousand-ton perday in single well, but the differential reserve between wells remains enigmatic. The traditional sedimentary analysis maintained the extended development of reefal buildups along the paleohighs located in rift margin, contributing framework pore space for prolific reserve. However, the recent core observations show the grainy facies are common, including carbonate sands, oolites and bioclasts, which provide good pore space. Based on new nine types of electrofacies, the facies model was built, illustrating reef facies with common frame of Cladosiphonia sinensis extended in limited coverage, with patchy deposits above grainy base. The result could not support the previous knowledge that the large extension of reefal facies and their dominant contributions to high production. The facies model further agrees with the humid and warm environments which are friendly for biological development happened in the Middle Eocene period of East Asia. The energy-driven heterogeneity of facies also illustrate the fluctuation of lake levels, especially the high energy settings above rift paleohighs, where bioclasts reworking commonly happens with deficient buildup left. The possibly shallow water conditions are favorable to experience the meteroric dissolutions happened in good reservoirs, as well as dolomitization within lacustrine carbonates. The lake expansion and contraction cycles recorded in the Es4 interval of the Middle Eocene rift lacustrine settings are probably dominant controls on facies characteristics, as well as the reservoir heterogeneity. As for the paleographic aspect, the favorable facies and reservoirs located in paleohighs of rift lake away from siliciclastic inputs in basin margins. The warm, shallow water environments and possibly surrounding hydrothermal fluids facilitate carbonate factories, contributing to the typically good reservoir for lacustrine hydrocarbon reserve.

E-mail: ly2021.syky@sinopec.com

Keywords: carbonate platform, Cretaceous, microfacies, OAE, carbonate reservoir

The Cretaceous Mishrif carbonates formed in the Cenomanian-Turonian period contain giant hydrocarbon reserve, which is known as the prolific resources in Tethys regions. The heterogeneous nature of carbonate rocks make the challenges in exploration and development activities, which make the facies models are in real need. This study introduces a case analysis of the Mishrif platform carbonate, applying the integrated method based on petrographic properties, core facies, and logging database (including conventional well logs, borehole images and downhole nuclear magnetism resonance data among 6 cored wells and over 150 open hole wells), establishing the facies models for the Mishrif carbonates. There are 14 typical microfacies developed in the Mishrif carbonates, mainly include the burrowed bioclastic wackestone (MF3), peloidal wackestone (MF4), planktonic pelagic mudstone (MF5), echinoderm bioclastic packstone (MF7), limestone conglomerates (MF10), foraminifera packstone (MF13), bioclastic grainstone(MF14), bioclastic floatstone (MF15), miliolid foraminifera wackestone (MF16), dasyclad green wackestone (MF17), benthic foraminifera bioclastic wackestone and packstone (MF20), fenestral bindstone (MF23), intraclast wackestone (MF24), various skeletal bioclastic grainstone and packstone (MF26). Based on microfacies and eletrofacies, the carbonate ramp facies model was established. The results show that the Mishrif ramp facies varies during the time of late Cenomanian and early Turonian. These facies evolution are deeply influenced by eustatic levels, which also reflecting the uplifts in regional event. The carbonate ramp settings of inner ramp bioclatic shoals, rudist biostromes are the good reserve for reservoirs. Both the petrographic and paleontological features illustrate the ramp shifting from inner sites to outer settings, with the organic mudstone deposits in the sea level rising. The facies and carbon isotope positive excursion also record the OAE2 characteritics with the recovery of coral and rudist deposits. The faceis models provide detailed measures to characterize the Mishrif carbonates. The facies/electrofacies models have the implications for reservoir architecture analysis, re-understanding the subsurface reservoir models, as well as production strategies, which provide comparisons for local reserves as well.

Genetic Analysis of Low Resistivity Reservoir: A Case Study

Jingmin Guo[1*], Hongliang Song[1], Feiteng Wang[1], Bowei Liu[1], Qin Peng[1]
1. Bohai Oilfield Research Institute, Tianjin Branch of CNOOC (China) Co., Ltd, Tianjin, CHINA
E-mail: 303467342@qq.com

Keywords: low resistivity reservoir, genetic Analysis, smectite content and morphology, rock framework, reservoir conductivity, micro-characteristics

A typical low resistivity reservoir is developed in the N_1gIII formation of C Oilfield Bohai Sea Areaand analyzing the influential factors of reservoir resistivity is of great significance to the efficient development.
In the research X-ray diffraction (XRD)scanning electron microscopy (SEM)cast thin sectionscation exchange capacity (CEC) testdigital core modeling were used to study the clay mineral content and morphology,rock framework grains contact relationship,reservoir conductivityand then reservoir micro-characteristics and the influential factors of reservoir resistivity were discussed.
The results showed that the reservoir resistivity is influenced by the combination of clay mineral contentmorphologyand rock framework grains contact relationship.
The content of smectite in clay minerals of normal resistance reservoir is 16 ~ 28%and the content of smectite in low resistance reservoir is 52 ~ 70%, which is positively related to the cation exchange capacity.
Smectite is distributed in two types. The first type is thin filmwhich wraps rock framework grainsleading to the formation of a conductive film on the surface of rock framework grainsand this type accounts for about 80%; A small amount of smectite exists between rock grains in flocculent and dispersed formand the smectite between grains accounts for about 20%this type is relatively dispersed and fails to form a continuous conductive structure.
Moreover the rock framework grains of N_1gIIIformation are in point contact to line contact due to compaction, which leads to the contact of smectite conductive film on the surface of rock framework grains and the formation of continuous conductive structure.
According to the digital core experiment, smectite is in film shape and rock framework grains are in contact with each other. Moreover, smectite is easy to form a continuous conductive structure while the content is greater than 45%, which is consistent with the understanding of the study area.

Thickness prediction and sedimentary architecture characterization by the combination of well logs and seismic data in lacustrine gravity flow deposits

Ruijing Liu[1*], Dali Yue[1], Wei Li[1], Wurong Wang[1]
1. College of Geosciences, State Key Laboratory of Petroleum Resources and Prospecting, China University of Petroleum (Beijing) , Beijing, CHINA

Keywords: Sedimentary architecture, Seismic attribute, Frequence-decomposed inversion, Lacustrine gravity flow, Qingcheng oilfield

The Chang 7 formation in Qingcheng Oilfield of Ordos Basin develops abundant hydrocarbon reservoirs, which were generally related to lacustrine gravity flow. And Chang 7 formation contains three sand-groups, each sand-groups can be divided into many of zones. The reservoirs of Chang 7 formation are tight sandbodies, and their geological structures are complex. This work aims to fully understand their distribution and features, mainly including predicting the thickness distribution and characterizing the sedimentary architecture of compound sandbodies by combining the well logs and seismic data. For Zhuang 214 block of Qingcheng Oilfield, the sedimentary architecture of gravity-flow deposition was characterized and a 3D lithological model was established, by combining the fusion of frequency-decomposed seismic attributes and intelligent seismic inversion. Firstly, the original seismic cube was decomposed into multiple seismic volumes with different dominant frequencies using the method of continuous wavelet transform, i.e., frequency-decomposed seismic volume (FDSV). These FDSVs and their seismic attributes were selected according to the thickness interpreted from well logs. Distribution and thickness of sandbodies at sand-groups were predicted by fusing the seismic attributes. Secondly, the frequency-decomposed inversion was performed on the original seismic data. A 3D lithological model was modelled with the algorithm of sequential collaborative indication Kriging based on the well logs and seismic inversion result, in which the seismic inversion result is the collaborative data. The radio of sand thickness to its related zone thickness can be extracted by the 3D lithological model and multiplied by its related zone thickness to obtain the sand thickness distribution of each zone. Finally, under the restriction of the thickness of sandbodies, the fine characterization of single sandbodies was completed. The results indicate that: (1) compared to the single attribute, the correlation between the fused seismic attributes and the sand thickness improves greatly. (2) The 3D lithological model modelled using the seismic inversion results can further improve the prediction accuracy of thickness, and sand thickness of all zones were predicted. (3) The sandbodies of three sand-groups show obvious progradational sedimentary characteristics. The high value area of sand thickness advances along the provenance direction. (4) Single lobes are distributed in tongue shape, and their scale is controlled by A/S ratio. The scale of single sandbodies decreases when A/S radio increase, but increases when A/S radio decrease. The thickness of single sandbodies is mainly less than 6m and the width between 300m and 2000m.

Keywords: depression basin, shallow-water delta, depositional feature, growth pattern, Poyang Lake

Large shallow-water deltas in depression basin contribute to the main potential increase of onshore lithologic reservoirs in China. The Baoqian delta of the Upper Cretaceous in southern Songliao Basin and the modern Ganjiang delta in Poyang Lake were analyzed. The particular focus was put on the paleo-environmentdepositional features and growth pattern of this type of delta.1Depression basins are favorable for large shallow[1]water deltas. Unconfined morphology results in the frequent rise and fall of lake-levelwhich controls the delta dimension in dip direction.2There are two different types of deltas in the Upper Cretaceous of southern Songliao Basin. One is deep-water delta characterized by lobe shape and easily-identified depositional faciesmainly including distributary channelsmouth barsand interdistributary bays. Another is shallow-water delta characterized by bird's foot shape and obscure boundaries between depositional faciesmainly including distribu[1]tary channels and interdistributary bayswith mouth bar less developed.3The remote sensing for modern sedimentary systems reveals the evolution of Ganjiang middle delta in Poyang Lake in recent 50 yearsshowing the transition from disperse branch shape to connective network shape.4Large shallow-water delta in depression basins is a complex consisting of several deltas formed in multi-scenarios. The sand-bodies of distributary channels are the most significant reservoir and carry massive lithologic reservoirs. They are distributed horizontally in a net pattern and control the distribution of lithologic reservoirs.

Reservoir Characteristics and Sedimentary Models of the Third Member of Dongying Formation on the Western Slope of Liaozhong Sag

Jun Xie[1*], Liande Zhou[1], Youchun Lai[1], Haisong Jia[1], Xijie Wang[1]
1. Bohai Oilfield Research Institute, Tianjin Branch of CNOOC Ltd., Tianjin, CHINA
E-mail: 345327042@qq.com

Keywords: sublacustrine fan, sediment gravity flow, seismic response characteristics, sedimentary model, reservoir prediction

With the increasing exploration degree in Bohai Oilfield, the lithologic trap related to sublacustrine fan has become a hot field with the Paleogene sandstone as its reservoirs, but the genetic types and subtly characterization of sand bodies are still unclear. Based on drilling, coring, logging, analytical testing and 3D seismic data and guided by theory about sediment gravity flow, this paper takes the third member of Dongying Formation of the western slope of Liaozhong Sag as the research object to strengthen the application of prediction technology of new reservoirs and provide theoretical support for oil and gas exploration in this area.

Braided river delta deposits are well developed on the slope, which can be uncemented under the trigger of slump and then transported into the lake floor and form the sublacustrine fan deposition. Four types of sediment gravity flow, including slides, slump, debris flow, and turbidity current are developed in this area. The sublacustrine fan sediments are divided into the inner fan subfacies dominated by slides-slump, the middle fan subfacies dominated by debris flow and the outer fan subfacies dominated by turbidity current. And the sedimentary model of the sublacustrine fan on the western slope of Liaozhong Sag is established. (Different subfacies of sublacustrine fans have obvious seismic response, which can be characterized by strong parallel reflection, imbricated reflection and weak discontinueous reflection. Reservoir inversion, slice and multi-attribute analysis are also used to track the envelope related to the top of the reservoir. Under the constraints of seismic attributes and formation thickness, these responses are used to subtly depicted the petroliferous fans. The study result shows that it is important for lithology oil and gas exploration in Bohai Sea Area to discover more sublacustrine fans by the established sedimentary model and seismic response. Due to the bulk freezing characteristics of slides-slump and debris flow, sand-rich bodies can also develop on the slope of lake floor. And due to the superposition of multiple gravity flow events, debris flow can form continuous sand bodies of medium fan and advance to the central basin, which has great significance to expand the exploration in the field of deep water.

Intelligent fluvial sand body prediction and architecture characterization of Guantao Formation in Chengdao oilfield, Bohai bay basin, China

Dali YUE[1*], Jian LI[2], Wei LI[1], Haina ZHANG[2], Xueting ZHANG[1]
1. College of Geosciences, China University of Petroleum, Beijing, Beijing, CHINA
2. Shengli Oil Field Company, SINOPEC, Dongying, Shandong, CHINA
E-mail: yuedali@cup.edu.cn

Keywords: Sand body prediction, Architecture characterization, Intelligent seismic attribute fusion, Frequency-decomposed genetic inversion, Fluvial reservoir

The study of the fluvial successions is the most important hydrocarbon clastic reservoirs in China, characterizing meander belts and point bars in fluvial reservoirs is significant for reducing drilling risks and improving the recovery of oil and gas. Although many valuable studies have been done in the past decades, the research on quantitative sand body prediction and fine architecture characterization combined with well and seismic data has been relatively weak. Therefore, a fluvial reservoir case in Chengdao oilfield is selected in this research, intelligent frequency-decomposed attributes fusion, fusing seismic attributes of target and neighboring zones, and frequency-decomposed genetic inversion are used to predict sand body and architecture distribution, the research results and conclusions are as follows.

Three intelligent methods for sand body prediction are proposed to improve the interpretation of seismic data during the characterization of fluvial reservoirs and the establishment of fluvial models. (1) The method is proposed, which combines the frequency decomposition, attribute optimization and machine learning, and can predict the sand thickness quantitively. (2) Frequency decomposition and genetic inversion are combined, forming a new inversion method, to predict sand body distribution effectively. (3) A novel method is proposed that combines multiple seismic attributes of the target interval and of its interfering neighboring zones, implemented by a supervised machine learning, which remarkedly reduces the interference of the neighboring zones.

On the basis of sand body prediction, combined with well logging response characteristics, the distribution of meander belt, point bar and abandoned channel are characterized. The three important symbols of point bar are composite positive rhythms, thick sand-bodies, and being adjacent to abandoned channels. Corresponding to these features, point bars show the characteristics of seismic response with high fusing seismic attributes and high genetic inversion properties, while abandoned channels show low fusing attributes and low genetic inversion properties with the characteristics of flat top and convex bottom. Based on the application of using fusing seismic attributes and inversion properties to predict the location of the point bar, the span of the point bar is calculated through empirical formula, the scale of point bar is recognized, and the identification of subsurface point bar is effectively guided. The constraint of dynamic data also provides a basis for point bar identification. This method proposed in this paper can provide implications to the oilfield with similar sedimentary characteristics and data condition.

Study of provenance, sedimentary environment and paleoclimate of Permian Jiamuhe Formation in Shawan Sag, Junggar Basin

Yao Zongquan[1*], Jianatayi Deleqiati[1], Jia Chunming[2], Pan Tuo[2], Yu Haitao[2]
1. School of Geology and Mining Engineering Xinjiang University, Xinjiang University, Urumqi, Xinjiang , CHINA
2. Exploration and Development Institute, PetroChina Xinjiang Oilfield Company, Urumqi, Xinjiang , CHINA
E-mail: 407465819@qq.com

Keywords: provenance system, sedimentary environment, paleo climate, Jiamuhe Formation, Shawa Sag, Junggar Basin

many years of oil and gas exploration practice has proved that shawan sag in Junggar Basin has great potential, but its provenance is unknown, sedimentary system is not clear, sandbodies distribution are unknown, which restrict further oil and gas exploration. Based on detailed description of legalistic cores, comprehensive analysis of logging, seismic and outcrop data. This paper makes a thorough study of the study area by using grain size analysis, Q-type cluster aanlysis of heavy minerals, statistics of detrital particles and elemental geochemistry analysis. The provenance system, formation mechanism and distribution on law of sandbodies are clarified, and paleoclimate chages are summarized.

1) The provenance system of Permian Jiamuhe Formation in Shawa Sag is characterized by “a system of provenance, three provenance directions” and “a major provenance, three secondary provenances”. The REE distribution patterns of the samples all showed a right-leaning distribution patten, with negative Eu anomalies and a “V” type in the figure, indicating stable provenance in the study area. In the LREE(La~Eu) segment, the element distribution curve has a high slope and an obvious “right-leaning” degree, indicating a high degree of fractionation between LREE elements. On the contrary, the distribution curve of HREE(Dy~Lu) indicating a low degree of fractionation between HREE. In La/ Th-Hf, most of the samples fall on the acidic rocks in the acidic island arc region, which are dominated by granite and felsic volcanic rocks. The results of cluster analysis showed that the provenance of the south and the north had broad homology. According to multidimensional scale analysis of heavy minerals and REE, principal component analysis, the provenance of the study area can be divided into three types. The primary provenance in NW direction and secondary provenance in other directions.

2)“One provenance system and two kinds of sedimentary environment” developed in the study area. Jiamuhe Formation is mainly composed of coarsen gravelly sandstone, volcanic recks and poor structural maturity. Sedimentary structure is not developed, but scour surface, the reddish mudstone and “floating conglomerate” are mostly along the fault zone, indicating a near provenance and rapid sedimentary environment. Volcanic sedimentary facies, lithofacies of clastic rocks and their lithofacies assemblages were established. There are volcanic sedimentary facies dominated by tuff and andesite in the study area. the fluvial fan-delta facies, dominated by gravelly sandstone, was affected by provenance and hongche fault zone, and developed three fan bodies with different provenance directions.

3)Based on the determination of 25 elements in 40 samples from Jiamuhe Formation. The paleosedimenraty characteristics are reconstructed by analyzing the contents and ratios. Th/U values ranged from 0.67~8.33, with an average of 5.59. One δU is greater than 1, and the others are all less than1. V/(V+Ni) values range from 0.79-0.99, with an average of 0.88, indicating that H2S exists in stratified water and anaerobic environment in formation water. Sr/Ba ranges from 0.25-1.02, with an average of 0.57, and is mainly dry heat. Sr/Cu values range from 6.13 to 45.24, with an average of 21.55>. 10 indicates that the climate is relatively dry and hot.

A MPS-based novel method of reconstructing 3D reservoir models from 2D images using seismic constraints

Lixin Wang[1], Yanshu Yin[1*]
1. School of Geosciences, Yangtze University, Wuhan, Hubei, CHINA
E-mail: yys@yangtzeu.edu.cn

Keywords: two-dimensional images, three-dimensional reservoir modeling, Seismic constraint, Probability aggregation, multiple-point geostatistics

While multi-point geostatistics (MPS) be used to model complex underground reservoirs, this method relies heavily on high-quality three-dimensional (3D) training images that may be difficult to acquire in real field studies. Furthermore, the original MPS technique does not include seismic data, which may noticeably improve underground reservoir predictions. Our proposed model, Se3DRCS, is a novel method to reconstruct 3D geological models from two-dimensional (2D) images and seismic information. In Se3DRCS, we are able to perform MPS-based modeling using 2D training images, rather than 3D images. These 2D images are produced by analyzing well profiles and sedimentary facies planes. After using the Se3DRCS method to obtain an initial geological model, we then generate elastic parameters and synthetic seismograms via direct sampling and convolution with the extracted seismic wavelets, respectively. By comparing the observed and synthetic seismic records, we refine the simulation results using the adaptive sampling method. The initial geological model is then updated with conditional data after each subsequent simulation iteration. When the error between the observed and synthetic seismograms falls below a reasonable threshold value, we have arrived at the best-fitting geological model. Our results indicate that the Se3DRCS method is capable of predicting the data elicited from wells with an accuracy of up to 82.88%, providing constraints on the distribution of branch channels in a delta reservoir, and reproducing local complex non-stationary geological features.

Terminal Fan Analysis of the Paleogene Lower Fourth Member of the Shahejie Formation in the Bonan sag, Jiyang Depression, China

Arthur Paterne MIOUMNDE[1*]

1. Laboratory of Deep Oil and Gas, China University of Petroleum East-China, Qingdao, China, Qingdao, Shandong, CHINA
E-mail: arthurmioumnde@yahoo.fr

Keywords: Terminal Fan, Lower Fourth Member, Shahejie Formation, Bonan sag.

The Lower 4th member of the Paleogene Shahejie Formation in Bonan sag, Bohai Bay Basin, East China was taken as the target for our study object to identify the potential and favorable reservoirs for further studies on a great scale. In Bonan down warping region, Paleogene stratona deposits are mainly terrigenous clastic materials that formed in arid or semi-arid regions. From a classical view, on the face of it, four depositional systems were developed in the Bonan sag. Among them, the fan delta developed in the central part of the study area, consisting of gray-white fine glutenite with poor sorting and rounding. The braided river delta is developed in the southern part with the lithology of light gray conglomerate, pebbly sandstone, and sandstone. Sedimentary structures like parallel bedding, cross-bedding and scour are visible. Floodplain sedimentary facies is mainly developed in the inundating plain that in some weather conditions has the characteristics of shallow lake facies. However, insufficiencies appeared, in the instance of presence explanation on multiple colors of mudstones, the relatively strong and low levels of total organic carbon (TOC) which are very disparate in the area. Consequently, given the conditions of deposits, the depositional system which occurs in the area suggests that it would rather be terminal fan deposits. Although some scholars have conducted studies on terminal fans abroad and in China, the concept remains unfamiliar and deserves to be more elucidated, that will be the case in this study. In that case, the study approach must be reviewed for oil exploration.

Characteristics of stratigraphic structure of nanhua-Sinian rift-depression sedimentary system and its control on source, reservoir and cap in Tarim Basin

1*

1. , , , , CHINA
E-mail: heyf3@cnpc.com.cn

Keywords: Tarim basin, Rift-depression sedimentary system; Ancient source rocks; Control Source,, Control reservoir, Control trap

Based on outcrop, drilling and gravity, magneto-electric and seismic (2-3D) data, the wave group characteristics of Nanhua-Sinian were calibrated using virtual well synthetic record calibration method.Optimize the 2-3D seismic data, build the frame section, establish the sequence structure model, determine the stratigraphic interpretation scheme, and carry out geological series and mapping work of the whole basin.The stratigraphic structure and distribution range of The Nanhua-Cambrian system are analyzed in detail based on the framework section and basin map. It is concluded that the Nanhua-Sinian strata have obvious characteristics of rift basin and developed two structural backgrounds of rift and depression.The stratigraphic structure can be divided into four seismic reflection types corresponding to four sedimentary facies combinations according to the characteristics of internal wave group and the termination relation of reflection axis.The nanhua-Sinian system can be divided into three second-order sequences by identifying four large unconformities and three Marine flooding surfaces.According to the outcrop and drilling data, the paleo-rift has the characteristics of controlling source, controlling reservoir and controlling trap: controlling the development range of ancient source rocks of Sinian-Cambrian, controlling the development location of ancient reservoirs and ancient traps of paleo-slope and paleo-uplift.Based on the exploration practice of the ancient carbonate reservoirs in Anyue Gas field of Sichuan Basin, it is considered that the paleo-uplift surrounding the hydrocarbon generation depression is a favorable exploration area. The slope of the central margin of the Nanhua-Sinian rift, the uplift area and the Cambrian platform margin zone are surrounded by the tectonic sedimentary background with large-scale accumulation. It has laid a solid foundation for the search and evaluation of ancient traps in ultra-deep ancient carbonate rocks in Tarim Basin.

3. Geological Brigade 115, Bureau of Geology and Mineral Exploration and Development of Guizhou Province, Qingzhen, Guiyang, Guizhou, CHINA

E-mail: duyuansheng126@126.com

Keywords: Jiujialu Formation, Central Guizhou, Paleogeomorphology, Bauxite

The Lower Carboniferous Jiujialu Formation bauxite deposits are widespread in central Guizhou, south China (Ling et al., 2015, 2017; Wang et al., 2018). We collected data from ~700 drillcores in central Guizhou to reconstruct geomorphological characteristics for the period of formation of those bauxite deposits, which indicates that thicker bauxite deposit are concentrated in relatively deep depressions. We undertook a petrological, mineralogical, and geochemical study of the Xiuwen deposit in drillcore ZK43-20 which is located within the karstic depression revealed on geomorphological reconstructions to gain insights into its formation history. Deposits of Jiujialu Formation within the drillcore of ZK43-20 contains Al-rich deposits in the upper member and Fe-rich deposits in the lower member. Bauxite ores are characterized by high Al_2O_3 and Al-mineral content, while low SiO_2 content. Bauxitic claystone is characterized by relatively lower Al_2O_3 and higher SiO_2, clay mineral (mostly illite and kaolinite) content. Geochemical characteristics of samples from the study drillcore indicates that leaching is the main control on quality of bauxite ore, while a low groundwater table and water-permeable underlying units contributed to the formation of high-grade bauxite ores in the study area. The formation of high-grade bauxite ores was accompanied by the further losses of most mobile elements (e.g., KNa, Ca, Mg, Si) and further relative enrichment of Al under intense chemical weathering and leaching processes. On the other hand, trace elements (particularly Li) and rare earth elements are relatively enriched in bauxitic claystones and Fe-rich claystones. Sedimentary features, geochemistry characteristics and paleosalinity analysis indicate Fe-rich deposits of Jiujialu Formation are residual, while Al-rich deposits are formed in the subaerial environment while the leaching process and geomorphology influence the formation.

Lacustrine shallow-water delta front formation processes and main controlling factors

cheng chen[1*]
1. Unconventional Research Institute, CNOOC, Beijing, CHINA
E-mail: mqx1415@126.com

Keywords: shallow-water delta, inner delta front, outer delta front, fluviation, sediment supply, water-level oscillation

Although the shallow-water delta facies have been studied for decades, the formation process of this kind of delta remains poorly documented. Differences in the morphology and facies architecture are potentially significant for exploration and development of these kinds of reservoirs. In this article, facies analysis was applied to the Yanchang Formation exposed in the Ordos Basin of China, while the delta front formation process was studied by observation and description of the Ganjiang modern delta at Poyang Lake, China. We documented the shallow-water delta microfacies and their spatial arrangement and analyzed them in the context of formation processes under different fluvial and wave force conditions. Seasonal water-level oscillation separated the delta front into the delta inner front (DIF) and outer front (DOF), which differentiates the shallow-water delta from a traditional Gilbert delta. Three facies sets were recognized in the DIF: (i) distributary channel, (ii) preserved mouth bar, and (iii) interdistributary silt and mud; and four facies were recognized in the DOF (i) distal channel, (ii) mouth bar, (iii) fluxoturbidite, and (iv) sheet sand. Because of the seasonal submergence of the DIF, fluviation dominated during drawdown and wave action dominated when the water level was high. Channels at the DIF can be classified into the main channel, which is characterized by large scale and low width to depth (w/d) ratio, and the migration channel, which is characterized by high w/d ratios. The mouth bar also developed under shallow-water conditions. At the DIF, few mouth bar sand deposits are preserved because of the erosion by the migrating channels, but mouth bars are well preserved at the DOF. Because the DIF channels are the main reservoirs, we studied the physical property distribution within the different channels. The best porosity and permeability values were located in the core of the main channel; the flank, top, and bottom of the channel had lower porosity and permeability. The physical property distribution in the migration channels is similar to that of the main channel, but porosity and permeability decrease along with the lateral migration direction of channels as well.

Quantitative identification of the conglomerate diagenetic trap

Yongqiang Qu[1*], Jianguo Pan[1]
1. Northwest Branch of Research Institute of Petroleum Exploration & Development , PetroChina, Lanzhou, Gansu, CHINA
E-mail: quyongq@petrochina.com.cn

Keywords: diagenetic trap, critical physical property, quantitative identification, Junggar Basin

The lithology of the reservoir of conglomerate diagenetic trap is the same as that of the surrounding rock, and the physical property difference is small. It is very difficult to define the reservoir and non-reservoir. In order to describe diagenetic traps in detail and improve the identification accuracy of conglomerate diagenetic traps, we start with the analysis of oil and gas filling power and resistance, and confirm that the effectiveness of diagenetic traps is controlled by the pore structure characteristics of reservoir and surrounding rock, so as to establish the relationship between critical physical properties and depth. The sensitive parameters are optimized, the functional relationship between reservoir physical properties and small angle elastic impedance is established, and the quantitative identification of effective reservoirs under different depth conditions is solved by using seismic data volume, so as to realize the spatial characterization of variable depth of diagenetic traps. This method is applied to Triassic Baikouquan Formation of Mahu sag, Junggar basin. It is the first time to recognize that the reservoir critical physical properties of oil and gas filling in conglomerate diagenetic trap change with buried depth, and quantitatively characterize the differences of diagenetic trap formation conditions at different depths. The carefully identified conglomerate diagenetic trap provides an effective basis for drilling well deployment.

Sedimentological and Diagenetic control on the ASR viability in the Edwards aquifer (New Braunfels, Texas)

Christophe Wakamya Simbo[1*]
1. Geosciences, Colorado State University, Fort Collins, COLORADO, UNITED STATES
E-mail: simbo@rams.colostate.edu

Keywords: Aquifer storage and recovery, sustainable, water resources, sedimentology, diagenesis, storage zone

The Edwards aquifer is a sole source aquifer providing drinking water to over 2 million people in South-central Texas. It is a two-layered aquifer, the upper layer being the Pearson formation (storage zone 1), and the lower layer, the Kainer formation (storage zone 2) — both separated by the confining layer, the Regional Dense member (RDM). With increasing population and extreme climate conditions, the stress on freshwater availability has increased and annual water demand has been projected to surpass the maximum year supply by 2024 in New Braunfels (Texas). Aquifer storage and recovery (ASR) has proved successful in converting seasonally available water supplies to reliable, resilient, and sustainable water resources, even in brackish aquifers. It is a cost-effective engineered method for storing water during times when water is available and recovering it when needed. However, an efficient and successful ASR operation depends on site-specific hydrogeological and hydrogeochemical conditions. This study characterizes the sedimentology of the two-layered Edwards aquifer system by (1) describing the initial and diagenetic texture and fabric of the aquifer matrix, (2) placing diagenetic events into a paragenetic sequence, and (3) evaluating the abundance of porosity types by point counting and inferring their distribution pattern in enhancing the permeability. The objectives are to decipher the main diagenetic processes and porosity types to better guide ASR operations. This will help target storage zone(s) that would allow optimal ASR recovery efficiency with water quality meeting minimum requirements. Dolomitization, fracturing, and dissolution are late diagenetic processes and may play a major role in the aquifer's storativity and transmissivity. Due to their brittleness, dolomitic sections appear to have been readily fractured compared to micritic sections. In addition to intercrystalline porosity developed by dolomitization, fractures, and dissolution likely enhanced connectivity between pores. Intercrystalline porosity is abundant from 618 to 7111 ft depth (current ASR storage zone) and 756 to 825 ft depth. Well preserved compaction features observed in the confining unit (RDM) separating both aquifer zones probably contribute to its low permeability. However, partially cemented fractures in the Regional Dense Member present potential pathways connecting both aquifer zones. These cemented fractures may be weak zones likely to re-fracture due to an increased pumping induced gradient following recovery of water stored in one aquifer zone. This study suggests implementation of two ASR wells screened in dolomitic portions of the Kainer formation and Pearson formation of the Edwards aquifer in order to limit head pressure differential that would have been generated from pumping in only one storage aquifer zone.

Depositional Architecture of Mouth Bar in Lacustrine Fan Delta Front through unmanned aerial vehicle (UAV): Insights from the Lower Cretaceous Xiguayuan Formation of Sangyuan outcrop, Luanping Basin

Ke Zhang[1*], Shenghe Wu[1], Yunjie Xu[1]
1. College of Geosciences, China University of Petroleum (Beijing), Beijing, CHINA
E-mail: 346211611@qq.com

Keywords: Sangyuan outcrop, Fan delta front, Mouth bar, Development, Vertical garin-size trend

Fan delta, as an important sedimentary type at the margin of basin, is an important place for the enrichment of petroleum, natural gas and other geological resources. Although many studies about sedimentary characteristics of fan delta front in lacustrine basin have been done in the past decades, it is poorly understood that the depositional architecture of mouth bar. Unmanned aerial vehicle (UAV) observation was used to investigate the lacustrine fan delta of Sangyuan outcrop within Xiguayuan Formation of Lower Cretaceous in Luanping Basin, aiming to analyze the sedimentary characteristics of mouth bar and discuss the development degree. The mouth bar with flat bottom and convex top mainly consist of sandy and gravelly accretions. The sandy accretion shows an overall coarsening upward trend, and gravelly accretion shows the fining upward trend. The vertical grain-size trend of mouth bar is controlled by superposition patterns of the accretion bodies, which shows either coarsening upward trend or fining upward trend. The mouth bar is widely developed in study area, which accounts for 36.88% of glutenite bodies in Sangyuan outcrop. The distributary channels, tongue-shaped debris deposits and sheet sand account for 53.42%, 8.39% and 1.31%, respectively.

Configuration characterization of distributary channel-type shallow water delta reservoir: A case study of oil formation L60 in PL Oilfield, Bohai Sea

Xiaohan Liu[1*], Yanlong Ren[1]
1. Bohai Oilfield Research Institute, CNOOC China Limited, Tianjin Branch, Tianjin, CHINA
E-mail: 623104373@qq.com

Keywords: Seismic attribute optimization, shallow water delta, distributary channel, Reservoir configuration, Bohai Sea

The L60 oil formation of PL oilfield in Bohai Sea is composed of delta front subfacies, and the reservoir is mainly developed with distributary channel microfacies. The reservoir thickness changes rapidly and inter-bedded reservoirs are relatively developed. The commonly used amplitude seismic attribute cannot effectively identify this reservoir and find difficult to describe fine reservoirs. In this study, the seismic attributes are classified and optimized to improve the prediction accuracy of inter-well reservoirs. On this basis, combined with core and logging data, the reservoir configuration of offshore distributary channel-type shallow water delta sand body is studied, and the classification of sand body configuration, interface recognition standard and sand body superposition model are established. Through the optimization analysis of seismic attributes, the average instantaneous frequency attribute has a good correlation with the thickness of reservoir sand body of L60 oil formation in the study area, and the distribution characteristics of sand body are re-recognized based on this attribute. The shallow water delta sand bodies in the area can be divided into four configuration levels: delta body, delta front sedimentary body, composite channel and single distributary channel. The longitudinal interface of single distributary channel includes mudstone interface, siliceous interface and physical interface of erosion origin. Lateral interface recognition including river edge, thickness difference of channel sand body and interchannel discontinuous sand body. The sand body superposition model can be divided into four types: isolated type, docking type, lateral cut superposition type and lateral superposition type. Finally, the shallow water delta channel sand body configuration model in the study area is established, which provides a basis for pre-drilling well location optimization and horizontal well deployment.

Configuration anatomy and application of composite sand body based on seismic attributes: Taking Guantao Formation in Well Block5 in Oilfield P of Bohai Bay Basin as an example

Mingyang Chen[1*]
1. Bohai Oilfield Research Institute, CNOOC China Limited, Tianjin Branch, Tianjin, CHINA
E-mail: chenmy12@cnooc.com.cn

Keywords: Composite sand body, forward modeling, seismic attributes, onfiguration

Well Block5 in Oilfield P of Bohai Bay Basin has entered a high water-cut period. The main reservoir of Guantao Formation is the L50 sand body, which is a composite channel bar sand body reservoir. Implementing horizontal wells to excavate the remaining oil, it is difficult to drill due to the impact of bottom water flooding, poor top reservoirs, and internal barrier interlayers. It is necessary to carry out the fine configuration anatomy of the L50 sand body to guide the deployment and implementation of horizontal wells. This topic is based on the high-resolution seismic data, combined with the understanding of reservoir stacking mode and forward modeling, it is proposed to use the root mean square amplitude attribute combined with the minimum curvature attribute to analyze the boundary and superposition relationship of main and secondary channels in the composite sand body, and complete the sedimentary model of L50 sand body and the characterization of the internal structure of composite channel bar sand body.The result was indicative that: The boundary channel and internal main channel in L50 sand body are relatively stable, the internal secondary channel migrates frequently, and the sand body has experienced three stages of development, maturity and decline. It is considered that the horizontal well should avoid the main channel on the plane and the top poor reservoir on the vertically. The research results guide the optimization of horizontal wells and the implementation while drilling, and contribute to the efficient tapping of oilfield potential.

Evolution mechanism of bedrock weathering crust and its control significance to reservoir in Dongying Sag, Bohai Bay Basin

Maolin Zhu[1], Zhen Liu[1*]
1. College of Geosciences, China University of Petroleum (Beijing), Beijing, CHINA
E-mail: liuzhenjr@163.com

Keywords: bedrock weathering crust, evolution mechanism, main influencing factors, distribution characteristics, Dongying sag

The exploration potential of the bedrock reservoir is notably large, and clarifying the evolution mechanism and main influencing factors of bedrock weathering crust is the premise of predicting the distribution of favorable reservoirs. Based on cores and thin section observations, outcrop surveys, conventional logging data, image logging analysis and seismic interpretations, our study systematically explores the dynamic mechanism of the formation, transformation and preservation of bedrock weathering crust reservoirs in Dongying Sag, Bohai Bay Basin. The results indicate that the vertical structure of bedrock weathering crusts in the study area is a double layer composed of a top eluvium or dissolution layer (completely weathered layer) and a bottom disintegration layer (semiweathered layer) and the dissolution and eluvium layers are the products of different evolution stages on top of the disintegration layer. In the early evolution of the weathering crust, the disintegration layer began to develop into a dissolution layer, and a double layer with dissolution layer and disintegration layer appeared; in the middle-stage evolution of the weathering crust, the dissolution layer evolved into an eluvium, forming a double layer with eluvium and disintegration layer. In the late evolution of the weathering crust, only the disintegration layer was preserved. Bedrock weathering crust reservoir has undergone structural tilting, fracture destruction, fluvial abrasion and other transformation effects when it is formed, and it is believed that the preservation effect brought by the later stratigraphic coverage is crucial to the bedrock weathering crust. The earlier the later stratigraphic coverage occurs, the better it is for the preservation of bedrock weathering crust reservoirs. There is a huge difference in the types of weathering crust on different elevations, different slopes and different structural belts. Only disintegration layers are developed at the top of the structure, eluvia are developed in the marginal areas of the high structural part, and dissolution layers are developed in middle- low structural parts. The disintegration layer is widely distributed. The analysis of the formation, transformation and preservation evolution mechanism of bedrock weathering crust not only gives us a more comprehensive understanding of the evolution of bedrock reservoirs, but also provides new ideas and theoretical support for further exploration of bedrock reservoirs in other rift basins worldwide.

Organic matter thermal maturation and organic pore development and preservation in black shales

Bei Liu[1*]

1. School of Earth Resources, China University of Geosciences (Wuhan), Wuhan, Hubei, CHINA
E-mail: liubeicugb@outlook.com

Keywords: Organic matter, maceral, thermal maturation, organic pores, solid bitumen, black shales

Organic matter (OM) quantity, quality, and thermal maturity are key parameters in source rock evaluation and shale reservoir characterization. OM-hosted pores are important constituents of the pore system in shale reservoirs, and they, to a large degree, control the gas content and porosity of shales. OM in black shales can be classified into four types of kerogens (kerogen type I, II, III, and IV) based on H/C and O/C atomic ratios and five maceral groups (vitrinite, inertinite, liptinite, zooclasts, and secondary organic matter) with each group consisting of multiple macerals. Different macerals have different origins, and varying potential of hydrocarbon generation and development of organic pores. Oil-prone macerals such as alginite and bituminite generally disappear after peak oil window maturity (Ro 0.8–1.0%) due to hydrocarbon generation. Organic pores in black shales can be primary or secondary, the latter of which is the dominant type. Primary pores are pores inherited from the biological structure of the original OM such as cellular pores in inertinite, but they are typically filled with diagenetic minerals. Secondary organic pores occur in solid bitumen or pyrobitumen, and their development is related to thermal maturation of oil-prone macerals. The development of secondary organic pores is controlled by OM type and thermal maturity, and their preservation depends on thermal maturity, OM content, mineralogical composition of shales, as well as pore pressure. When conducting source rock evaluation, the hydrocarbon generation potential of OM should be studied based on a good understanding of maceral types, composition, and their hydrocarbon generation potential. In order to accurately assess the contribution of organic pores to the pore system of shale reservoirs, the influence of OM type, content, and thermal maturity should be taken into consideration.

Sedimentary characteristics and sand body distribution law of Chang 81 reservoir in Heshui area, Ordos Basin

Hongliang HUO[1], Chenglin LIU[1*]
1. College of Geosciences, China University of Petroleum (Beijing), Beijing, CHINA
E-mail: 694200908@qq.com

Keywords: Heshui area, Shallow water delta front,Chang 81,Sand body structure,Distribution

Abstract: Shallow water delta deposits developed in the Chang 8 Member in the Ordos Basin. This paper takes the Chang 81 Member in the Heshui area as an example to study the structure and distribution of sand bodies. On the basis of previous studies, through the observation of core slices, combined with the analysis of logging and logging data, it is determined that the Chang 81 Member in the study area mainly develops shallow water delta front deposits, and underwater distributary channel sand bodies are the main reservoirs. The long 81 is divided into three sub-layers from top to bottom according to the deposition cycle. According to the response characteristics of sand body log curves and the relationship of vertical superposition, the sand bodies of Chang 81 Member are mainly divided into the following types: multi-phase channel superposition type, single-phase channel type, sand bar type and isolated type. body. The sand bodies are distributed in the NE-SW direction as a whole, and the sand bodies are multi-stage. The thickness of the sand bodies developed in each depositional stage and the location of the sand bodies fork or intersect are different. The distribution pattern is complex: the multi-stage superimposed sand bodies are mainly distributed in Chang 811, Chang 812 and partly in Chang 813; other types of sand bodies are partially distributed in each layer, and the main type is single-stage channel-type sand bodies. The overall distribution frequency of multi-stage superimposed sand bodies is low and the thickness is large, and they are high-quality reservoir sand bodies in the Chang 81 oil layer group in the study area. The sand bodies with better performance are the main reservoir sand bodies in the study area; the isolated sand bodies are less than 3m thick, with weak depositional energy, impure sand quality and poor reservoir physical properties, are invalid reservoir sand bodies and are widely distributed on the flanks of the main channel. On the whole, the sand body quality of Chang 811 period is better than that of Chang 812 period, and the sand body quality of Chang 813 period is the worst.

Differential sedimentary response of coal seams in coal-bearing rock series and oil and gas exploration:A case study of J1b Formation in Mahu slope area

1*

1. , , , , CHINA
E-mail: mengxc_hz@petrochina.com.cn

Keywords: coal-bearing rock, J1b Formation, Stable thick coal seam,Limited thin coal seam,Coal humic acid

The coal-bearing rock in the different sedimentary response of different kinds of coal seam, and the effect of adjacent glutenite diagenetic into reservoir research is relatively weak at present, through the field outcrop, sporopollen combination, well - seismic profile, core phase sequence, logging response, such as scanning electron microscope, electron probe energy spectrum data, a stable thick coal seam in the studied area, limited thin coal seam are analyzed in different sedimentary response. The results showed that represented by thrust faults I and II of the basin edge the oscillation behavior of resurrection of boundary faults and the basin basement subsidence, provides the study area with thick layers of peat accumulation, wide wide slow - ancient slope cover lake invasion, hinder the swamp drainage to prevent the oxidation of the organic matter, reduce the river gradient - weakening terrigenous clastic interfere with the four aspects, such as favorable conditions, A large area of stable thick coal seam was formed near the first lake flood surface in the lacustrine basin, and the maceral indicates that the coal forming swamp has maintained a good hysteretic water reduction condition. The limited thin coal seams are scattered and have obvious phase-controlled characteristics, and are mostly distributed in the low energy facies zones such as interfan/interchannel with weak hydrodynamics. The maceral indicates that the coal forming swamp has a semi-oxidation stage with poor local hysteretic reduction conditions. In penecongenic-early diagenetic stage, humic acid in coal measures formed dissolution pores in feldspar grains of early diagenetic stage, and the dissolution particles were dominated by calcium-rich plagioclase. The occurrence of kaolinite cement products is mainly close to the inner ring edge of particles, and its purity is high. Complete kaolinite particles and partial kaolinite particles are formed by the process of dissolution of feldspar particles, kaolinite filling and collapse polycondensation. The former is of high purity and the latter is of low purity. In the middle diagenetic stage, organic carboxylic acid of hydrocarbon source forms dissolution pores in feldspar grains in the middle diagenetic stage, and the dissolution components are mainly potassium feldspar, and the dissolution residual components are mainly albite. The occurrence of cemented kaolinite is mainly the outer ring edge of particles or filling intergranular pores with low purity. The influence of humic acid in coal measures on the quality of adjacent conglomerate reservoir is mainly inhibition. The vertical radiation thickness of stable thick coal seam is 10-30m, the porosity of conglomerate in radiation zone decreases by 2.3%-5.2%, and the permeability decreases by 1.3-2.1mD. The vertical radiation thickness of limited thin coal seam is 3m-8m, the porosity of conglomerate in radiation zone decreases by 1.2%-3.5%, and the permeability decreases by 0.8-1.9md. The high content of rigid particles is the prerequisite for the effective preservation of the original intergranular pores, especially the humic acid solution pores in the penicsyngenetic and early diagenetic coal measures. The removal degree of dissolution products such as kaolinite and silica further restricts the effectiveness of the pores.

Major geologic events affect organic matter enrichment in the upper Guadalupian in South China

Hengye Wei[1*]

1. School of Geiscience and Technology, Southwest Petroleum University, Chengdu, Sichuan, CHINA

E-mail: weihengye@163.com

Keywords: Organic matter enrichment, Emeishan LIP, Kuhfeng Formation, Organic-carbon isotope, Hg concentration

Extraordinarily high organic matter enrichment occurs in the black shale/chert in the Kuhfeng Formation of South China. This OM-rich interval is one of the most interesting shale gas exploration targets in China. The formation process of this black rocks in the Guadalupian is the key for unconventional petroleum exploration in this field. My work presents a significant organic-carbon isotopic composition and Hg anomalies evidences for uplift of Emeishan large igneous province and its contribution to the extraordinarily high organic matter accumulation in the Kuhufeng Formation. OM burial responsed to the Emeishan LIP uplift via abrupt increasing of TOC content, suggesting that rapid crustal uplift and volcanism triggered the onset of extraordinarily high OM enrichment.

Characteristics and origin of calcite cementation in Ahe Formation sandstone reservoirs in Dibei area of Kuqa Depression

Zhanghua Han[1*], Kelai Xi[1], Xianzhang Yang[2], Zhenping Xu[2], Lu Zhou[2]
1. School of Earth Science and Technology, China University of Petroleum, Qingdao, Shandong Province, CHINA
2. Institute of Petroleum Exploration and Development, Tarim Oil Field, Korla, Xinjiang, CHINA
E-mail: 634437808@qq.com

Keywords: Calcite, Deep fluids, Coal measures strata, Jurassic, Kuqa depression

Calcite cements are widely developed in clastic rock reservoirs and are one of the key factors causing reservoir diagenetic heterogeneity. Taking tight sandstone reservoirs in Dibei area of Kuqa Depression as the research object, core observation, thin section identification, QEMSEM analysis, X-diffraction analysis, field emission scanning electron microscopy analysis, cathodoluminescence analysis (CL), electron probe analysis (EPMA), laser in-situ micro-element analysis, carbon and oxygen isotope testing and other technical methods, on the basis of systematic research on petrological characteristics of tight sandstone reservoirs, finely characterized the petrographic, geochemical and chemical properties of calcite cement in sandstone reservoirs. The spatial distribution and other characteristics indicate that the distribution of calcite cement is controlled by the coal-measure source rocks and the northern Yiqikelike Fault zone. The lithology of the sandstone in the study area is mainly coarse sandstone, and the rock composition is mainly lithic sandstone. In the reservoir close to the first-level fault, the deep fluid activity controls the calcite cementation; while the calcite development in the reservoir far from the first-level deep fault is mainly affected by the second- and third-level oil source faults communicate with the control of the coal measure strata. The calcite content near the deep and large faults is high, and the cementation methods are various, mainly porosity cementation, with the characteristics of high iron-magnesium, high iron/manganese, and light rare earth elements enrichment. And the calcite cement content increases with decreasing distance from the Yiqikelike Fault.the diagenetic fluid may be controlled by deep and large faults, and it is mainly bright-yellow luminescent under cathodoluminescence. The calcite content of reservoirs far from deep and large faults is low, and the formation of carbonate cements is controlled by the fluid during the evolution of coal-measure organic matter. The greater the influence of Yangxia formation coal seam, the lower the negative bias of carbon isotope of carbonate cement.

Keywords: Deposition, Diagenesis, Black shales, Fine-grained sediments, Organic matter enrichment, Sweet spot

After two decades of revolutionary development, the commercial exploitation of unconventional hydrocarbon resources (e.g., shale oil/gas and tight oil/gas) has profoundly changed the global energy structure. The sweet spot, the most prolific intervals (areas) in unconventional hydrocarbon resources, generally consists of the most organic-rich deposits, or sandstones/carbonate rocks closely associated with them. Although the roles of diagenesis and hydrocarbon accumulation are indispensable, the formation of sweet-spot intervals (areas) is fundamentally controlled by their depositional settings, resulting from coupled global or regional geological events such as tectonic activity, sea-level change, climate change, bottom-water anoxia, volcanic eruption, and biotic mass extinction during certain geological time intervals. Mudstones with extraordinarily high organic matter content and their associated high-quality reservoir rocks resulting from the coupling of geological events not only provide a prerequisite for the massive generation of hydrocarbon but also abundant hydrocarbon storage space. Considering four typical unconventional hydrocarbon systems as case studies, i.e., the Ordovician–Silurian Wufeng–Longmaxi Formation of the Sichuan Basin, the Devonian Marcellus Shale of the Appalachian Basin, the Devonian–Carboniferous Bakken Formation of the Williston Basin, and the Triassic Yanchang Formation of the Ordos Basin, their formations were controlled by coupled geological events, resulting in the favorable environment for the production, preservation, and accumulation of organic matter, as well as hydrocarbon generation, migration, accumulation, and extraction. Unconventional petroleum sedimentology, which focuses on the coupling effect of geological events, is key to understanding the formation and distribution of sweet-spot intervals (areas) in unconventional petroleum systems.

Analysis of main controlling factors of deep marine shale reservoir of Wufeng-Longmaxi in southern Sichuan, China

chen song[1], Jianghui Meng[1], Renfang Pan[1*]
1. School of Earth Sciences, Yangtze University, Wuhan, Hubei Province, CHINA
E-mail: pan@yangtzeu.edu.cn

Keywords: Sichuan Basin, Wufeng-Longmaxi formation, deep marine shale, organic matter abundance, gas bearing property, reservoir

Abstract: The geological conditions for the formation of high-quality reservoirs of marine shale in China mainly include organic matter abundance, high thermal maturity, high brittleness and so on. The main controlling factors of deep marine shale reservoir of Wufeng-Longmaxi in Changning-Luzhou- Weiyuan-Dazu block in southern Sichuan were studied by comprehensively using core test data such as logging, geochemistry and XRD diffraction. It was shows that biological siliceous rock, siliceous shale and clay siliceous mixed shale facies were conducive to the development of organic pores, while carbonaceous silty shale facies was not conducive to the development of organic pores. The abundance of organic matter was controlled by redox environment at low deposition rate and paleo-productivity at high deposition rate. The limit was 10 m/MA: at low deposition rate, the higher the reduction degree, the faster the deposition rate, the higher the abundance of organic matter; At high deposition rate, the higher the paleo-productivity, the slower the deposition rate and the higher the abundance of organic matter. The redox environment and paleo-productivity further affected the total gas content through the control of TOC, and the relevant parameters were significantly positively correlated with the gas content. The face rate of shale organic matter increases with the increase of thermal evolution, and will not increase when Ro reached about 3.5%. Therefore, the relatively high thermal evolution was of certain constructive significance. The micropore volume and mesopore volume of shale are positively correlated with the gas content, and mesopore volume had a better linear relationship with the gas content, while the macropore volume had no obvious correlation with the gas content. In a word, lithofacies controls the content of brittle minerals and the development of micro pores in shale; Redox environment, paleo-productivity and sedimentation rate control the abundance of organic matter; Micro pore structure and pore water control the gas bearing property of shale; Thermal evolution controls organic matter pore development and reservoir effectiveness

Pore structure characteristics and evaluation of carbonate reservoir: a case study of the Lower Carboniferous in the Marsel exploration area, Chu-Saresu Basin

Kanyuan Shi[1,2], Xiongqi Pang[1,2*], Junqing Chen[1,3]

1. State Key Laboratory of Petroleum Resources and Prospecting, China University of Petroleum, Beijing, Beijing, CHINA
2. College of Geosciences, China University of Petroleum, Beijing, Beijing, CHINA
3. College of Science, China University of Petroleum, Beijing, Beijing, CHINA

E-mail: pangxqcup@163.com

Keywords: Chu-Saresu Basin, Carbonate reservoir, Pore structure, Fractal dimension

The pore structure of the carbonate reservoir determines the fluidity and storage characteristics of oil and gas, and it is vital for reservoir evaluation as well as oil and gas production. The Visean and Serpukhovian carbonate reservoirs in the Marsel exploration area of Chu-Saresu Basin possess a complex lithology and pore structure, which seriously affect the production efficiency. In this study, the pore structure of the reservoir was studied via X-ray diffraction, conventional petrophysical measurements, cast thin section analysis, scanning electron microscopy, and high pressure mercury injection. The results show that the lithology in this area mainly comprises fine-grained limestone, bioclastic limestone and silty limestone and that the mineral assemblage is quite different. The correlation between porosity and permeability is poor, and most cores are tight. The types of carbonate reservoir space are complex and diverse. The primary pores are mainly biological cavity pores. The secondary dissolution pores dominated by intergranular dissolution pores, intragranular dissolution pores and microfractures are the dominant storage spaces of the Carboniferous carbonate reservoir in this area. Structural fractures are relatively developed in this area, which can increase the percolation capacity of the reservoir. However, some structural fractures are filled with calcite, which destroys their effectiveness and reduces the percolation capacity of the reservoir. Based on the shape of capillary pressure curves and the relevant parameters obtained, the samples are divided into three types, of which the physical properties decrease from type-I, type-III through type-II. Based on the correlation between fractal dimension and pore structure parameters, it can be concluded that the pore structure becomes increasingly complex with increasing fractal dimension. Therefore, fractal dimension can characterize the complexity of reservoir micropore structures in the study area. Based on the results obtained via imaging logging, the fractures of well A2 include conductivity fractures, fissures, and resistive fractures. Finally, it is concluded that the formation of high-porosity and permeability zones is caused by quasi syngenetic dolomitization and syngenetic-quasi syngenetic dissolution.

E-mail: liangwanle@cug.edu.cn

Keywords: Source rocks, Depositional environment, Organic matter, Northern tectonic belt, Kuqa Depression

Five units of the Triassic-Jurassic are excellent hydrocarbon source rocks in the northern tectonic belt in the Kuqa Depression, Tarim Basin, NW China. These source rocks of the Triassic Huangshanjie and Taliqike and Jurassic Yangxia, Kezilenuer and Qiakemake formations (Fms) were studied to reveal vertical heterogeneities, environmental evolution, and depositional models using geochemical methods. Our study samples are thermally mature, and contain abundant organic matter (OM) within type II-III kerogens. Maceral are dominated vitrinite, and paleoclimates were relatively warm and humid. Multiple indicators imply suboxic brackish to freshwater conditions during the Huangshanjie Fm stage, freshwater swamps during the Taliqike Fm stage and suboxic to oxic deltaic plains and bays during the Yangxia Fm stage. After the drier climate, freshwater delta fronts with an unstable thermocline formed during the Kezilenuer Fm period, and brackish semi-deep lakes with dysoxic environments formed during the Qiakemake Fm period. The environmental changes are compatible with the variations in OM sources; that is, high water inflow and aquatic organisms supported moderate to high primary productivity during the Huangshanjie Fm stage, whereas mixed terrigenous and aquatic OM sources were dominant during the Taliqike Fm stage. Important contributions from terrigenous higher plants and algae occurred during the Yangxia Fm stage; higher contributions from terrigenous OM occurred during the Kezilenuer Fm period, and significant contributions from phytoplankton occurred during the Qiakemake Fm period. Subsidence-sedimentation led to changes in lake conditions, which caused changes in organisms and bioproductivity. The depositional environments affect the production, degradation and preservation of OM, while organisms consume, provide and disturb OM. The characteristics and interactions of environments and OM contributed to the development of source rocks. These synergistic models are beneficial to predict similar efficient source rocks in other lacustrine superimposed basins.

Organic matter of the Ordovician-Silurian transitional shales using scanning electron microscopy

zhaodong xi[1*]
1. School of Energy Resources, china univeristy of geoscience (Beijing), Beijing, CHINA
E-mail: xizhaod@cugb.edu.cn

Keywords: Shale gas, Organic matter, SEM, Pyrobitumen, Organic pore

Fine-grained organic matter (OM) particles are commonly widely dispersed in shale deposits. However, carrying out investigations of pores hosted by OM particles and the nature of grain interactions of OM particles and associated detrital grains using optical microscopy is difficult at best. Scanning electron microscopy (SEM) is much better suited for characterizing the microstructure of dispersed OM particles and has found wide application in the study of unconventional oil and gas systems. Scanning electron microscopy was used to define the types of OM contained in marine shale deposits of the Wufeng and Longmaxi formations spanning the Ordovician-Silurian transition in South China. Of particular interest is the development of OM-hosted pores and identification of the factors that controlled their formation. The dominant OM type contained in the studied deposits is pyrobitumen with subordinate graptolitic OM and sparse OM of unknown origin. Pyrobitumen is present in four forms, including pore fillings among authigenic quartz grains, within framboidal pyrite, and between authigenic clay grains and massive material. Diagenetic alteration has given rise to OM pores of differing morphology, size, and time of formation. Common small, equisized circular or oval OM pores are most developed and appear to have formed in association with the generation of hydrocarbons. Shale deposits containing abundant pyrobitumen filling interparticle pores among authigenic quartz crystals display robust reservoir and fracturing capacity. Sedimentary environment appears to have been the main factor affecting the type of OM and the nature of its association with detrital and authigenic minerals. Results of this study demonstrate that a sedimentary environment is a primary requisite for the formation of highly prospective/high yielding hydrocarbon shale reservoir deposits.

Reconstructing Late Ordovician – early Silurian tectonic and sedimentary evolution of the western Sichuan basin

Feng Liang [1*], Qing Zhang[1], Shangwen Zhou[1], Yuman Wang[1], Bin Lu[1], Wen Liu[1]

1. Unconventional oil and gas research department , Research Institute of Petroleum Expolration & Development CNPC, Beijing, Beijing , CHINA

E-mail: liangfeng05@petrochina.com.cn

Keywords: Late Ordovician – early Silurian, tectonic and sedimentary evolution, western Sichuan basin,temporal and spatial distribution,ancient uplift,Kwangsian orogeny

The Late Ordovician – early Silurian is one of the key time boundaries of major global geological events (Melchin et al., 2013). The marine black shale formed in this period has attracted much attention because it is the main horizon of global shale gas exploration (Zou et al., 2019), and its shale deposition mechanism has attracted much attention (e.g., Armstrong et al., 2009). However, previous studies have believed that the deposition of marine black shale at this stage mainly is controlled by the fluctuation of global sea level (Challands et al., 2008; Meinhold et al., 2013; Li et al., 2017). The Upper Ordovician – lower Silurian Wufeng – Longmaxi shale has been considered as the most potential for unconventional oil and gas development marine object. At the same time, the Sichuan Basin, being located in the western South China Plate and covered extensively by Wufeng – Longmaxi marine shale, had experienced tectonic effects of Kwangsian orogeny (Chen et al., 2014; Xu et al., 2016), which had caused the Wufeng – Longmaxi shale deposited into the area being restricted by the peripheral uplift or oldland (Chen et al., 2018). It is a pity, the study about shale depositional mechanism being affected by Kwangsian orogeny is relatively scarce. The most controversial is spatial-temporal uplift process of the western Sichuan basin which had cut off the connection with the Paleo-Tethys ocean and the Sichuan basin, because present field outcrop data could not provide convincing geological evidences. So the drilling wells being located into the Weiyuan – Zigong area have been chosen in order to explore the spatial – temporal evolution process of the western Sichuan basin during the Late Ordovician – early Silurian. Based on sedimentology, petrography, temporal and spatial distribution of sedimentary thickness and geochemical data, paleogeographic characteristics of Weiyuan – Neijiang area could be divided three depositional stages: (1) during the Wufeng stage, the study area was directly connecting with the Paleo-Tethys ocean without barrier from marignal ancient uplift, because the reef limestones and radiolarian cherts extensively were deposited into the western margins of the Sichuan Basin; (2) during Guangyinqiao stage, expansion of the Neijiang uplift was controlled by the global sea-level dramatic drop because of the Hirnantian Glaciation, but there was still without barrier from western marignal ancient uplift; (3) during the Longamxi stage (Normalograptus persculptus – Coronograptus cyphus), there was obvious transition from open marine to strongly restricted basin in the study area, being supported by anoxic geochemical index of the Longmaxi shale, which implies the western margin of the Weiyuan – Neijiang area should be uplifted which was caused by compression from eastern Kwangsian orogeny. The paleo-marine environment bounded by three uplift or arch is conducive to the enrichment of organic matter of the marine Longmaxi shale.

Keywords: Unconventional petroleum, Heterogeneity, Micro-/nano-scaled pore system, Organic-rich shales, Fine-grained deposition

Lacustrine shale oil has become one of the major replacement areas of oil and gas exploration in China. The laminar structure, a unique fabric feature of shale, has attracted increasing attentions because it can significantly influence the evaluation of source rock quality, reservoir quality and engineering quality. In this paper, the organic-rich shales in fresh-brackish lake basins, saline lake basins and transgressive lake basins are taken as targets to analyze the laminar structure characteristics and discuss the influence of laminar structure on the selection of sweet spots. The results show that: (1) The laminar structure varies in different lake basin types, and is affected by the salinity. The carbonate laminar mainly develops in the saline lake basins, but less in the fresh-brackish lake basins. (2) Very fine segmentation at sub-millimeter level and heterogeneity of laminar structure is obtained; and the difference of TOC and pore structure between different laminae are identified. It is suggested that the quality of a certain laminae type changes in different basins. (3) Laminar structure determines the microscopic migration and accumulation characteristics of shale oil and the enrichment mode of "primary source and reservoir", affecting the retained hydrocarbon content, fluid mobility and fracturing. Fine evaluation of continental shale laminar structure and searching for the distribution area of high-quality shale lithofacies are the critical issues for oil and gas exploration from the outer-source to inner-source, which are the basis for the discovery of economic and effective resources within the source and have important significance for the optimization of shale oil "sweet spot" and "sweet spot section".

Sedimentary environment characteristic of transitional shales in the lower member of Longtan Formation, Western Guizhou: Insights into the influence of Emeishan large igneous province and organic matter accumulation

Luheng Bai[1], Wanzhong Shi[1*]
1. School of Earth Resources, China University of Geosciences, Wuhan, Hubei Province, CHINA
E-mail: 760231842@qq.com

Keywords: Longtan Formation, transitional shale, sedimentary environment, Emeishan large igneous province, lagoonal shale

The marine-continental transitional shale in the upper Permian Longtan Formation is not only an important target of shale gas exploration and development, but also an important research object of extreme paleoenvironmental events in Middle-Late Permian. Based on X-ray diffraction (XRD), polished sections, scanning electron microscopy (SEM), total organic carbon content (TOC) and elemental geochemistry, the paleoenvironment characteristics of the transitional shale in the lower member of Longtan Formation in Western Guizhou were studied, including primary productivity, paleo-redox conditions, paleoclimate, provenance. The influence of Emeishan large igneous province on sedimentary environment and the organic matter enrichment mechanism of transitional shale are analyzed. The results show that in the Middle-Late Permian transition, with the Dongwu movement and the eruption of Emeishan basalt, the paleogeographic pattern of high in the west and low in the east was formed in the Upper Yangtze region. The Western Guizhou was in a marine and continental transitional environment, and the lower member of Longtan Formation was deposited in a marginal tidal flat-lagoon environment. Influenced by seawater and rivers, sand and mud were interbedded frequently, and the organic matter content in shale were generally more than 5%. Longtan shales were deposited in a complex environment with warm and humid paleoclimate, anoxic-reducing, brackish to saline bottom water, high terrigenous detrital input and high deposition rate. The weathering products of Emeishan basalt were the main source of longtan Formation. The mineral and element composition characteristics of shale are closely related to Emeishan basalt. In addition, transitional shale was accompanied by a small amount of volcanic ash and hydrothermal input, and the elements carried by the hydrothermal increased the salinity of water, and was conducive to the anoxic-reducing environment. In general, the organic matter enrichment in transitional shale of the lower member of Longtan Formation is closely related to sedimentary facies. The shale deposited in mire has the highest organic matter content (>20%), followed by the shale deposited in tidal flat (10%). The organic matter content in lagoonal shale is the lowest (5%). Lagoonal shales are dominant in the lower member of Longtan Formation, and their organic matter enrichment mechanism is mainly “preservation model”. The lagoonal shales were deposited in a warm and humid, brackish-saline water, anoxic-reducing environment, with good preservation conditions for organic matter. The primary productivity was low and organic matter mainly came from higher plants. However, hot and humid climate strengthened terrestrial weathering and increased terrigenous detritus, diluting the organic matter content in shale. Higher deposition rate reduced the decomposition time of organic matter and was beneficial to the preservation of organic matter.

Laboratory evidences for the possible genesis of poor development of organic-pores in the Lower Cambrian organic-rich shale, South China

Dongjun Song[1,2*], Jincai Tuo[2], Shuang Dai[1]

1. School of Earth Sciences, Lanzhou University & Key Laboratory of Strategic Mineral Resources of The Upper Yellow River, Ministry of Natural Resources, Lanzhou, Gansu Province, CHINA

E-mail: songdj@lzu.edu.cn

Keywords: Paleozoic shales, shale gas, simulation experiment, system sealing capacity, OM carbonization.

Many comparative investigations on the different development of organic-pores (OPs) and gas-bearing characteristics in the Silurian and Cambrian organic-rich shales of southern China are presented, while the genesis of the poor OP development and lower gas content in the Cambrian shale is still controversial. Here, artificial experiments were performed to reveal the impacts of system sealing capacity and organic carbonization on OP development in shales at overmatured stage. Closed and semi-closed pyrolysis was conducted on a low-mature lacustrine shale sample using the same instrument characterized by lithostatic pressure and limited reactive space. The results suggested that the different gas contents of the Cambrian and Silurian shales in southern China may be associated with the differences in the system sealing capacities of shales, although the sedimentary environment of the studied sample is lacustrine, and the lower methane content of the Cambrian shale gas is probably ascribed to semi-closed system. However, variations in organic porosity based on mass balance calculations demonstrated that the organic porosity evolution is collectively affected by system sealing capacity and thermal maturity at lower matured stages, whereas that is independent of system sealing capacity at high- and overmatured stages. This provides direct evidence that the difference in system sealing capacity is not the predominant factor leading to different OP developments in the Silurian and Cambrian shales. A semi-closed pyrolysis of a high-mature marine shale may unravel the possible origins of the poor OP development in the Cambrian shale. The results showed that intense carbonization of organic matter (OM) occurs after 3.49% R_{mc} (Raman maturity). During OM carbonization, preexisting OPs become interconnected and coalesce to form organic cracks, leading to an increase in the average pore diameter of OP. When combining the burial characteristics of the Cambrian overmatured shale in South China, the coupling between OM carbonization and mechanical compaction is invoked to explain the common perception that poor OP development in the marine shale. This study provides a direct laboratory evidence for the different gas contents and OP developments in the two marine gas shales.

Characteristics and Formation Mechanism of Chang 7 Tight Sandstone Oil in Ordos Basin, China

Wenxue Han[1*], Shizhen Tao[2], Lianhua Hou[2], Zhi Yang[2]
1. School of Geosciences, China University of Petroleum, Qingdao, Shandong, CHINA
2. Research Institute of Petroleum Exploration & Development, Petrochina, Beijing, CHINA
E-mail: wxh2018@sdust.edu.cn

Keywords: Chang 7 Member, Tight sandstone reservoirs, Formation mechanism, Unconventional tight sandstone, NMR

Tight sandstone reservoirs develop extensively in Chang 7 Member in Longdong area, Ordos Basin, China, and tight oil is abundant. Unconventional tight sandstone reservoirs need a special experimental techniques and analysis methods, which is different from the conventional reservoirs of high porosity and permeability. This study adopted tight rock analysis (TRA), nuclear magnetic resonance (NMR), core and thin section observation, and formation micro-Scanner image (FMI) materials, in order to characterize the reservoirs precisely. The formation mechanical of tight sandstone reservoirs were then analyzed on this basis.

The results of the experiments show that: (1). Destructive diagenesis is very strong and effective porosity, bound hydrocarbon (% of BV) decrease with depth. The physical property is poor due to high hydromica content, whose average value is 10.4%. (2). According to the centrifugal experiment, this study sets 0.1μm as the lower limit of pore throat of tight sandstone reservoirs, which is consistent with high pressure mercury data. (3). The movable fluid saturation is high, whose average value is 55%, and the correlation between movable fluid saturation and porosity and permeability is poor, whose correlation coefficient is 0.24 and 0.70, respectively. (4). Chang 7 tight sandstone reservoir is prone to be fractured and favorable for later recovery due to high content of quartz, whose average value is 40.4%, the micro-cracks develop widely and they greatly improve the oil and gas migration and accumulation capacity.

The formation mechanism of tight sandstone reservoirs are:mechanical compaction, pressure solution, cementation, metasomatism, the control of sedimentary micro-facies and interstitial material.

Differential reservoir evolution controlled by sandstone particle size and composition: Eocene Pinghu Formation, West subsag of Xihu sag, the China East Sea Shelf Basin

Li Zhiyuan[1], Zhilong Huang[1*]

1. College of Geosciences, State Key Laboratory of Petroleum Resources and Prospecting, China University of Petroleum, Beijing, Beijing, CHINA

E-mail: huangzhilong1962@163.com

Keywords: Low permeability tight reservoir, Sedimentary and diagenetic factors, Differential diagenesis, Differential pore evolution

The reservoirs of the Pinghu Formation in the West Sub-sag of the Xihu Sag are deeply buried, mainly low-permeability-tight reservoirs, and there are certain differences in the physical properties of the reservoirs. Sandstone particle size and composition are key factors controlling reservoir quality. Particle size and composition are the basis for the evolution of the reservoir, resulting in the differential diagenetic evolution of the reservoir during the process of burial diagenesis, resulting in the formation of reservoirs with different physical properties: Reservoirs with coarser grained, more soluble components contain more dissolved porosity, and strong resistance to compaction, which in turn leads to better physical properties of the reservoir. Reservoirs with finer grained, less soluble components, and more argillaceous reservoirs contain low dissolved porosity, more carbonate rock cements, and weak resistance to compaction, which in turn leads to poorer physical properties of the reservoir. Therefore, feldspar-rich medium-sandstones with high feldspar content, such as medium-grained and medium-fine-grained detrital feldspar sandstones, have strong dissolution and relatively good reservoir physical properties, and the reservoirs are not yet tight. Strong compaction and weak dissolution are important reasons for the poor physical properties of feldspar-poor sandstones such as medium-grained, medium-fine-grained feldspar lithic sandstones, and tight reservoirs. Fine-very fine sandstone and very fine sandstone have high mud content, strong carbonate cementation, and generally tight reservoirs.

Research progress of oil shale in situ conversion experiment

Hao Yu[1], Pingchang Sun[1*]

College of Earth Science, Jilin university, Changchun, Jilin Province, CHINA

E-mail: sunpingchang711@126.com

Keywords: oil shale,catalyzer,In situ transformation technology,Underground water separation technology

With the continuous progress of global science and technology and the continuous development of economy, the demand for energy in the world's industry and people's life is also gradually increasing, and the importance of solving the energy problem is increasingly prominent. As one of the potential energy sources in the future, the exploitation and utilization of oil shale is the focus of current research. However, the development of oil shale is mainly ground distillation, which requires a lot of water resources and produces a lot of waste residue, which brings pressure to environmental protection work. Therefore, the in-situ conversion technology of oil shale gradually attracts people's attention, and the in-situ conversion technology is also the future trend of oil shale industry development under environmental protection conditions. However, there are many technologies, catalysts and auxiliary technologies for in-situ oil shale development, and the advantages and disadvantages of different technologies are not clear. Therefore, this paper conducts research on domestic and foreign research materials and data, and summarizes and analyzes the current mainstream oil shale in-situ conversion technology, catalyst and water-isolation auxiliary technology. Widely recognized shale in situ conversion technology at present stage has electric heating and convection heating, radiation heating and combustion underground four, has its advantages and disadvantages of various technologies: electric heating method research earlier but slow heat transfer, heat convection heating but high efficiency heat transfer process vulnerable, radiation heat penetrability strong but limited range of heating, underground combustion heating speed but not easy to control. In order to assist the higher rate conversion of oil shale, the catalysts and their principles, including $CoCl_2 \cdot 6H_2O$, $NiCl_2 \cdot 6H_2O$, calcium-modified HZSM-5 zeolite, SO_3H-APG, pyrite and corn straw, were also summarized in this paper, which can be classified into four categories: metal salts, clay, native minerals and biomass. In addition, in response to the oil shale in situ transformation of groundwater pollution, on the frozen wall, gas drive water and grouting closed three water assistive technology is summarized, and based on the general background of the our country to protect the environment and reduce the cost of industrial demand, reveal the type suitable for domestic oil shale in situ conversion technology for convection heating in situ conversion technology. Further analysis of the development trend of in-situ conversion of oil shale:1Using solar energy and other new energy, reasonable distribution of drilling spacing, reduce costs;2The research and application of underground sealing technology should be strengthened to reduce groundwater pollution caused by in-situ conversion. It provides reference and help for the future research and development of in-situ conversion of oil shale in China.

Pore structure characteristics and its relationship with diagenesis in sandstone reservoirs of Huagang Formation in Xihu Sag, East China Sea Basin

Tong Qu[1], Zhilong Huang[1,2*]
1. State Key Laboratory of Petroleum Resources and Prospecting, China University of Petroleum (Beijing), Beijng, CHINA
2. College of Geosciences, China University of Petroleum (Beijing), Beijing, CHINA
E-mail: huangzhilong1962@163.com

Keywords: Pore structure characteristics, Diagenetic influence, Sandstone reservoir, Xihu Depression

The pore structure of sandstone reservoirs and its diagenetic influence of Pinghu Formation (E2p) and Huagang Formation (E3h) in Xihu Depression is comprehensively evaluated. The pores of sandstone samples mainly include primary intergranular pores, intergranular and intragranular dissolved pores, and micropores related to clay aggregates. Thin section and scanning electron microscope (SEM) observation results show that more intergranular solution pores, moldic pores and inter-crystalline pores of kaolinite are developed in E2p. Compared with E2p, E3h has smaller pores, narrower and more curved throats. A new parameter, pore structure index (PSI), is established for comprehensively evaluating the pore structure. The effects of three main kinds of diagenesis on pore structure are analyzed. Mechanical compaction is the main reason for the reduction of pores, which has serious damages to the pore structure by making the mineral particles arranged more closely and creating smaller pores and narrower throats. Different types of cement have different effects on reservoirs. The inter-crystalline pores of kaolinite can compensate for some pores reduced by compaction and cementation, which can improve the pore structure. The development of illite has a significant damage on reservoir quality by occupying the pore spaces and blocking the throats. The inhibition of chlorite on the quartz overgrowth and its blocking effects on throats are negligible, therefore having little effect on the reservoir quality. Carbonate cement and quartz overgrowth both occupy part of pores and throats, which can reduce pore connectivity thus damages the pore structure. Quartz overgrowth has a weaker impact compared to carbonate cementation. Dissolution is the key function to improve the reservoir. The proportion of dissolution pores in sandstone samples in the study area can reach 67.91% ~ 94.96%, which can increase the porosity and enhance pore connectivity. This work is of great application value in sandstone reservoir quality evaluation.

Characters and Genesis of Under-Compacted Sandstone- a case in Lenghu VII Tectonic Belt, Northern Qaidam Basin

Guo Jia Jia[1*]

1. Experimental Research Center of Basin, Research Institute of Petroleum Exploration & Development Northwestern Branch, Lanzhou, Gansu, CHINA
E-mail: 1173644412@qq.com

Keywords: deep buried reservoir, under-compacted sandstone, sedimentary environment, dissolution of calcite, Qaidam Basin

Based on recovering core observation and thin section identification, combined with scanning electron microscope images and statistics of physical property, XRD, trace elements and carbon and oxygen isotopes, the genesis of under-compacted sandstone of the Xiaganchaigou Formation(Fm) of the Paleogene in Lenghu VII structure in the northern Qaidam Basin has been confirmed through a detailed comparison with normal one on the aspects of sedimentary environment, petrological and diagenesis characters. The result show that the under-compacted sandstone developed in underwater distributary channel with less argillaceous matrix, and the particle size is medium to fine. The average porosity can reach 9.70%, and permeability reach to 1.89 mD, which is dominated by intergranular pore. The under-compacted sandstone formed because of the intrusion of organic acid fluid which lead to the dissolution of calcite cements and restoring of primary pores. The conclusion can be drawn from these aspects: Firstly, the total clay minerals content of under-compacted sandstone (6.6%~11.9%) is similar with normal one (7.9%~12.1%), however honeycomb-like chlorite grain-coatings is much abundant (33%~58% in total clays) in under-compacted sandstone, indicating transformation from I/S under intrusion of Mg-rich fluid; Secondly, the carbonate cements of under-compacted sandstone (5.7%~17.3%) and normal one (4.1%~20.3%) are both dominated by micrite calcite, and early calcite residues result from dissolution only could be found in under-compacted sandstone. The δ18O value (17.36‰ ~ -10.54‰) and the δ13C values (-5.12 to -3.51‰) indicate inorganic carbon, however, the little negative bias of δ13C of under-compacted sandstone indicate more organic carbon mixed compared to normal one; Thirdly, the minor changes of V/Zr, Ni/Zr, Co/Zr, Sr/Zr and Mo/Zr values suggest a similar and stable paleoenviroment in both sandstones. The weaker correlations among U/Zr, Ni/Zr and V/Zr indicate that U/Zr is affected not only by environment, but also by fluid intrusion. However, U/Zr is much large (3.6~23.9) in under-compacted sandstone comparing to normal ones (0.83~3.69), which indicates an acid fluid invasion originating from source rock.

Petrographic characteristics and gas-bearing evaluation of the shales of Dayuaba Formation, southern Guizhou

Bowei Yang[1], Wanzhong Shi[1*]
1. School of Earth Resources, China University Of Geosciencewuhan, Wuhan, Hubei, CHINA
E-mail: 593695532@qq.com

Keywords: southern Guizhou, Dawuba Formation, petrographic characteristics, quantitative calculation of gas content, key controlling factors

The Dawuba Formation of Lower Carboniferous in southern Guizhou is an important marine shale series. As a key research area in the Dian-Qian-Gui Basin in southern China, there are still few studies on shale Petrographic characteristics and gas-bearing evaluation in this area. Taking Qianshuidi 1 well as the research object, based on the core description, thin section identification, X-ray diffraction analysis, scanning electron microscopy and methane isothermal adsorption, the shale lithofacies and gas-bearing properties of Dawuba Formation was systematically analyzed in this study. The shale of the Dawuba Formation in southern Guizhou is dominated by clay minerals and carbonate minerals, and the content of siliceous minerals is relatively small. According to the three-end lithofacies division scheme of siliceous minerals, carbonate minerals and clay minerals, the shale facies types of the Dabuba Formation are mainly included calcareous shale (C, C-2), argillaceous-rich calcareous shale (C-3), siliceous argillaceous shale (CM-1) and mixed shale (M-2, M-3), among which the argillaceous-rich calcareous shale is the most favorable lithofacies. The average shale gas content of the Dabuba Formation in the study area is 0.51 m^3/t, ranging from 0.21 to 1.13 m^3/t, which is generally low. The theoretical gas content calculated based on Langmuir model and Lewis model is significantly higher than the measured gas content. According to the geological conditions of southern Guizhou area, the parameters such as temperature, water content, porosity and TOC were optimized and modified to obtain a new characterization formula suitable for the study area, and their correlation index R reached 0.92. By analyzing the main controlling factors of shale gas content in the Dawuba Formation, it is found that the low measured gas content is mainly controlled by poor gas generation conditions (average organic carbon content is 0.82%) and poor preservation conditions (preservation index P < 0.3). The above research results can support the prediction of shale gas enrichment areas and provide suggestions for the subsequent shale gas exploration and development in the southern Guizhou Area.

E-mail: 2021079841@qq.com

Keywords: Effective reservoirs, Formation mechanism, Differential diagenesis, Tight sandstone, Linnan Sag

Tight oil in Linnan Sag has great development potential. At present, it is unclear about the formation mechanism and distribution law of effective reservoirs, which is the direct reason for the difficulty of oil and gas exploration in the middle and deep layers. In this paper, the formation mechanism of effective tight sandstone reservoirs in the lower Es3 member of Jiangjiadian area in Linnan Sag was studied by comprehensive utilization of core, grain size analysis, casting thin section, X-ray diffraction, mercury injection, scanning electron microscopy, inclusions and isotopes. The results show that the study area is the delta front mouth bar and distal bar microfacies. The larger the particle size is, the better the sorting is, and the less the mud matrix is, the larger the porosity is. The reservoirs in the study area have undergone compaction, metasomatism, cementation and dissolution, and are mainly in the middle diagenetic stage A. The diagenetic evolution sequence is as follows: compaction action→early carbonate cementation under original alkaline formation water environment→dissolution of debris and feldspar in acidic environment + phase I quartz secondary enlargement + late carbonate cementation→late carbonate cementation in alkaline environment + dissolution of enlarged edge of quartz→re-dissolution of feldspar and lithic in weak acidic environment+ dissolution of carbonate cements + phase II quartz secondary enlargement→late pyrite cementation. According to quantitative calculation of diagenesis evolution process, the original porosity of sandstone is 34.2%-37.4%, the loss porosity of compaction is 33.0%-37.0%, the increased porosity of dissolution is 1.6%-23.0%, and the loss porosity of cementation is 0-39.3%. The strength of pore-increasing effect caused by corrosion and pore-reducing effect caused by cementation are the key factors for reservoir effectiveness in the study area. Dissolution siltstone and calcareous siltstone are mainly developed in the study area, and the difference comparison shows that the lower limit of effective reservoir porosity in the study area is about 7%, and the occurrence of micron-sized pores is closely related to the effectiveness. Based on the study of lithofacies and diagenesis, taking a group of 'mud-coated sand' combination as an example, the formation mechanism of effective reservoir is analyzed. Under the control of different lithofacies, the dissolved siltstone facies is affected by the release of organic acids from the thermal evolution of organic matter and the leaching of atmospheric freshwater. The feldspar cuttings are dissolved and the authigenic kaolinite and quartz are precipitated near. Calcareous cementation siltstone is affected by alkaline fluid environment, and its dissolution is weak. Late calcite and dolomite cementation mainly occur. Based on the analysis of effective reservoir formation mechanism, the effective reservoir genetic model of 'early atmospheric pressure open system→middle weak overpressure sealing system→late atmospheric pressure open system' is established. This paper can not only deepen the understanding of the formation mechanism of effective tight sandstone reservoirs, but also have guiding significance for the exploration deployment of tight oil in the study area and the scale increase of reserves and efficiency.

Keywords: Shale, Organic matter, Longmaxi Formation,enrichment Law, Controlling Factors

Based on TOC test, XRD test, trace element and major element test data, organic matter enrichment rule and main control factors of Longmaxi formation shale in Changning area of southern Sichuan Basin were studied. The results show that:(1) the $S_1l_1^1$ shale TOC in the study area is between 0.46% and 8.35% (average value: 3.75%); Vertically, TOC shows a trend of decreasing first, then increasing and then decreasing from bottom to top, showing the characteristics of “sandwich cake”. On the plane, the TOC value of $S_1l_1^{1-1}$- $S_1l_1^{1-2}$ are the highest in the southeast and gradually decreases in the north and southwest; The high TOC value of $S_1l_1^{1-3}$-$S_1l_1^{1-4}$ has the enrichment rule of migration to the central X2 well area. (2) The TOC of $S_1l_1^1$ shale in the Changning area is logarithmically related to the sedimentary environment index; it is negatively correlated with terrigenous influx and a complex correlation with paleoproductivity. (3) The enrichment of organic matter of the $S_1l_1^1$ in the study area is mainly the coupled superposition of the paleoenvironment, palaeoproductivity, terrigenous input and other factors. when the paleoproductivity is less than 2200μg/g, the preservation conditions (ie. sedimentary environment) are the most important factors to control the enrichment of organic matter. When the paleoproductivity is greater than 2200μg/g, ultra-high paleoproductivity is the main controlling factor of organic matter enrichment. The moderately-strongly restriction environment and warm, humid paleoclimate conditions of $S_1l_1^1$ in the study area are conducive to the enrichment and preservation of organic matter. However, the two have little effect on the differential enrichment of organic matter in each sublayer of $S_1l_1^1$. (4) From $S_1l_1^{1-1}$ to the lower part of the $S_1l_1^{1-3}$ is anoxic depositional environment, which provides good preservation conditions for organic matter enrichment, and is the main controlling factor of organic matter enrichment, followed by paleoproductivity. Starting from $S_1l_1^{1-2}$, it shows the adverse effects of terrigenous influx on organic matter enrichment. The middle to the upper part of $S_1l_1^{1-3}$ is a dysoxic sedimentary environment. When the paleoproductivity is low, the enrichment of organic matter is mainly controlled by terrigenous input; but when the paleoproductivity is high, the organic matter enrichment is controlled by paleoproductivity and terrigenous input. The top of $S_1l_1^{1-3}$ is an oxygenic depositional environment, TOC is mainly controlled by paleoproductivity and sedimentary environment, followed by terrigenous input. The $S_1l_1^{1-4}$ is mostly oxygenic sedimentary conditions, when paleoproductivity is low (Babio<1100μg/g), the main controlling factor for organic matter enrichment is sedimentary environment. When paleoproductivity is high (1100μg/g$_{11}^2$

New understanding of Yanchang Formation sedimentation and isochronous stratigraphic division scheme in Ordos Basin

Jingwei Cui[1*]

1. Research center of petroleum geology and experiment, Research institute of petroleum exploration and development,CNPC, Beijing, CHINA

E-mail: jingwei.cui@126.com

Keywords: Progradation body, Stratigraphic correlation, U-Pb dating, Yanchang Formation, Ordos basin

Currently, the oil production in Yanchang Formation, Ordos Basin is more than 35 million tons per year. It is well known that chemostratigraphy correlation is significantly critical in oil production. Marker bed and equisection method are traditionally applied in define of oil formation. However, this kind of stratigraphy correlation approach has been increasingly questioned. With the constrain of drilling date, the high precision dating data in tuff from Chang 7 oil formation in various sedimentary systems and high precision seismic stratigraphic interpretation and stratigraphic isotope chronology are carried out respectively by using the high quality 3D seismic data newly collected from blocks to the north of Qingcheng. The diachronism is also supported by high-precision ziron dating from different sedimentary systems in Chang 7 period. It is the first time to identify 11 prograding bodies from the top of Chang 73 oil formation to the bottom of Chang 2 oil formation these blocks. 6 prograding bodies are described in Chang 7 oil formation, suggesting stratum diachronism in current stratigraphic correlation of Yanchang Formation. We proposed that high precision dating is urgently required to be a marker in Chang 7 oil formation from diverse provenance systems. Coupled with elevated frequency seismic data and thin-bed correlation by geophysical logging, a high sequence stratigraphic framework could be redefined and chemostratigraphy correlation could be established in Yanchang formation. This study could be in favor of refining reservoir distribution patterns in Yanchang Formation, and provide a valuable lesson for the study of deep-water sedimentary evolution and chemostratigraphy correlation in other lacustrine basins in the future.

The organic matter accumulation of the Pliensbachian-Toarcian lacustrine shale in the Sichuan Basin, SW China

Jianglin He[1*], Ankun Zhao[1], Dong Wang[1], Qiyu Wang[1]
1. Sedimentary department, Chengdu Center of Geological Survey, China Geological Survey, Chengdu, Sichuan, CHINA
E-mail: 5hjl998@163.com

Keywords: Organic matter accumulation, Lacustrine shale, T-OAE, Shale gas, Sichuan basin

Pliensbachian-Toarcian lacustrine shale in the Sichuan Basin is characterized by two organic matter-rich layers (Dongyuemiao and Da′anzhai members) interlayered with an organic matter-poor layer (Ma'anshan member). Both the organic-rich layers are promising target layers for shale oil and gas in China, meanwhile, they are a terrestrial sedimentary record for the Toarcian Oceanic Anoxic Event (T-OAE). What the factors dominated the enrichment of the organic matter in them? It is not only benefit to the exploration of shale gas and oil, but also to probing the way to carbon complement. Basing on the paleo-environment analysis and the correlation with organic matter accumulation in the Pliensbachian-Toarcian lacustrine shale on the subaqueous paleo-uplift in the Sichuan Basin according to lithofacies and geochemical proxies. We concluded that lake stratification and oxygen deficiency were gradually strengthened in an upward sequence from Pliensbachian Dongyuemiao member to late Toarcian Da′anzhai member. However, primary productivity was reduced. Chemical weathering was strongest during the early Toarcian stage (Ma'anshan member). The organic matter accumulation in these lacustrine shales is closely related to environmental changes caused by tectono-sedimentary evolution and depositional conditions of the Sichuan Basin. The Pliensbachian Dongyuemiao member was dominated by high primary productivity and low terrigenous detrital input. In the case of the deposition of early Toarcian Ma'anshan member, the organic matter was difficult to preserve due to the high sedimentation rate and the lack of anoxic water conditions. However, the late Toarcian Da'anzhai member was primarily composed of chemical precipitation that was closely correlated with the climate changes during T-OAE. The organic matter accumulation in this member was positively correlated with salinity-induced stratification and elevated CO_2 concentration.

Formation mechanism of rhythmic bedding in the Lower Silurian Longmaxi black shales on the Yangtze platform, South China

Bao Zhang[1*]
1. Key Laboratory of Tectonics and Petroleum Resources of Ministry of Education, China University of GeosciencesWuhan, Wuhan, Hubei Province , CHINA
E-mail: zbmz101@163.com

Keywords: Mineralogical characteristics, Diagenesis, Shale deposition

Shales have long been considered as deposited under quiescent conditions. However, recent studies on silty laminated shales have emphasized the modification of sediments by bottom currents. The presence of laminae tends to induce rock damage and increase the brittleness of shales. A model for the formation of rhythmic bedding in black shales is proposed in this study on the basis of detailed sedimentological studies and geochemical characterization of the Lower Silurian Longmaxi Formation shales in southern China through scanning electron microscope with energy dispersive spectroscopy, X–ray diffraction, X–ray fluorescence spectrometry, and inductively coupled plasma mass spectrometry. Rhythmic laminations are mainly composed of argillaceous shale and siliceous shale. Argillaceous shale is mainly composed of terrestrial chlorite and albite enriched with U, Th, and light rare earth elements (LREEs). In comparison, siliceous shale is mainly composed of authigenic quartz and illite enriched with Si, P, Cu, and middle rare earth elements (MREEs). The preferential alignment of graptolites, sedimentary structures, and the higher Si/Al, Ti/Al, Ca/Al and Sr/Al values in siliceous shales indicate that the sediments were reworked by bottom currents through erosion and winnowing. Differences in bottom current activity result in significant differences in redox conditions, clastic input, and paleoproductivity between the two shales during their deposition. Intermittent bottom current activities play an important role in the formation of rhythmic bedding in the Longmaxi Formation shales of the Sichuan Basin. The synergistic effect of the complexation of residual organic matter and the physical charge adsorption of clay minerals results in the enrichment of LREEs in argillaceous shale; authigenic quartz and illite may capture MREEs in pore water during diagenesis, causing MREE enrichment in siliceous shale. Different authigenic minerals further enhanced the differences between the two shales during diagenesis. Bottom current mainly affects the Yichang and Fuling areas in the Sichuan Basin, and has less impact on the Changning area. Thermohaline–induced circulation and wind forces may be the main controlling factors responsible for the formation of bottom currents. Understanding the genesis of rhythmic bedding in shales can help clarify shale anisotropy and induced deformation during hydraulic fracturing.

PETROLOGIC AND GEOCHEMICAL CHARACTERISTICS OF CARBONATE CEMENTS IN THE UPPER TRIASSIC XUJIAHE FORMATION TIGHT GAS SANDSTONE, WESTERN SICHUAN BASIN, CHINA

Liangbiao Lin[1*], Yu Yu[2], Fengbin Liu[1], Fanchi Nan[1]

E-mail: linliangbiao08@cdut.cn

Keywords: Sichuan Basin, carbonate cements, pore fluid, genesis model, reservoir quality

Early calcite, when dissolved by organic acids, can generate porosity in sandstones. Mineralogical, petrographic, and geochemical analyses determined the timing and origin of carbonate cements in the fourth sandstone member of the Upper Triassic Xujiahe Formation (Xu4 sandstone) in the western Sichuan Basin. Two phases of carbonate cement identified are the crystalline calcite and carbonate filling of secondary pores, which consists of calcite, dolomite, ankerite, and ferrocalcite. Early calcite precipitated during the Middle Jurassic period with low Na^+ and K^+ contents, the carbon isotope compositions show that early calcite precipitated from alkaline fluid after deposition. $\delta^{18}O$ values of the fluid indicate an involvement of meteoric and alkaline water. The burial history and fluid inclusions indicate that late calcite formed during the Late Jurassic. The relatively high Na^+ and K^+ contents and carbon isotope compositions suggest that organic acids participated in the formation; the $\delta^{18}O$ values of the fluid are slightly higher than that of early calcite due to the reduction in the influence of meteoric water as burial depth increased. Dolomite cement precipitated from Late Jurassic to Early Cretaceous and has the same carbon source as late calcite. The transformation of smectite to illite likely sourced the calcium and magnesium. Active water-rock interactions in an open diagenetic system are the leading cause of carbonate mineral precipitation.

The Relationship between clay minerals and organic matter enrichment in lacustrine shale: A Case Study on Yanchang Formation of Triassic in Ordos Basin, China

Zhiguo Mao[1*]

1. Research Institute of Petroleum Exploration and Development, PetroChina, Beijing, CHINA

E-mail: owenmao@126.com

Keywords: lacustrine shale, Clay minerals, Abundance of organic matter, Hydrocarbon generation potential, Ordos Basin, Yanchang Formation

With the successful exploration and development of shale oil and gas, shale has become an important research object of oil and gas exploration. Clay minerals and organic matter, as the two main components of shale, have complex relationship with each other. In order to clarify the influence of the structure, type and quantity of clay minerals on the enrichment of organic matter, 536 gray black or black mudstone and shale core samples of well F75 and well D81 of Triassic Yanchang Formation in Ordos Basin were selected for clay mineral analysis, organic carbon determination and rock pyrolysis analysis. The test results show that the clay mineral content of the above samples is mainly concentrated in the range of 30% ~ 60%, with an average of 45.9%; The main types of clay minerals are Yimeng mixed layer, illite, kaolinite and chlorite; TOC is mainly concentrated between 2% ~ 6%, with an average of 3.90%. Hydrocarbon generation potential (S1 + S2) is mainly concentrated between 6.00 ~ 24.00mg/g, with an average of 13.58mg/g. It is a good and high-quality source rock. It is found that when the clay mineral content is less than 65%, the clay mineral content is positively correlated with TOC. With the increase of clay content, TOC also increases. For every 1% increase of clay mineral content, TOC increases by 0.05%, that is, the characteristics of rich organic matter with high clay content reflect the enrichment of clay minerals on organic matter; Different clay minerals have different enrichment of organic matter. The content of Yimeng mixed layer is about 30% and the content of chlorite is about 30%, which is the most conducive to the enrichment of organic matter. Too high or too low is unfavorable, while the higher the content of illite and kaolinite, the more conducive to the enrichment of organic matter; The hydrocarbon generation potential of shales is directly related to the enrichment of clay minerals on organic matter. The stronger the enrichment of clay minerals on organic matter, the higher the hydrocarbon generation potential, on the contrary, the lower the hydrocarbon generation potential. Generally speaking, to a certain extent, the content of clay minerals controls the enrichment of organic matter and its hydrocarbon generation potential. There are differences in the enrichment of organic matter by different types of clay minerals, which can provide reference for resource evaluation, exploration and development of shale oil and gas.

The reservoir quality of favorable reservoirs and their controlling factors in saline lacustrine tight reservoirs of Middle Permian Lucaogou Formation, southeastern Junggar Basin, northwestern China

Wenze Yang[1,2], Jiagen Hou[1*], Yuming Liu[1], Ke Ma[1]
1. College of Geosciences, China University of Petroleum-Beijing, Beijing, CHINA
2. Geology section, Department of Earth and Environmental Sciences, Katholieke Universiteit Leuven, Leuven, Vlaams-Brabant, BELGIUM
E-mail: jghou63@hotmail.com

Keywords: Favorable reservoirs, tight reservoirs, reservoir quality, sedimentary microfacies, diagenetic evolution

As a vital type of unconventional reservoirs, tight reservoirs are widely distributed in lacustrine basins in China. These reservoirs are featured by complex lithology, poor reservoir quality, nanoscale pore throats and strong heterogeneity of pore structures, which significantly impact the distribution of favorable reservoirs and hydrocarbon production. This study evaluated the tight reservoirs of the second member of Permian Lucaogou Formation and revealed the controlling factors of the favorable reservoirs based on fifty-one cores from seven wells in Jimsar Sag of Junggar Basin, northwestern China. Based on 1740 data of helium porosity, air permeability and movable fluid saturation measurement, the permeability of favorable reservoirs is higher than 0.01mD and the movable fluid saturation is higher than 14.6%. The porosity of favorable carbonate reservoirs is higher than 6.2% while that of clastic reservoirs is higher than 8.8%. According to the results of thin section analyses, scanning electron microscopy (SEM), pressure-controlled mercury injection (PMI), rate-controlled mercury injection (RMI) and X-ray computed tomography (CT), the favorable reservoirs are characterized by the development of dissolution pores and contracted or narrow sheeted throats with the average pore throat radius greater than 0.025μm and the connecting pore throat radius greater than 0.129μm. As the main lithofacies of favorable reservoirs, dolomitic siltstone and silty dolomite have great number of throats with the radius greater than 0.1μm and good pore throat connectivity. Deposited in a saline lacustrine environment, dolomitic siltstone mainly develops in sandy beach-bar, which distributes in shore-shallow lake zone. In the eogenetic A period, the chlorite-coatings in thick sandy beach-bar reservoirs resist strong compaction and preserve a wealth of primary intergranular pores. Although a number of pores are filled by later carbonate cements, during the eogenetic B and mesogenetic A period, organic acids released from the thermal evolution of organic matter are transported into sandy beach-bar reservoirs, resulting in extensive dissolution of carbonate cements, tuffaceous component and feldspar grains. The strong dissolution leads to the development of a large number of intergranular pores, wide throats and pore network with good connectivity, resulted in remarkable increase of porosity (ave 7.9%). In an evaporitic environment, silty dolomite widely develops in dolomitic sandy flat, which continuously distributes along the edge of lacustrine basin and near terrigenous provenance. Compared with sandy beach-bar reservoirs, compaction causes less damage to the porosity of dolomitic sandy flat reservoirs. Although fewer primary pores develop in dolomitic sandy flat reservoirs, fewer carbonate cements fill in intergranular pores and the reduction of porosity in dolomitic sandy flat reservoirs (ave 7.0%) is obviously lower than that in sandy beach-bar reservoirs (ave 14.3%). These research results are crucial to evaluation and predication of favorable reservoirs in similar continental tight reservoirs.

Sedimentary characteristics of Late Carboniferous and Early Permian coal measures and its control on symbiotic gas reservoirs in Shouyang area

Zhenguo Wang[1*], Lifang Kang[1]
1. Research and development centre of CBM, China United Coalbed Methane Corporation Ltd., Taiyuan, ShanXi, CHINA
E-mail: wangzhg10@cnooc.com.cn

Keywords: Late Carboniferous-Early Permian,Coal system gas,Sedimentary,symbiotic association

In recent years, the Ordos Basin has made a major breakthroughof coal-measure symbiotic gas reservoirs.However, the exploration target of Qinshui Basin, which is in the same structural unit, is still focused on coalbed methane.The late Carboniferous-Early Permian sedimentary environment in the Shouyang block in the northern Qinshui Basin is a transitional marine-land sedimentary environment. Among them, the Coal-3 in Shanxi Formation and the Coal-9 and Coal-15 in Taiyuan Formation which have a high degree of thermal evolution are good source rocks;The sea-land transitional phase is conducive to the development of various types of reservoir-cap combinations. These conditions indicate that this area has the basic geological conditions for the development of coal-system gas symbiotic gas reservoirs.Based on previous studies and the data of 108 CBM exploration wells, the sedimentary characteristics of the Late Carboniferous-Early Permian coal measures have been carefully studied.The Taiyuan Formation is divided into three subfacies and the Shanxi Formation is divided into one subfacies.Based on the above results, 8 typical lithofacies combinations are summarized, and 3 types and 4 types of coal gas storage cover are obtained through comprehensive analysis.Based on the above results, this paper summarizes 8 typical lithofacies combinations and defines 4 types of coal-based gas symbiotic gas reservoir combinations.Finally, the potential areas of various symbiotic gas reservoirs in Shouyang block are predicted.

Keywords: shale lithofacies, occurrence state, main control factors, microscopic stepwise migration and accumulation model, Fengcheng Formation

As a substitute resource of conventional oil and gas resources, Continental shale oil has broad exploration and development prospects. The occurrence state of shale oil is very important to characterize the mobility of shale oil. However, the unclear occurrence characteristics and main controlling factors of shale oil in Fengcheng Formation shale in Hashan area of Junggar basin limit the evaluation of its shale oil resources. In this paper, by means of X-ray diffraction, TOC, rock pyrolysis, scanning electron microscope and two-dimensional nuclear magnetic resonance (NMR) experiments, combined with core observation and thin section identification, the occurrence characteristics of shale oil in Fengcheng Formation shale in Hashan area of Junggar basin is systematically studied. The results show that there are four types of lithofacies in Fengcheng Formation, which are limestone (dolomite) lithofacies, siltstone lithofacies, peperite lithofacies and tuff lithofacies. The free shale oil mainly occurs in fractures and dissolution pores (veins) and matrix pores with large pore size. Adsorbed shale oil mainly adsorbs kerogen and the surface of inorganic minerals. Lithofacies types, rock fabric, organic matter evolution and reservoir space are the main controlling factors of shale oil occurrence. Finally, the occurrence model of matrix type and fracture type shale oil in Fengcheng Formation and the microscopic stepwise migration and accumulation model of shale oil in different pore and fracture types are established. This paper provides a geological basis and reference for the evaluation of continental shale oil.

Sedimentary characteristics and shale quality in the first member of Cretaceous Qingshankou Formation, Songliao Basin, China

Yi Cai[1], Rukai Zhu[1*], Zhong Luo[1], Songtao Wu[1], Tianshu Zhang[1], Chang Liu[1], Jingya Zhang[1], Miao Yuan[1]
1. Oil and Gas Geology Institute, Research Institute of Petroleum Exploration and Development, Beijing, CHINA
E-mail: zrk@petrochina.com.cn

Keywords: sedimentary characteristics, shale quality, lacustrine, Qingshankou Formation, Songliao Basin

The first member of the cretaceous Qingshankou Formation (K_2qn) was a representative type of Songliao Basin lacustrine shales. The typical characteristics of this lacustrine shale was its high clay contents (as much as 55% in some samples), which was quite different to marine siliclastic shales. Therefore, it is extremely significant to study the sedimentary characteristics and properties of lacustrine shale, as is the foundation for sweet spotting of shale oil in Songliao Basin. Based on core observation, thin section identification, high-density element scanning and organic geochemical analysis, the mineralogy, lithofacies and geochemical characteristics were dicussed in this research. The results indicated that four main lithofacies could be distinguished by their different mineral compositions, laminae assemblages and bioclastic compoments: (i) felsic shale (FS), (ii) clay shale (CS), (iii) bio-bearing shale (BS), and (iv) mixed shale (MS). The clay minerals content in the CS (average: 46.72 wt%) and MS (average: 41.11 wt%) was higher than that in FS (average: 39.97 wt%) and BS (average: 35.48 wt%). Furthermore, five types of lamination were defined: (1) Feldspar and Quartz Lamination (FQL), (2) Clay Lamination (CLL), (3) Siliceous Clay Lamination (SCL), (4) Ostracods Lamination (OSL), and (5) Organic Matter Lamination (OML). Pyrolysis and organic carbon measurements showed that the organic matter types mainly included type I and type II, and the lithofacies that had the highest TOC content was CS (average 2.22 wt%), which was followed by BS (average 1.78 wt%), MS (average 1.75 wt%), and FS (average 1.62 wt%). It was discovered that FS, CS, and MS samples had very high S_1 values, indicating that these rocks have larger free hydrocarbon contents. As to the hydrocarbon generation potential, CS was the best among these four lithofacies, and geochemical analysis showed that the micro-migration might exist within the source rocks. A new lithofacies scheme and laminae associations were defined in this study, and the mineralogy and source rock property varied among different lithofacies, which could throw light on E&D targeting for unconventional resources.

The impact of laminae characteristics and types on Organic matter enrichment of Chang 73 sub-member in Ordos Basin, NW China

Congsheng Bian[1*], Wenzhi Zhao[1], Wei Liu[1], Yongxin Li[1], Kun Wang[1], Xu Zeng[1], Jing Dong[1]
1. Research institute of petroleum exploration and development, Petrochina, Beijing, CHINA
E-mail: biancongsheng@126.com

Keywords: Lamina types,organic-rich shale,shale oil, Chang 7 Member, Triassic Yanchang Formation, Ordos Basin

The Chang 7 member in Ordos Basin is an important shale oil exploration layer, with new shale-oil discoveries in recent years. TheChang 73 sub-member is rich in organic shale, which is the main source rock of shale oil in the Yanchang formation. In order to clarify the lamina structure, composition, types and distribution characteristics in Chang 73 sub-member and its influence on organic matter enrichment, a full coring well in Chang 73 sub-member located in deep-lacustrine facies is selected to obtain intensive systematic core samples. Core observation, thin section identification, X-ray fluorescence element analysis, X-diffraction analysis, scanning electron microscope, electron probe, rock pyrolysis, and other techniques, are performed to systematically analyze the morphology, structure, thickness, mineral compositions, and organic matter content of the shale lamina in the Chang 73 sub-member. Five types of lamina types are identified: Silty felsic lamina (SF), tuffaceous lamina (TF), organic rich clay lamina (ORC), organic-bearing clay lamina (OBC) and Homogeneous clay lamina (HC), which are further subdivided into eight subtypes. The lamina types change greatly vertically in the Chang 73 sub-member, in which the lower part is mainly silty felsic lamina and tuffaceous lamina, the middle part is mainly organic rich and organic clay lamina, and the upper part is mainly clay lamina and a small amount of silty felsic lamina. Differences laminae show various organic matter types, organic matter content (TOC), and organic matter occurrence states, which can be divided into four occurrence types. The organic matter content of organic rich clay lamina and tuffaceous lamina is high, while that of silty felsic lamina is lower. The relationship between shale lamina and organic matter enrichment is established according to the correlation analysis of laminar characteristics, mineral content and organic matter content. Among them, the organic rich lamina is richest of TOC and is a favorable "sweet point" for shale oil exploration.

Densification of sandstone reservoirs: new evidences from primordial sedimentation and diagenesis in Fuyu tight reservoir, Songliao Basin, China

Ge Liu[1], Zhenxue Jiang[1*]

1. Unconventional Oil and Gas Science and Technology Research Institute, China University of Petroleum, Beijing, Beijing, CHINA

E-mail: jiangzx@cup.edu.cn

Keywords: Fuyu reservoir, Diagenesis,Primary deposition,Reservoir property

The original deposition determines the composition and structure of the original material of the reservoir at the microscopic level, and the diagenetic evolution of the reservoir also affects the difference of reservoir physical properties. In order to study the control effect of original sedimentation and diagenesis on reservoir physical properties, the control effect of microscopic pore-throat characteristics on reservoir physical properties was clarified by core observation, cast thin section, physical property testing, high-pressure mercury injection and scanning electron microscopy. The results show that the porosity of Fuyu reservoir mainly ranges from 11% to 21%, with an average of 15%. The permeability ranges from 0.01 to 5×10-3μm2, with an average of 2×10-3μm2. The pore types of Fuyu reservoir are mainly dissolution pores and intergranular pores, among which the large pores (>20μm) are less, and the small pores (1-10 μm) and micro-nano pores (<1μm) are dominant. The main laryngeal types were pore constricted larynx, lamellar larynx, curved lamellar larynx and bundle larynx. The laryngeal radius mainly ranges from 1 μm to 10μm. The fuyu reservoir is mainly composed of massive bedding, parallel bedding and cross bedding. The frequency mode peaks of cross-bedding sediment are 1.02 ~ 1.18 φ, the mode peaks of parallel bedding are 1.10 ~ 1.23 φ, and the mode peaks of massive bedding are 1.20 ~ 1.32 φ. Cross - bedded samples have larger pore - throat radius. The content of chlorite in cross bedding is high, and the chlorite film in chlorite has a strong limiting force on the development of quartz secondary growth, which plays a crucial role in the preservation of primary pores in tight reservoirs, so that the development degree of intergranular pores is higher, and the physical properties of reservoirs are better. Feldspar and rock debris occupy a high proportion in tight reservoir, and the two kinds of particles have low stability and are easy to dissolve and form inner pores of dissolution grains. Feldspar particles are easily dissolved by acid and indirectly form internal and intergranular pores. The existence of dissolution pores improves the percolation ability of pores in tight reservoirs, thus improving the physical properties of reservoirs.

The oldest known stomatocysts with pyrite discovered in the Triassic Chang7 shale, Ordos Basin, China and palaeo-environment reconstruction

Weiwei Yang[1*], Liqin Xie[1]

1. Experimental Research Center, Petroleum Exploration and Development Research InstituteChangqing Oilfield Company, CNPC, Xi'an, Shanxi, CHINA

E-mail: yww1_cq@petrochina.com.cn

Keywords: Stomatocysts, oldest known, morphology,ecology,Triassic,Ordos Basin

A variety of chrysophyte cyst fossils, discovered in the Triassic hot shales of Ordos Basin, has been provided as the oldest known cyst fossils. Further studies are necessary to understand its great scientific significance. Fifty-eight core samples with abundant cysts were prepared and observed under scanning electron microscope after gold coating. Four categories, including 24 morphotypes of stomatocysts, were found in the shale samples, among which 10 types are new to science. The distribution of chrysophyte cysts was aperiodic and discontinuous, indicating that environmental changes caused by sudden geological events might be dominant factors for cyst distribution. The lacustrine environment during the Ladinian Age, with fresh to brackish water, oxygen-containing bottom water, and abundant nutrients, is favorable for chrysophyceae reproduction. From the available fossil records, chrysophyceae was speculated to be the earliest siliceous algae on earth, or a new species appearing during ecosystem restoration after the end-Permian mass extinction.

E-mail: linliangbiao08@cdut.cn

Keywords: Ordos Basin, Huaqing area, Member 6 of Yanchang Formation, fractal dimension, influencing factors

Tight sandstone oil and gas is an important field of oil and gas exploration and development in recent years. It is great significance to clarify the pore throat structure characteristics of tight sandstone reservoirs to guide production practice. This paper takes the tight sandstone of the sixth member of Yanchang Formation in Huaqing area, Ordos Basin as an example. Based on high-pressure mercury intrusion, casting thin sections and scanning electron microscopy, combined with tube bundle and spherical fractal models, the pore-throat structure and influencing factors of tight sandstone reservoirs were studied. According to the curve characteristics of spherical and tube-bundle fractal models, the pore-throat structures of tight sandstone reservoirs are divided into three categories. Type I is the smaller pore throat, Type II is the medium pore throat, and Type III is the larger pore throat. The results show that the fractal dimension of class I pore-throat distribution is 2.1289~2.9477, with an average of 2.4453; the fractal dimension of class II pore-throat is distributed from 3.1433 to 6.222, with an average of 4.3972; the fractal dimension of class III pore-throat is distributed in the range of 2.1376-3.3559, with an average is 2.6688. Type I pore-throat fractal dimension is the smallest, and type II pore-throat fractal dimension is the largest. It shows that the gap between the pore and throat radius of the smaller pore throat is the smallest, and the uniformity of the pore throat is the best. The gap between the pore and throat radius of the medium pore throat is the largest, and the uniformity of the pore throat is the worst; the larger pore throat is between the two. The main influencing factors for the difference of fractal dimension of different pore throats are diagenesis, rock composition and pore-throat combination type. Diagenesis and rock composition mainly affect the type and development degree of pore-throat, as well as the combination of pore-throat. Type I pore throats are mainly composed of intercrystalline pores and tube bundle throats, with small roars for small pores. Type II and type III pore throats are dominated by residual primary intergranular pore-sheet throat, curved sheet throat assemblage and dissolution pore-necked throat assemblage, with small throats for large pores. The structural differences of different pore throats are manifested in fractal dimension and mercury intrusion parameters and their interrelationships. This paper provides a theoretical basis for the exploration and development of tight sandstone reservoirs.

The Ri-Qing-Wei Basin oil-gas accumulation condition——contrast with Jiaolai Basin

Yue Zhang[1,2], Yaoqi Zhou[1*]
1. School of Geoscience and Techology, China University of Petroleurm, Qingdao, Shangdong, CHINA
2. Shengli Oilfield Company,Sinopec, Exploration and Development Research Institute, Dongying, Shangdong, CHINA
E-mail: zhouyq@upc.com.cn

Keywords: The Ri-Qing-Wei Basin, Jiaolai Basin,Tectonic Evolution, Source Rocks,Reservoir Physical Properties.

During the Jurassic-Cretaceous period, the subduction, rollback and the change of subduction direction of the paleo-Pacific plate had an important influence on the development of eastern China and coastal basins. Due to the subduction of the paleo-Pacific plate to the Eurasian plate in the late Mesozoic, the Sulu orogenic belt between the North China plate and the Yangtze plate was subjected to the lithospheric mantle subsidence to produce a passive continental rift. Under the passive tensile action of the Laiyang period , a series of rift basins with Ri-Qing-Wei Basin as the central rift were formed. After the active rifting stage in the Qingshan period and the depression stage in the Wang period, the middle part experienced thermal uplift and two compressional strike-slip processes , and finally formed the structural form of the current basin. The current drilled wells in the Jiaolai Basin have good oil and gas display in the Laiyang Group, among which the source rocks in the Shuinan section of the Laiyang Group in the Laiyang Sag are the best. The Ri-Qing-Wei Basin is adjacent to the Jiaolai Basin, east of the Tanlu Fault Zone, developed on the Sulu orogenic belt, and separated by Jiaonan uplift in the middle. The Jiaolai Basin is located between the Tan-Lu fault zone and the Wulian-Mouji fault zone. In the right-lateral strike-slip stage at the end of Wang period, the Jiaolai Basin was subjected to strong compression and uplift, and the strata were uplifted on a large scale. As a result, the Wang group as a caprock was eroded, and the source rocks in the Laiyang period were oxidized, resulting in the destruction of oil and gas reservoirs. Ri-Qing-Wei Basin is clamped by Rongcheng fault zone and Wulian fault zone.The Ri-Qing-Wei Basin in Laiyang period is a central rift basin. The source rock in Laiyang period is deeper and thicker, and the uplift at the end of Wang ’ s later period has little effect on its destruction. The magmatic activity in the Qingshan period will have a positive impact on the source rock, but it is not a key factor. The key factor affecting the source rock is the burial depth. The sedimentary filling history, tectonic evolution, burial history, geothermal history and organic geochemical characteristics of source rocks in different basins are comprehensively compared and analyzed by using field profile, drilling, core data and seismic profile. The results show that the Laiyang Group of the Late Mesozoic in the Ri-Qing-Wei Basin has great exploration potential in unconventional fields.

Pore-throat characteristics of shale reservoirs in the Lower Cambrian Niutitang Formation in northern Guizhou

Biao Zhu[1], Niuniu Zou[1*]
1. , , , , CHINA
E-mail: niuniu9728@126.com

Keywords: northern Guizhou,Niutitang Formation,FE-SEM, NMR,low temperature nitrogen adsorption

The shale reservoirs of the Lower Cambrian Niutitang Formation in northern Guizhou have strong hydrocarbon-generating capacity and great development potential. The research on the pore throat structure characteristics of the reservoirs is the basis for oil and gas development. Through field emission scanning electron microscopy (FE-SEM), nuclear magnetic resonance (NMR)experiment, and low-temperature N2 adsorption-desorption experiment, the pore-throat characteristics of shale reservoirs in the Lower Cambrian Niutitang Formation in northern Guizhou were researched. The results show that the pore types of the organic-rich shale reservoirs in the Lower Cambrian Niutitang Formation of Yongfeng 1 Well are compound pores, caves and fractures, mainly organic pores and intercrystalline pores (mainly pyrite intercrystalline pores), intracrystalline pores (mainlysiliceous minerals intracrystalline pores) and micro-cracks, the degree of pore development is controlled by minerals, organic matter and later reformation; the sample pore size distribution is complex, the pore structure is poor, and the storage space is mainly concentrated in the micropores , mesopores, macropores, few small pores, the pore size ranges from 0.1-1nm, 2-4nm, 10-100nm; the average specific surface area of the sample is 9.5366m2/g, the average pore volume is 0.01084 cm3/g, the average The pore size is about 3.708 nm; the pore morphology of the sample is complex, with cylindrical, cracked and ink bottle shapes developed

E-mail: Liuxiaoping@cup.edu.cn

Keywords: lacustrine shale, microstructure, fracability, image recognition and analysis

Rock fracability is a key indicator to measure the effect of fracturing, and the microstructure play a crucial role in controlling the mechanical properties. This study aims to reveal the effect mechanism of the microstructure heterogeneity on lacustrine shale fracability. In this study, we took X-ray diffraction, argon ion polishing-field emission scanning electron microscope, energy spectrum, rock slice/light. To carry out systematic research on the microstructure and structure of shale reservoirs and their influence on the fracability of the reservoir using test methods such as flake microscopic observation, organic geochemical testing, triaxial stress experiment, and rock acoustic wave testing. Moreover, images of lacustrine shale samples from the Paleogene Formation in the Eastern China were systematically analyzed using Image-J software. This paper is the first to analyses the unique effect of microstructure on fracability of lacustrine shale. The quantitative characteristics of microstructure in shale samples were extracted from the FE-SEM images. Studies have shown that the microstructure of lacustrine shale have strong longitudinal heterogeneity, the fracturing index of fine-grained sedimentary rocks is controlled by the microstructure. The lower the organic matter and clay content, the higher the carbonate mineral content, the fewer mineral particles and areal density, and the larger the particles, the greater the fracturing ability. The better, and the smaller the number of laminae and the density per unit area in the sedimentary structure, the wider the width, the stronger the fracturing ability.

Keywords: Fine-grained Sedimentary Rocks, Enrichment of Organic Matter, Sedimentary Environment, Haian sag

Multiple sets of dark fine-grained sedimentary rocks are developed in continental strata, which is a potential favorable target for shale oil exploration and development. The current lack of in-depth understanding of organic matter enrichment mechanisms in continental sedimentary environments has restricted the progress of shale oil exploration and development. Taking the typical fine-grained mixed sedimentary rocks of Paleogene in Subei Basin in eastern China as the research object. XRD, determination of organic carbon content, trace elements and carbon and oxygen isotopes were used to analyze the sedimentary environment of dark shale and its influence on organic matter in the second member of Funing Formation(FM) in Qutang Sub-Sag of Haian Sag in Subei Basin. Fine-grained sedimentary rocks are mainly mixed and clayey shale; the average abundance of organic matter is 1.32%, and the vertical heterogeneity is obvious; trace elements such as Sr and Ba are significantly enriched, while Ni and Co are relatively depleted; the $\delta^{13}C_{Org}$ average is 27.35%, and the $\delta^{13}C_{Car}$ and $\delta^{18}O_{Car}$ averages are 0.88 ‰ and -5.90 ‰ respectively. The main sedimentary environment of the dark fine-grained mixed sedimentary rocks in the second member of Funing FM is a relatively deep, freshwater to brackish water, semi-arid to semi-humid, semi-reduced to semi-oxidized environment. there is a strong correlation between carbon and oxygen isotopes in the carbonate components of the second member of Funing FM, indicating a relatively closed lake system. Paleo-water depth and paleo-redox conditions in sedimentary environment are important conditions to control the enrichment of organic matter, it's meaning that, with the increase of water depth, the more reductive the water column is, the more favorable the organic matter enrichment. At TOC<1%, the enrichment of saprophytic kerogen was more conducive as the water body modification effect diminished, and at TOC>1%, sapropelic kerogen content is gradually stabilized.

Main-controlling factors of the high-quality reservoir in the deep strata of the Guaizihu Depression, Yin-E Basin

shuang wu[1], jun wang[1*]
1. Institute Of Sedimentary Geology, Chengdu University of Technology, Chengdu, Sichuan, CHINA
E-mail: cdut_wangjun@foxmail.com

Keywords: deep-buried clastic rock, differential densification, diagenesis, the Guaizihu Depression

This paper studies the differential densification mechanism of cretaceous tight sandstone reservoirs and the development model of high-quality reservoirs in the Guaizihu Depression of Yin-E Basin. This study fills in the shortcomings of previous research on tight sand reservoir heterogeneity in the Yin-E Basin. The research results are of great significance for predicting high-quality reservoir development areas. The reservoir in the study area is characterized by apparent heterogeneity with porosity ranging from 0.3%-16.7% and permeability ranging from 0.01mD-90.41mD. We studied cement's types, occurrence, and formation sequence in a clastic reservoir based on the regional sedimentary background. We also analyzed the effect of microscopic characteristics of a reservoir on pore evolution by using the data of core observation, cast thin section, mercury injection test, scanning electron microscopy, and X-ray diffraction test. Furthermore, we studied the influence of sedimentary facies, diagenesis, and post-diagenesis on reservoir differences. The results show that:

(1) Tight reservoirs are mainly developed in beach bar microfacies, with poor initial physical properties and high plastic mineral content. The average porosity reduced by compaction and cementation is 22.2% and 11.5%, respectively, and the average porosity increased by dissolution is 1.1%. In addition, clastic rocks rich in tuff debris are developed in the upper part of the tight reservoir, and carbonate cement generated by the diagenesis can densify the lower reservoir.

(2) High-quality reservoirs are mainly developed in underwater distributary channel microfacies, with promising initial physical properties. The high-quality reservoir has low plastic mineral content and high content of rigid particles, so the reservoir has weak cementation and high compressive ability. The average pore reduction amount of compaction and cementation is 21.7% and 9.4%, respectively, and the average porosity increase is 5.9%. The diagenetic evolution of "early alkali and late acid" is conducive to developing chlorite rim cement early and inhibits late carbonate cement deposition, which protects the primary intergranular pores in the reservoir to a certain extent.

(3) The sedimentary facies zone determines the spatial distribution of the high-quality sand body and the initial reservoir's physical properties. Diagenesis promotes the differentiation of reservoir porosity and permeability. Moreover, overpressure increases the compaction ability of the reservoir and facilitates the development of deep secondary pores. In short, all these factors act on forming a high-quality deep reservoir.

(4) Secondary dissolution pores and secondary dissolution fractures are the keys to forming high porosity and permeability reservoirs in clastic reservoirs in the study area. Organic acid acidification is the main reason for the appearance of secondary pores. Combined with the distribution area of the dissolution zone, it is concluded that the south depression step slope zone is the development area of the dissolution reservoir, which is the next favorable exploration area.

Architecture characteristics of sand bodies in the Chang 7 Member and prediction of favorable areas in the Heshui area, Ordos Basin

HongLiang HUO[1], ChengLin LIU[1*]
1. College of Geosciences, China University of Petroleum (Beijing), Beijing, CHINA
E-mail: 694200908@qq.com

Keywords: Heshui area,Chang 7,Sandy clastic flow,Sand structure,Favorable area prediction

Abstract: The Ordos Basin is rich in oil and gas resources. In recent years, the Chang 7 Member of the Mesozoic Yanchang Formation has shown huge resource potential under the guidance of deep-water sedimentary theory, and has achieved good oil exploration results. In this study, the Chang 7 Member in the Heshui area was taken as an example. Through the observation of core data, combined with the comprehensive analysis of logging data, the different types of sand bodies in the deep-water gravity flow system of the Chang 7 oil layer group in the Heshui area of the Ordos Basin were systematically studied. Architecture features and favorable zone predictions were made. The Chang 7 sedimentary period in the Heshui area was located on the slope in the southwest of the basin. Influenced by the Indosinian movement, there were frequent tectonic activities such as volcanoes and earthquakes. The delta front sediments formed a sufficient and continuous provenance supply due to slumping. After the slump, sediments accumulated rapidly, and large-scale sandy debris flows, turbidity currents and other gravity flows were developed deep-water sandstones during the Chang 71 and Chang 72 periods,. The reservoir rock types of the Chang 7 Member in the Heshui area are mainly feldspar lithic fine sandstone and lithic feldspar silt fine sandstone, and sand and mud interbed frequently. with poor physical properties, the average porosity is 9.86%, the permeability is 0.167mD, and the argillaceous content is high. The Chang 7 member sand bodies in the study area were divided into multi-layer superimposed type, thick sand-thin mud type, sand-mud interbed type and thick mud type, among which the multi-layer superimposed type and thick sand-thin mud type are high-quality reservoirs. The high-quality sand bodies in the study area are controlled by the sedimentary microfacies of sandy clastic flow, and are formed by rapid accumulation in multiple stages, and are located in the area of relatively deep lake water, and the sediments are hard to be reformed by lake waves. Therefore, the sedimentary sand body order is more mixed, the sorting is relatively poor, and the heterogeneity is strong. According to the plane distribution characteristics of sand bodies, physical properties and sedimentary microfacies, combined with oil test and production data, the favorable storage sand of the Chang 7 reservoir is mainly thick sand-thin mud type, and the local high-porosity area of thick sand-thin sand-mud interlayer sand can also be high-quality reservoirs, mainly distributed in the middle and south of the research area.

Movable fluid characteristics of tight sandstone reservoirs and their sedimentary and diagenetic control: A case study of the Yanchang formation, Ordos Basin

Dehao Feng[1], Chenglin Liu[1,2*]

1. College of Geosciences, China University of Petroleum(Beijing), Beijing, CHINA
2. State Key Laboratory of Petroleum Resources and Prospecting, China University of Petroleum (Beijing), Beijing, CHINA
E-mail: liucl@cup.edu.cn

Keywords: tight sandstone, movable fluid, pore-throat structure, fluid mobility, Ordos basin

The tight sandstone of the Upper Triassic Yanchang formation constitutes important oil reservoirs in the Ordos Basin, Central China. The movable fluid characteristics of tight sandstone reservoir directly affect the oil production and recovery efficiency. Therefore, it is crucial to quantitatively characterize the fluid mobility and influencing factors of tight sandstone. Here, we presented the results of a detailed investigation on the movable fluid in the Yanchang formation in the Nanliang Oilfield, where fluvial channel sandstones intercalate with distributary interchannel muds in a delta setting. Multiple experiments, including cast thin-section, scanning electron microscope, X-ray diffraction, X-ray computed tomography, high-pressure mercury intrusion, and nuclear magnetic resonance were carried out on 16 samples from 12 wells. The integration of micro pore-throat structure investigation with petrographical observations and core descriptions reveals that the fluid mobility is dominantly driven by mudstone proximity, diagenetic mineral, petrophysical property, and pore-throat structure. According to the distribution and combination of pore-throat size and type, it can be identified that there are three types of pore-throat structure (type I, II, and III) and three pore-throat spaces (nanopore, submicron pore, and micron pore), which correspond to different occurrence characteristics of movable fluid. The differences of three pore-throat structure are pore-throat size, connectivity, and heterogeneity. Movable fluid mainly occurs in submicron and micron pores in type I pore-throat structure, submicron pores in type II, and nano and submicron pores in type III. The type I is characterized by large pore throats, high connectivity and weak heterogeneity, with the highest fluid mobility. The type II is dominated by submicron pores, with poor connectivity and moderate heterogeneity. The type III pore-throat structure is characterized by nanopores, lowest connectivity and strong heterogeneity, with the lowest fluid mobility. The fluid fluidity is a significant positive correlation with quartz and feldspar content, showing the residual intergranular pore and feldspar dissolved pore can significantly improve fluid mobility. On the contrary, it is negatively correlated with clay and carbonate minerals because they can block pore-throat and reduce fluid mobility. Detailed analysis of Spatial distribution of movable fluid shows it is distinctly related to mudstone proximity, thickness of single sandbody, and mudstone/formation (M/F) ratio. Typically, thick sandstones forming thick beds in mudstone-poor sequences are commonly low in carbonate and clay mineral cement and relative high in movable fluid. In contrast, sandstones occurring as thin beds in mudstone-rich depositional sequences (high M/F ratio) typically exhibit high carbonate and clay mineral cement, so its movable fluid content is low. The frequent material exchange between sandstone and adjacent mudstone leads to the enhancement of the cementation of clay carbonate minerals, where it may be a devastating factor for pore-throat structure and fluid mobility. This study provides new insights into predicting the best reservoir sandstones with high fluid mobility.

Characteristics and Oil-bearing Analysis of Shale Reservoir in Qingshankou Formation in Sanzhao Sag, Songliao Basin

Surong Zhang[1], Chang Liu[1*]

1. Institute of Petroleum and Natural Gas Geology, Research Institute of Petroleum Exploration and Development, CNPC, Beijing, CHINA

E-mail: liuchang2020911@petrochina.com.cn

Keywords: shale oil, Qingshankou Formation, lamina, oil-bearing

The continental shale of Qingshankou Formation in Songliao Basin has excellent potential for shale oil resources and has made substantial breakthroughs in exploration and development. The characteristics and oil-bearing properties of shale reservoirs are the keys to evaluate shale oil resource and sweet spot interval selection. The Qingshankou Formation shale lithofacies characteristics, laminae types, reservoir space geochemical and oil-bearing properties were studied by thin section identification, element scanning analysis, field emission scanning electron microscopy and confocal laser analysis. The results show that minerals of Qingshankou Formation shale in Sanzhao Sag, Songliao Basin are mainly clay minerals, quartz, carbonate minerals and pyrite; bright feldspar-quartz laminae, dark clay laminae and black organic-rich laminae are developed. Reservoir space includes intergranular pores, dissolution pores, clay mineral interlayer pores (fractures), organic matter pores, and intercrystalline pores of pyrite. The pore morphology of feldspar-quartz laminae is like the ink bottle, and the pore diameter distribution ranges from 0 to 200 nm, mainly between 0 to 50 nm, with an average of 14 nm. The particles are cemented mainly by carbonate minerals or clay minerals, which decrease the pore volume, but it can be increased by the dissolution of mineral particles, such as feldspar, calcite. While the pore shape of the clay laminae is slit-type pores, and the pore diameter distribution ranges from 0 to 600 nm, mainly between 0 to 50 nm, with an average of 17 nm. In terms of oil-bearing characteristics, the volume of light hydrocarbons in feldspar-quartz lamina shale is 13.71%, and that of heavy hydrocarbons is 11.35%; the volume of light hydrocarbons in clay lamina is 11.55%, that of heavy hydrocarbons is 15.44%. Compared with clay laminae, feldspar-quartz lamina has a higher ratio of light hydrocarbons to heavy hydrocarbons. The different distribution of light and heavy hydrocarbons of Qingshankou Formation in Sanzhao Sag is controlled by thermal evolution and burial time. The shale of Qingshankou Formation in Sanzhao Sag of Songliao Basin are buried for a short period of medium-low maturity, resulting in more heavy hydrocarbons in clay lamina and more light hydrocarbons in Feldspar-Quartz lamina.

3. School of Geoscience and Technology, Southwest Petroleum University, Chengdu, Sichuan, CHINA
E-mail: 939802641@qq.com

Keywords: Low pressure gas adsorption, small angle X-ray scattering, Fractal dimension, Pore structure

Fractal dimension is a key parameter of evaluate shale reservoir, which can be calculated based on the various experimental results. Low pressure gas adsorption (LPGA) and small angle X-rayscattering (SAXS) experiments were used to evaluate the pore fractal characteristics of bulk, washed and kerogen of shale samples of the Chang 7 member shale of the Upper Triassic Yanchang Formation in the Ordos Basin. The fractal dimensions of the two sets of experimental data were compared, and the application of the fractal dimensions in characterizing the pore structure and liquid hydrocarbon content of the shale was discussed in combination with the parameters of pyrolysis experiment. The following conclusions can be drawn from this study: (1) The fractal dimension of the bulk shale sample is slightly lower than that of the washed sample, and the fractal dimension of the kerogen sample is significantly lower than that of the other two groups of samples, which indicates that the presence of residual hydrocarbons increases the complexity of the pore structure and kerogen has a simpler pore structure. (2) Whether it is bulk shale, washed shale, or kerogen samples, the fractal dimension of most samples measured by SAXS data is higher than the fractal dimension measured by LPGA-N_2 data, which proves that a certain amount of uncracked liquid hydrocarbons exist within the pores of the lacustrine shale, forming many isolated disconnected pores. (3) The fractal dimension decreases with increasing TOC content, indicating that the fractal dimension of organic matter in shale is lower than that of other components. In addition, the fractal dimension decreases with increasing S_1 content, which makes the fractal dimension can be used to approximately reflect the residual hydrocarbon content in lacustrine shale.

Multi-factor control on the formation of tight sandstone reservoirA case study from the Carboniferous Yanghugou Formation in the western Ordos Basin

YUQING XIA[1], SIYI FU[1*]
1. , , , , CHINA
E-mail: fusiyi@cdut.edu.cn

Keywords: Tight sandstone,Reservoir quality,Diagenesis,Depositional facies,Ordos basin

The study of the formation mechanism of tight sandstone reservoirs has been a hot issue in the field of sedimentological research. The Upper Paleozoic Carboniferous in Ordos Basin is one of the main producers of tight sandstone gas in China. However, the previous researches on the formation mechanism of Carboniferous reservoirs mainly focus on the central-eastern and northern parts of the basin, while the western part of the basin is rarely reported due to the complex geological environment. Based on the observation and sampling of drilling cores, thin section identification under microscope, mercury intrusion and CT scanning analysis, combined with the latest research results of sedimentation, structure and provenance, this study explored the formation mechanism of tight sandstone reservoirs in the Carboniferous in the western Ordos Basin. The study shows that the Carboniferous sandstone reservoir is dominated by quartz arenite and litharenite, with an average porosity of 8.43% and average permeability of 0.405 mD, which is a typical low porosity and low permeability reservoir. The pore types are mainly secondary pores such as intergranular pores and intragranular pores, and the primary pores are almost invisible. Diagenesis, sedimentary environment and provenance are the key factors for the formation of reservoir in the study area: the dissolution of feldspar, rock fragments and cements by organic acids released by mature hydrocarbon materials effectively improves the reservoir quality.The compaction caused by long-term deep burial results in the disappearance of a large number of primary pores, and the cementation mainly composed of tuff, kaolinite, carbonate and silica reduces the reservoir quality significantly. The tidally influenced deltaic front subfacies in the study area has relatively good reservoir properties, followed by barrier sand dam facies. tidally influenced deltaic front has low mud content but high sand content due to continuous sieving and washing by tidal action, and the parent rocks have good physical properties. Compared with the barrier sand dam, the content of rock fragments and interstitial materials in the reservoir is relatively high, which provides material conditions for later dissolution. The supply of Carboniferous sediments in The Ordos Basin mainly came from the Alxa paleocontinent, which is dominated by sedimentary rocks and calcareous mudstones in the northwest, and the Yinshan paleocontinent, which is dominated by alkaline basalt in the northeast. Sedimentary rock fragments and calcareous rock fragments tend to lead to strong cementation and poor reservoir properties. However, the volcanic rock fragments easy to dissolve .and the cementation is weak, so the reservoir physical properties are relatively good. The above research results can provide reference for further exploration and development of the study area and similar basins.

Control of sedimentary characteristics of fluvial tight sandstone reservoir on diagenesis and differential densification process A case study of No.7 and No.8 sand formations of J2s21 Sub-Member in the North of Central Sichuan Basin

Linjie Feng[1], Yuqiang Jiang[1*], Yadong Zhou[1], Miao Li[1]
1. School of Geoscience and technology, Southwest Petroleum University, Chengdu, Sichuan, CHINA
E-mail: xnsyjyq3055@126.com

Keywords: tight sandstone, sedimentary characteristics, diagenesis, differential densification

In order to explore the differential densification mechanism of fluvial sandstone reservoir and clarify the relationship between sedimentation and diagenesis, integrated analysis of sedimentary components and structure characteristics, reservoir quality, pore structure, and types and degree of diagenetic alterations of No.7 and No.8 sand formation of $J2s^2_1$ Sub-Member in the North of Central Sichuan Basin was done in this study by employing core and cast thin section observation, scanning electron microscopy combined with EDS, X-ray diffraction, high-pressure mercury intrusion and nuclear magnetic resonance, and obtained the following understanding:

1. The No.7 and No.8 sand formations of $J2s^2_1$ Sub-Member belong to low curvature meandering river sedimentary system, with the characteristics of multi-stage channel sandbody superposition, single sandbody scouring contact and obvious positive grain sequence. Compared with No.8 sand formation, the No.7 sand formation has larger particle size and higher content of magmatic rock debris.

2. The difference of rock debris composition has an obvious influence on the properties of pore fluid in shallow burial period. Due to the intense hydrolysis and alteration of dark iron magnesium minerals in magmatic rock cuttings, The pore fluid of No.7 sand formation is more alkaline and rich in metal ions, which promotes the transformation of smectite film on the grain surface to chlorite. On the contrary, the chlorite content of No. 8 sand formation is low, and the grain surface mainly dominated by I/S mixed layers and illite.

3. The cement developed in syngenesis and early diagenesis stage has obvious sedimentary structure selectivity in alkaline fluid environment. With the decrease of sandstone particle size, the original hydrodynamic conditions, initial porosity and rigid component content gradually decrease, the sorting, pore structure and fluid exchange intensity in shallow burial period gradually deteriorate, and the content of chlorite also gradually decreases. On the contrary, the content of I/S mixed layers, illite and crystal stock calcite gradually increases.

4. The symbiotic association of cements and the degree of dissolution in the middle diagenesis stage is controlled by the pore fluid environment in the early diagenesis stage. Due to the alkaline pore fluid in the early diagenetic stage of No.7 sand formation, the development degree of dissolution in the middle diagenetic stage is limited, the reservoir space is dominated by residual primary pores, and the combination of grain-coating chlorite, authigenic albite and quartz cement is developed. In contrast, the dissolution in No.8 sand formation is relatively strong, the proportion of dissolution pores is relatively high, and the types of cements are diverse, the I/S mixed layers, filamentous illite, crystalline calcite, vermicular chlorite and authigenic quartz crystals have complex symbiotic relationship.

5. Compaction is the main cause of porosity loss of coarse-fine sandstone, but for some siltstone and fine sandstone, the damage of calcite cementation to pores is greater than that of compaction.

6. Weak sedimentary hydrodynamic conditions and high content of filamentous illite are the main reasons for the obvious deterioration of pore structure and permeability of No.8 sand formation compared with No.7 sand formation.

Sedimentary Characteristics and Seismic Response of Tight Sandstone Reservoirs: A Case Study of the Upper Triassic Xujiahe Formation in Central Sichuan

Tong Yu[1,2*], Hong Liu[1,2], Cheng Yin[1,2]
1. School of Geoscience and Technology, Southwest Petroleum University, Chengdu, Sichuan, CHINA
2. Natural Gas Geology Key Laboratory of Sichuan Province, Southwest Petroleum University, Chengdu, Sichuan, CHINA
E-mail: 99006880@qq.com

Keywords: Sichuan Basin,Upper Triassic,Braided river delta,Tight sandstone gas,Fracture system

The Triassic Xujiahe Formation in the Sichuan Basin is one of the most typical tight gas exploration formations in China. According to seismic, core, logging and logging data, the sedimentary characteristics of tight sandstone reservoirs and the "sweet spots" of tight gas reservoirs have been clarified. The second member of Xu is a typical braided river delta deposition, with high-energy underwater distributary channels, low-energy underwater distributary channels, between underwater distributary channels, and beach-bar sedimentary microfacies; based on seismic facies and forward modeling analysis, the amplitude-type envelope is selected The attributes characterize the distribution of sedimentary facies. It is believed that there are NW and NEE provenances in the Xu 2nd Member, and a small amount of provenance can be provided in the east. Under the background of the overall lake level decline, the underwater distributary channels are widely distributed; the Xu 2 Member has typical development In tight sandstone reservoirs, high-energy underwater distributary channels are the most favorable sedimentary facies belts for reservoir development, and the configuration of high-quality reservoirs and fault zones determines the “sweet spot” for oil and gas exploration in tight sandstones. Combined with the results of multi-scale fracture prediction, the spatial distribution of the “fractured body” reservoirs deposited in the braided river delta is finally described. "Desserts" section. The study proposes a prediction method for the sweet spot of tight sandstone "fractured body" reservoirs, which enriches the sedimentary research of tight oil and gas reservoirs and provides a reference for the exploration of the same type of unconventional tight oil and gas reservoirs.

Low resistivity reservoir genetic analysis based on sedimentological environment

Feiteng Wang[1*], Jingmin Guo[1], Dongmei Hou[1], Hongliang Song[1], Bowei Liu[1]
1. Bohai Oilfield Research Institute, Tianjin Branch of CNOOC Ltd., Tianjin, CHINA
E-mail: feiteng.wang@outlook.com

Keywords: low resistivity reservoir, genetic analysis, paleoclimate, hydrodynamic action

Low resistivity reservoir is widely distributed in N_1gIII formation, Bohai Sea area, and the genetic analysis has important research significance to clarify reservoir characteristics. Therefore, taking C oilfield, Bohai Sea area as an example, X-ray diffraction (XRD), cation exchange capacity (CEC) analysis, bound water mineralization degree measurement, scanning electron microscopy (SEM), grain size analysis, log interpretation, and productivity test were used to study the influence of sedimentological environment on reservoir resistivity. Through the above analyses, this study discussed the characteristics of paleoclimate and hydrodynamic action, and then the genesis of low resistivity reservoir were established. The results showed that the content of smectite is more than 60% while the climate is dry and cold, which leads to the high content of CEC (15-50 mmol/100g) and bound water mineralization degree (4-7 mg/L). Moreover, honeycomb-shaped smectite has a large surface area, and water molecules preferentially adsorb on it, so the resistivity is relative low. Humid and warm climate leads to the high kaolinite content (more than 70%) and low CEC (1-10 mmol/100g) and bound water mineralization degree (1-3 mg/L) content, while page-shaped kaolinite is not conducive to the enrichment of water molecules, which results in the normal resistivity. The low resistivity reservoir has a poor hydrodynamic action, which leads to a small grain median diameter (less than 50um), while the logging curve is campaniform and the average single well cumulative productivity is less than $1*10^5m^3$. The normal resistivity reservoir has a strong hydrodynamic action, while the grain median diameter is between 70 and 200um, and the logging curve is box like and the average single well cumulative productivity is more than $2*10^5m^3$. Taking resistivity of 4 Ω·m as the threshold value, and ensuring the resistivity greater than 4 Ω·m during drilling could improve single well productivity.

Lignite macrolithotypes sequence in the Erlian Basin and its control on nature fracture distribution

Ming Yuan[1], Shuaifeng Lyu[1*], Shengwei Wang[1]
1. School of Earth Resources, China University of Geosciences (Wuhan), Wuhan, Hubei, CHINA
E-mail: lyusf@cug.edu.cn

Keywords: lignite macrolithotypes, Erlian Basin, coal facies, natural fractures, CBM sweet spot

Lignite profiles in the Erlian Basin show a well-developed macrolithotype sequence, starting from the detritic coal, then to xylitic coal, and fusitic coal at last upwards in order. The petrography and palynology analysis shows that the macrolithotypes variation corresponds to the gradual drying of the swamps and shrinking influence of clastic-input. The detritic coal as the base of the cycle is related to low-position swamps with abundant water and clastic supplies. In contrast, xylitic coal in the upper part of the cycle is formed in the relatively dry swamp, less affected by the invasion of flooding and the clastics. And the fusitic coal is closely related to a further oxidizing environment.

Natural fractures which can provide good seepage channels for coalbed methane (CBM) and are conducive to the production of CBM in coal reservoirs, are controlled by macrolithotypes as observed in the profiles. Due to the weak mechanical strength identified by the mechanical tests, the xylitic coals have better natural fractures, being the favorable reservoir intervals. In profiles, xylitic coal is usually found in coal seams with a thickness larger than 2 m, indicating the complete coal facies cycle is thicker than 2 m. For ultra-thick coal seams, xylitic coal is likely to be divided into individual intervals by detritic coal, which could be identified through the cores or logging curves. This developed geological model of fracture based on the macrolithotype sequence can accurately predict the sweet spot to improve the efficiency of CBM exploration.

Pore evolution mechanism of shale in the first member of the Qingshankou Formation in the Songliao Basin

Xin Wang[1*]
1. School of Geosciences, China University of Petroleum (East China), Qingdao, Shandong, CHINA
E-mail: 1554147573@qq.com

Keywords: Shale, Pore evolution, Qingshankou Formation, Songliao Basin

Shale pore evolution is a complex physicochemical synergistic evolutionary process, and most current studies stagnate at the stage of revealing pore evolution characteristics and laws based on reservoir characterization techniques. Thus, the pore genesis and evolution mechanisms are not understood sufficiently well. Therefore, to reveal the mechanism of shale pore evolution, mineral component analysis, geochemical analysis, microscopic observation, and quantitative characterization of pores were conducted in the first member of the Qingshankou Formation in the northern Songliao Basin. With increasing maturity, the porosity, pore volume, and specific surface area all first decreased and then increased. Moreover, when 0.8% < Ro < 1.4%, porosity continues to be at the maximum and is dominated by small-scale pore development. The evolution process is mainly because of compaction, hydrocarbon generation, acid discharge of organic matter dissolution, cementation, and clay transformation, among which dissolution results in the reduction of mineral volume and the increasing pore size is mainly attributed to the dissolution of calcite, feldspar, and pyrite. The transformation of clay minerals is mainly influenced by temperature and pressure, and the pores are increased by reducing the mineral volume. Compaction and cementation are mainly caused by the pores being squeezed by the formation and filled by quartz, pyrite, and other cements, resulting in pore reduction, thus establishing the shale pore evolution model.

Reservoir characteristics and influencing factors of Yan-9 Formation in Huanxian area, Ordos Basin, China

Chang Gao[1], Jingchun Tian[2*]

1. Energy Department, Chengdu Institute of Geology and Mineral Resources, Ministry of Natural Resources, Chengdu, Sichuan, CHINA

2. Institute of Sedimentary Geology, Chengdu University of Technology, Chengdu, Sichuan, CHINA

E-mail: tjc@cdut.edu.cn

Keywords: Ordos Basin ,Huanxian area, Yan-9 oil Member, diagenesis, reservoir characteristics

The Ordos Basin is rich in oil and gas resources, and the Jurassic oil reservoir is one of the main oil layers of the Mesozoic in the basin. Based on analysis of casting thin sections, SEM, porosity and permeability, and pressure mercury testing, the reservoir characteristics of Jurassic Yan'an Formation Yan-9 oil Member are studied and the factors affecting the reservoirs are discussed. It shows that the Yan-9 oil Member is composed of feldspathic lithic sandstone and lithic quartz sandstone, with moderate to good compositional maturity, medium structural maturity. Intergranular pores and feldspar dissolved pores are the major reservoir space. The throats in the sandstone occur as elongated, middle to thin punctiform and flake. Physical properties of the reservoir sandstones are characterized by low porosity and low permeability with good correlation of porosity and permeability. It reveals that the development of the reservoir is affected by following factors: firstly, sedimentary microfacies determined the location of the reservoir; secondly, early chlorite cementation and dissolution enhanced the accumulation property of the reservoir.

Carbonate cements in Eocene turbidite sandstones, Dongying Depression, Bohai Bay Basin: origin, distribution, and effect on reservoir properties

Guoqiang Luan[1], Chunmei Dong[1*], Chengyan Lin[1], Lihua Ren[1]
1. School of Geoscience, China University of Petroleum (East China), Qingdao, Shandong, CHINA
E-mail: dongchunmei1@126.com

Keywords: Turbidite sandstone, Carbonate cements, Diagenesis, Geochemistry.

Diagenetic carbonate cements occur throughout Eocene turbidite lithic arkose in Niuzhuang Sag, Eastern China, displaying as sporadical siderite, dolomite, calcite 1 (C1), and massive ankerite (Ak) and calcite 2 (C2). Petrographic and geochemical investigations suggest that the non-ferroan C1 (δ13Ccar +3.1 to +4.7‰VPDB; δ18Ocar −12.5 to −10.5‰VPDB) was the earliest carbonate cement that was followed by Ak (δ13Ccar +0.2 to +5.1‰VPDB; δ18Ocar −12.8 to −10‰VPDB) and ferroan C2 (δ13Ccar +2 to +3.1‰VPDB; δ18Ocar −12.6‰ to −15.8‰ VPDB). The homogenization temperatures (Th, 74.3 to 105.8oC, 105.6 to 130.4oC, and 119.7 to 144.6oC, respectively) reflect the pattern of increasing temperature with progressive burial. The δ13Ccar values suggest that C1 and C2 were mainly derived from dissolution of carbonates in calcareous shales (δ13Ccar +3.5‰ to +6.3‰VPDB), with minor contributions from organic matter. The δ13Ccar values of Ak documented some contributions from magmatic carbon.

Ankerite and C2 were restricted under the top seal (geochemical barrier) of overpressure compartment and the of highly cemented zones occur mainly along faults. Carbonate cementation seems to negatively impact the reservoir quality when it exceeds 10%.

Keywords: coupling evolution model, thermal hydrocarbon generation, clay mineral transformation, diagenetic evolution process

Shale formation is an unconventional and complex oil-bearing system with the trinity of source, reservoir and cap. The coupling variation of thermal maturation hydrocarbon generation, nanoscale porosity and diagenesis is the key scientific issues affecting the shale gas accumulation. The main research methods of the coupling evolution of mature hydrocarbon generation, nanoscale porosity and diagenesis of shale are direct observation and physical simulation, both of which have their own advantages and limitations. In this research, a comprehensive study on hydrocarbon generation, nanoscale pore structure and diagenesis of natural marine shale samples from the low-mature Mesoproterozoic Xiamaling shale in Zhangjiakou of Hebei Province was carried out, and diagenetic physical simulation was carried out on the selected samples. Basic geochemical analysis, mineral composition and content testing, characterization of nanoscale pore structure and other qualitative and quantitative experiments were carried out on natural and thermal samples. Nanoscale pore structure evolution and diagenesis of the shale during thermal maturation were discussed. Thus, the coupling variation relationship among thermal maturity hydrocarbon generation, nanoscale pore structure and diagenesis of the Xiamaling shale is clearly and intuitively revealed.

The nanoscale pore system of the researched natural shale is composed of organic pores and matrix pores, the organic hydrocarbon generation and diagenesis are the two main issues influencing their generation and variation. During the variation process, hydrocarbon generation and diagenesis have different influences on the generation and variation of the nanoscale pore system, and then resulting in different variation trends. The simulation experiment show that, the nanoscale pore diameter did not change significantly, while the pore volume decreased first and then increased, reaching the minimum and maximum values at 350°C and 650°C, respectively. The surface area of micropores and mesoporous pores firstly decreased and then increased, reaching the minimum value at 350°C, while the surface area of macropores firstly increased and then decreased, reaching the minimum value and maximum value at 350°C and 650°C, respectively. The diagenetic evolution of the simulation experiment can be roughly divided into four stages, and the main diagenetic types are clay mineral transformation, dissolution, thermal maturation hydrocarbon generation, compaction and recrystallization. In this study, the diagenetic evolution process and pore evolution model of the shale were roughly divided, and the coupling evolution model of thermal mature hydrocarbon generation, diagenesis and pore structure of shale was established based on natural shale sample observation and thermal simulation experiment.

The established coupling evolution model in this research provides a qualitative and quantitative evaluation method for the organic matter hydrocarbon generation, diagenesis and nanoscale pore structure variation of the organic-rich shale. The model has important guiding significance for the reservoir evaluation, the shale gas accumulation mechanism, as well as shale gas exploration and development of the Mesoproterozoic Xiamaling shale in Zhangjiakou, Hebei, but also very important for the other low mature shale of the world.

Keywords: Shale oil, Sequence stratigraphy, Parasequence, Organic matter, Well log, Sweet-spot area prediction

Chang 7 Shale and Qingshankou Shale characterized by lacustrine black organic-rich shales, have become the target for shale oil exploration and development in the Upper Triassic Ordos Basin, and the Upper Cretaceous Songliao Basin, China, respectively. However, the heterogeneous enrichment of organic matter (OM) has led to controversy regarding source rock evaluation and difficulty in accurate prediction of favorable zones in the both basins. Sequence stratigraphy, as a tool for prediction of sedimentary deposits has encountered challenges in lacustrine deep-water environments because of rapid facies changes and limited lateral continuity of key beds. Based on the high order sequences division (parasequences and the T-R cycles within them), this study aims to illustrate the spatiotemporal coupling interaction among tectonic activity, volcanic eruption, climate and lake-level change, water anoxia, and gravity flow activity (e.g. hyperpycnal flow deposition) during high order sequences periods. Depositional sequences have a significant effect on the enrichment of OM, given 1) promising OM types controlled by late TST and early RST, 2) the OM enrichment determined by shale facies with different laminae combination types, and 3) the distribution of shale facies controlled by T-R cycles within parasequences. In particular, the most favorable locations are the longer transgression parts in parasequences in the late TST and early RST. A novel method is proposed to predict OM enrichment based on calibration of well logging and core lithology through analyses of thin sections and geochemical data from 238 core samples in Ordos Basin, and 220 core samples in Songliao Basin, as well as the available well-logging data from the selected wells. By linking meter-level depositional sequences with centimeter-level OM enrichment, this study provides an alternative approach to determine the sweet-spot intervals in a single well profile and realize isochronous inter-well sweet-spot area prediction for shale oil exploration.

Sedimentary environment and organic matter enrichment for the Upper Permian Longtan Formation transitional shale in Southern Anhui Province, South China

Jianghui Ding[1*], Xiangtong Yang[1], Ruyi Wang[1], Bo Huang[1], Huili Li[1], Shiyuan Qu[1]
1. Research Institute of Downhole Operation , CNPC Engineering Technology R & D Company Limited, Beijing, CHINA
E-mail: djhdream2015@163.com

Keywords: transitional shale, organic matter, sedimentary environment, controlling factors, Longtan Formation

The marine-continental transitional organic-rich shale in the Longtan Formation in Southern Anhui Province, South China is not only considered as an excellent source rock in the Lower Yangtze region, but also one of the important layers of shale gas exploration in China. In order to clarify the relationship between sedimentary environment and organic matter accumulation in such a setting, a case study was carried out from one core (Gangdi-1 well) and two outcrops (Changqiao outcrop and Daoshanchong outcrop) by conducting organic geochemical test, organic petrologic study, argon ion polishing-scanning electron microscopy (SEM) observation, elemental geochemical analysis. Results show that shales developed in a tidal flat-lagoon environment display high TOC contents ranging from 6.16% to 10.10% (average 8.50%), whereas these formed in a deltaic environment exhibit medium-high TOC contents varying from 0.93% to 6.70% (average 3.26%). These data also elucidate that the target shales in the Longtan Formation were deposited in a complex paleoenvironment with strong water-mass restriction that was mainly characterized by warm and humid paleoclimate, high primary productivity, oxic-to-dysoxic conditions, and a high sedimentary rate. Besides, the transitional shale formation is not determined by a single factor but is the result of the mutual configuration and coupling of multiple factors such as paleoclimate, paleoredox conditions, paleoproductivity, and sedimentary rate. All these factors will directly or indirectly affect the supply or preservation of organic matter. Furthermore, the “integrated model” for transitional organic matter accumulation is proposed. The model stresses two aspects: on one hand, the warm and humid paleoclimate not only facilitates the growth of higher plants, but also accelerates the chemical weathering rate of the parent rocks and increases the input of nutrients to the water column, which is conducive to the blooms of lower aquatic organisms. Both higher plant debris and lower aquatic organisms together provide abundant organic matter sources. On the other hand, although the oxidized water environment is usually unfavorable for organic matter preservation, a higher sedimentary rate can greatly shorten organic matter exposure time in the decomposition region of aerobic bacteria, and a number of organic matters cannot be oxidized or degraded through the rapid burial. These findings also add to our knowledge that despite the oxygenated water environment during transitional shale deposition, TOC contents are not necessarily lower.

Natural gas hydrate enrichment and occurrence under the control of different migration pathways in the Qiongdongnan Basin, South China Sea

Tingna Zuo[1], Ren Wang[1*]
1. School of Earth Resources, China University of Geosciences (Wuhan), Wuhan, Hubei, CHINA
E-mail: 1973453157@qq.com

Keywords: Qiongdongnan Basin, natural gas hydrate, enrichment, occurrence, migration pathways

The deep-water area of the Qiongdongnan Basin (QDNB) has considerable gas hydrate resources and these gas hydrates were recovered with multiple geomorphology occurrences, including massive, layers, nodules, fracture filling and disseminated. However, there are few studies on the migration efficiency of migration pathways and the occurrence of hydrate. In this study, 2D and 3D seismic and logging while drilling data, gas hydrate samples, and basin simulation have been used to explore the geological occurrence and enrichment mechanism of gas hydrates controlled by different migration pathways in the QDNB. Based on the seismic reflection characteristics, we identified that diapirs, fault structures and fractures constitute the three main types of natural gas migration pathways in the QDNB. In addition, according to the basin modeling results, drilling results, resistivity spectrum, hydrate core and relative saturation analysis, hydrate enrichment and occurrence controlled by different migration pathways had been explored. The results show that the gas chimney migration pathway is characterized by continuous vertical gas distribution, sufficient gas supply, and high migration efficiency, it makes a significant contribution to hydrate enrichment. The gas hydrate was characterized by massive, layers, veins and nodules at different depths. In addition, the characteristics of deep faults are high efficiency, long-distance and it also has a significant influence on hydrate enrichment. Thermogenic gas migrates vertically through faults and eventually enrichment in the gas hydrate stability zone (GHSZ), leading to the formation of the layers, plaque and near-fault gas hydrates. Compared with the other two migration pathways, the fracture system have low migration efficiency, it is not conducive to the formation of widely distributed, and high-saturation gas hydrate. natural gas migrates through fractures and microcracks, resulting in the formation of thin-bedded, fracture filling and disseminated gas hydrate. These conclusions indicate that the migration pathways are regionally distributed, and closely related to hydrate enrichment and occurrence.

Can Eocene lacustrine organic-rich shales formation in the South China Sea linked to astronomically forced climate change and the Middle Eocene Climatic Optimum (MECO)?

Xiaosong Wei[1], Detian Yan[1*]
1. Faculty of Earth Resources, China University of Geosciences (Wuhan), Wuhan, Hubei, CHINA
E-mail: yandetian@cug.edu.cn

Keywords: Organic-rich shales, Astronomical forcing, Middle Eocene Climatic Optimum, Eocene, South China Sea

The formation of organic-rich shales is believed to be caused by short-term geological events. However, the existing lacustrine sedimentary record in the South China Sea has an inadequate temporal resolution, limiting the study of geological events' temporal constraints and the coupling relationship with organic-rich shales. In this study, we performed a cyclostratigraphy analysis on the Eocene sedimentary records of two basins on the northern margin of the South China Sea. The astronomical time scale (ATS) was constructed by astronomical tuning with absolute ages. The time of the Eocene organic-rich shales in both basins, according to the ATS, is around 40 to 41 Ma, which corresponds to the Middle Eocene Climatic Optimum (MECO). This result suggests a potential link between organic-rich shale and MECO. To further explore the possible response mechanism for the formation of organic-rich shales, we reconstructed lake level variations of both basins using DYNOT and ρ1 noise modeling techniques. We then conducted a comprehensive comparative analysis of astronomical forcing, lake level changes, and geochemical changes of organic matter enrichment element ratios. Our results reveal that the development periods of organic-rich shales correspond to eccentricity maxima, relative lake level rise, and the MECO. Inversely, organic-lean shales correspond to eccentricity minima and relative lake level decline. These results could suggest that astronomically-induced climate change has positive feedback on forming organic-rich shales. High eccentricity intensifies monsoon rainfall and weathering intensity. Thus, nutrients from intensified monsoon rainfall and weathering promote algae blooms in the surface water, resulting in high primary productivity. The lake water becomes deep during the MECO than it was before. Therefore, the lake water stratifies, and organic matter deposits and is preserved under the bottom water of a fresh-brackish and weak oxidation-weak reducing environment, resulting in the so-called excellent-quality source rock.

The Accumulation Model of Quaternary Mudstone Gas Reservoir in Sanhu Depression, Qaidam Basin

Xiaoxue Liu[1*]

1. Unconventional Oil and Gas Science and Technology Research Institute, China University of Petroleum,Beijing, Beijing, CHINA

E-mail: Iris_1314_Iris@163.com

Keywords: Biogenetic Mudstone Gas Reservoir, Quaternary, Reservoir Forming Conditions, Accumulation Model, The Sanhu Depression

The study of formation conditions and accumulation model of biogenetic mudstone gas reservoir in Sanhu Depression is beneficial to improve the accumulation mechanism and enrichment rule of biogenetic gas reservoirs, and has important theoretical and practical significance for guiding the exploration and development of Quaternary mudstone gas reservoirs. Taking quaternary mudstone in Sanhu Depression as the research object, the reservoir forming conditions of quaternary mudstone in Sanhu Depression were determined and the accumulation model was established through soluble organic carbon analysis, porosity determination, chromatography-mass spectrometry analysis and other experiments. The results show that the high content of soluble organic carbon, herbaceous humic organic matter, as well as the cold and dry, are conducive to the generation of biogenetic mudstone gas. The Quaternary formation in Sanhu Depression has the characteristics of high porosity and low permeability. And a large number of micro-nano pores are developed, which provide a large amount of pore space for the occurrence of biogenetic gas. Besides, gas flow is given priority to fick diffusion and slip flow. Due to the self-sealing effect of mudstone, the biogenetic gas accumulates in situ. In the late Himalayan tectonic movement, the gas containment of mudstone was destroyed. By the buoyancy, gas migrated upward and gathered in mudstone of high part which was adjacent area of gas generating center, superimposed longitudinally with sandstone biogenetic gas reservoirs

Tight oil reservoir characteristics and controlling factors of Fengcheng Formation in Manan slope area of Junggar Basin

xiang shan[1*]

1. Department of Laboratory Research, Petrochina Hangzhou Research Institute of Geology, Hangzhou, Zhejiang, CHINA
E-mail: 472515756@qq.com

Keywords: Tight oil, Fengcheng Formation, Unconventional reservoir, Mahu depression, Junggar Basin

As unconventional oil and gas resources, tight oil and shale oil have become an important replacement of conventional oil and gas and an important type of increasing oil and gas reserves and production all over the world. Fengcheng Formation in Junggar basin is an important succeeding formation for continental tight oil and shale oil exploration in Western China. In recent years, Fengcheng Formation in Manan slope area in the northwest margin of Junggar basin has made a breakthrough in oil and gas exploration for the first time in the outer front of delta silty-muddy tight reservoir, but the characteristics and control factors of this type of reservoir are unclear, and there are no relevant research reports. Based on the data of cast thin section, physical properties, whole rock X-ray diffraction, field emission electron microscope, high-pressure mercury injection and physical properties, the petrological characteristics, pore characteristics and pore structure of Fengcheng Formation tight oil reservoir in Manan slope area of Junggar basin are analyzed. On this basis, the reservoir control factors are discussed. The results show that: on the plane, the content of terrigenous clasts in reservoir rocks decreases from the basin edge to the depression, The content of pyroclastic and authigenic minerals increases, which shows the orderly distribution law of sandy conglomerate → sandstone → tuffaceous sandstone → sedimentary tuff; Vertically, the bottom of Feng2 member is relatively fresh water sedimentary (tuffaceous) siltstone, the middle is salt water sedimentary cloud sandstone, and the top is sedimentary tuff affected by volcanic eruption. The tight oil reservoir lithology of Fengcheng Formation in slope area is mainly the combination of (tuffaceous) sandstone, dolomitic sandstone and sedimentary tuff. Among them, the physical property of (tuffaceous) sandstone is the best, the TOC content is the lowest. The physical property and TOC content of dolomitic sandstone are medium. The physical property of sedimentary tuff is the worst, but has the highest TOC content. The pore types of the reservoir are mainly residual intergranular pores and microfractures. The pore size is ten microns (1 ~ 20 μm) to hundreds of nanometers; The strong compaction caused by high tuffaceous matter is the main reason for the tight and low permeability of the reservoir. The devitrification of medium basic tuffaceous matter forms feldspar, which further destroys the pore structure of the reservoir; Reservoirs with higher content of terrigenous sand have higher porosity and wider pore throat; Micro fractures can effectively improve reservoir permeability. Reservoirs developed more fractures have better seepage capacity and higher oil production.

Chlorite characterization and diagenetic evolution as primary controls on Zhuhai Formation tight sandstone reservoir quality in Zhu-III sag, Pearl River Mouth Basin, South China Sea

Junfeng Zhang[1*]
1. School of Earth Resources, China University of Geosciences(Wuhan), Wuhan City, Hubei Province, CHINA
E-mail: ziyuanzhangjf@cug.edu.cn

Keywords: Tight sandstone, Reservoir, Diagenetic evolution, Chlorite

Zhu-III sag is a rich-hydrocarbon sag in the Pearl River Mouth Basin. The Oligocene Zhuhai Formation is a key exploration horizon in Zhu-III sag. However, the exploration results show that the reservoir is deeply buried and belongs to tight sandstone reservoir, the diagenesis is complex and the reservoir heterogeneity is strong. Therefore, looking for high-quality reservoirs, which are zones with relatively high porosity and permeability, is a key point of resource exploration. Based on the previous research results, this study analyzed the reservoir characteristics and diagenesis characteristics, established the pore evolution model of the study area, and defined the main controlling factors of reservoir development and used core observation, thin section, scanning electron microscope, X-ray diffraction and so on. The research shows that compaction is the main reason for the reservoir densification of Zhuhai Formation. There are two kinds of chlorites in Zhu-III sag. Chlorite coating can effectively improve the reservoir quality. Another is chlorite cement which can destroy the pore structure. Different stages of fluid filling have various effects on the reservoir in study area. Fluid in the early stage leads to the carbonate cement and that in late stage leads to the dissolution of carbonate cement. In general, we clarify the diagenesis and pore evolution in key zones in Zhu-III sag and its reservoir is mainly affected by compaction, dissolution, chlorite and fluid filling. This study of reservoir diagenetic evolution process and pore characteristics is crucial and helpful in the exploration and development of reservoir in Pearl River Mouth Basin and other basin.

Keywords: Crude oil emulsion,Microvisualization,Confocal laser technology

1. Introduction

The field produced fluid of shale oil has not been studied effectively. At present, shale oil has entered the stage of combining exploration and development. Shale oil is lighter and less dense than conventional oil, and its field produced fluid is significantly different from conventional oil produced fluid. At present, emulsification phenomenon appears in shale oil field produced liquid, and it is necessary to study the characteristics and laws of emulsion [1].

The original technology is not suitable for the study of shale oil emulsion.

(1)Shale oil is light in weight, low in density, and volatile. The droplet size is generally small (mostly less than 10μm). Under conventional fluorescence or laser beam, it will rapidly volatilize or fuse together, making it difficult to analyze and study it [2].

(2) The original enterprise technical standard "Emulsified Oil Analysis - Laser Confocal Analysis Method" (Q/SY1236-2008) is not applicable to the analysis of shale oil [3].

Therefore, it is of great significance to establish the visualization analysis technology of shale oil emulsion microzone.

2. Main research contents and conclusions

For the first time, a laser confocal automatic cooling and heating platform was used for digital characterization of microzone distribution of shale oil emulsion.

(1)The specific process is as follows:

A pipette was used to remove 1 drop (50μ L) of mid-layer emulsion and place it on a 75mm×25mm×1.5mm flat slide with a 20mm×20mm cover slide.After the emulsion is evenly diffused, it is placed on the microscope platform [4].

Liquid nitrogen is extracted by automatic cooling and heating platform, and the air outlet pipe is placed on the loading platform. The temperature of the air outlet is controlled at 5℃ to ensure that the sample is in a lower temperature environment.

(2)Analysis of type and distribution frequency of shale oil emulsion

Experimental principle: using fixed wavelength laser excitation of dispersed oil, emulsified oil samples, components of crude oil have specific wavelengths of fluorescence signals, and the principle of water not emit fluorescence signal, to identify types of dispersed oil, emulsified oil, by confocal laser 2 D data acquisition technology, quantitative analysis technology, implementation of dispersed oil and emulsified oil particle size distribution of quantitative statistics and analysis [5].

dispersed oilThe oil with the droplet diameter of 10μm ~ 100μm in the emulsion is called dispersed oil.

emulsified oilThe oil with the droplet diameter of 10-3μm ~ 10μm in the emulsion is called emulsified oil.

Choose a representative field of view, but do not duplicate it.

Distribution frequency statistics of droplets with different equivalent diameters:

The equivalent pore diameters were 0μm < D≤5μm, 5μm < D≤10μm, 10μm < D≤15μm, 15μm < D≤20μm, 20μm < D≤25μm, 25μm < D≤30μm, 30μm < D≤35μm, 35μm < D≤40μm, 40μm < D≤45μm, 45μm, respectivelyThe number of droplets in the range of < D≤50μm and D > 50μm was determined to determine the distribution law of droplets with different equivalent diameters

Exploration potential of Second White Specks Formation in Alberta, Canada

Lanyu Wu[1*], Jinrui Guo[1], Zhongmin Zhang[1], Danni Shi[1]
1. Oversea Exploration&Project Evaluation Department, Exploration & Production Research Institute, Sinopec, Beijing, CHINA
E-mail: wulanyu.syky@sinopec.com

Keywords: Second White Specks, shale, logging facies, exploration potential

Alberta basin possesses the largest deposits of oil and natural gas in Canada. The Second White Specks (2WS) is a major oil and gas source rock as well as a proven hydrocarbon reservoir of Late Cretaceous in Alberta basin, which becomes a hot spot in academic study.

The 2WS Formation was deposited during the Laramide orogeny. Relative sea-level rise connected cold, nutrient-rich waters from the Boreal Sea with the warm waters of the Tethys Sea during the Turonian, which forms laminated calcareous/siliceous mixed shale. Due to the basin has a high geothermal gradient, the 2WS Formation can enter the maturity threshold at the burial depth of 6500 ft. The overpressure was mainly formed with the transformation of organic matter to oil and gas, which is advantageous to the formation of shale microfractures and improves the seepage capacity of shale reservoir. High quality source rocks and the effective lithological combination are the main controlling factors for the formation of shale oil enrichment.

Based on logging facies analysis for typical wells with high / low production, the logging response characteristics and logging identification standard of high capacity reservoir are determined. High capacity reservoir generally has the logging response characteristics of low GR, medium AC and medium-high ILD. The lower limit of logging response of high capacity reservoir can provide basis for resource potential evaluation of 2WS Formation.

Dominant controls on oil shale deposition in the Upper Cretaceous Nenjiang Formation, NE China: Evidence from petrographic and geochemical analyses

Ruiqian Chen[1*], Fei Shang[2], Zhuang Li[1]

1. Department of Petroleum Geology, China University of Petroleum Beijing, Beijing, CHINA

2. Department of Petroleum Geology, Research Institute of Petroleum Exploration & Development, China National Petroleum Corporation, Beijing, CHINA

E-mail: richen@cup.edu.cn

Keywords: Marine transgression, Organic-rich shale, Upper Cretaceous, Nenjiang Formation, Stable isotopes

The Songliao Basin located in northeast China is one of the most petroliferous basins in the world. The Upper Cretaceous Nenjiang Formation is an important source rock in the basin owing to its rich development of oil shale successions. From outcrop observation, we found that the oil shale successions can be divided into two types. The type I oil shale (TY1) is composed of multiple thin oil shale layers (~1m) interbedded with organic-poor shale layers and is typically developed in the first member of Nenjiang Formation (k_2n_1), whereas the type II oil shale (TY2) developed one thick succession of oil shale (~ 10 -15m) and was mainly found in the second member of the Nenjiang Formation (k_2n_2). To compare the difference in forming mechanisms with two types of oil shale successions, petrographic characteristics, stable isotopic compositions, and geochemical elements were analyzed from two outcrops (i.e., Yaojia Station and Houjingou Outcrops). Based on the results, a notable higher $\delta^{13}C_{org}$ values are recorded in the TY1, suggesting accelerated primary productivity. The observation of tuff layers and the relatively high P and Fe contents reveal that the frequent volcanic activities would have brought nutrient supply to the Songliao paleolake, thereby stimulating primary productivity and contributing to the deposition of multiple thin-layered oil shales. In contrast, the TY2 show decreased bulk sediment $\delta^{15}N$ suggests intensified denitrification under anoxic conditions. Combined with elevated trace elemental ratios and increasing trend of CIA, we attributed these changes to marine transgression that occurred at the beginning of k_2n_2 deposition. Such conditions increased the accommodation space and favored the formation of stratified, anoxic bottom waters, which might have promoted organic matter preservation and further responsible for the deposition of thick oil shale succession in k_2n_2.

Division and discrimination of hydrocarbon dynamic field in Huizhou Sag, Pearl River Mouth Basin

Tingting You[1], Xiongqi Pang[1*]
1. College of Geosciences, China University of Petroleum (Beijing), Beijing, Changping District, Beijing, CHINA
E-mail: Pangxq@cup.edu.cn

Keywords: The lower boundary of buoyancy-controlled hydrocarbon accumulation,the bottom boundary of hydrocarbon accumulation,hydrocarbon dynamic fields,Huizhou sag

With the in-depth exploration of the middle and shallow layers, the exploration difficulty and risk of conventional structural traps in the middle and shallow layers of the Huizhou Sag, Zhuyi Depression, Pearl River Mouth Basin have become increasingly difficult. The exploration of deep paleogene oil and gas has become the main research direction of oil and gas exploration in recent years. However, in addition to the partial reserves obtained in the Zhuhai Formation, the reserves found in the depressions of Enping and Wenchang Formations are not evenly distributed, and the dynamic boundary distribution of deep unconventional oil and gas resources is unknown, which seriously restricts the exploration process of deep oil and gas in Huizhou depression. In view of this, based on geological, logging interpretation, oil test and high-pressure mercury injection data, the statistical analysis of reservoir physical properties and reservoir examples method are used to analyze the distribution characteristics of reservoir porosity and permeability as well as the distribution law of oil, gas and water. It is concluded that the lower boundary of buoyancy-controlled hydrocarbon accumulation in Huizhou depression corresponds to porosity of 8.5%, permeability of 1mD and depth of 3500-4000m. The calculation methods of the minimum flow pore throat radius and the potential difference between the inside and outside of the reservoir were used to analyze the seepage capacity of reservoir pore-throat and the ratio of potential energy at the reservoir interface with the depth, which were verified by the actual drilling results. It was concluded that the porosity corresponding to the bottom limit of hydrocarbon accumulation in Huizhou Depression was 1.72%-2% , the pore-throat radius was about 0.0325um and the depth ranges from 6000-6500m. The research results have important practical significance for the prediction of the boundary range of favorable exploration areas, the evaluation of oil and gas resource potential and the deployment of oil and gas exploration plans in Huizhou depression.

Biogenic microcrystalline quartz and its influence on pore development of marine shale reservoirs: Lower Paleozoic Wufeng and Gaojiabian Formations, Lower Yangtze Platform, China

Baxiu Wang[1], Penghui Zhang[1,2*]

1. College of Oceanography, Hohai University, Nanjing, Jiangsu, CHINA

2. Laboratory for Marine Mineral Resources, Pilot National Laboratory for Marine Science and Technology, Qingdao, Shandong, CHINA

E-mail: zph010@163.com

Keywords: marine shale, biogenic microcrystalline quartz, silica sources, geomechanical properties, pore evolution, Wufeng-Gaojiabian Formations

Quartz is one of the most important minerals in marine shales, displays several forms and has multiple origins. In addition, different types of quartz may contribute differently to the geomechanical properties and pore evolution, but their relationships have been less extensively investigated. In this study, a suite of the Upper Ordovician Wufeng and the Lower Silurian Gaojiabian marine shale samples were collected from well GD-1 of the Lower Yangtze Platform in order to better understand quartz types, silica sources, as well as the influence of biogenic microcrystalline quartz on geomechanical properties and pore evolution, with the applications of X-ray diffraction analysis, geochemical analysis, optical microscopy, field emission scanning electron microscope combined with cathodoluminescence (SEM-CL) technique. The results show that quartz types of Well GD-1 are mainly detrital quartz, microcrystalline quartz and organism skeletal quartz. Detrital quartz is characterized by bright luminescence. Microcrystalline quartz is non or low luminnescene, indicative of authigenic origin. Siliceous organism fragments such as radiolarians and sponge spicules, biogenic silica content, Al-Fe-Mn ternary diagram and negative correlation of SiO_2 with Zr, indicate that siliceous organisms provide an important silica source for microcrystalline quartz. Biogenic microcrystalline quartz in the studied shale can be interconnected to form a rigid siliceous matrix framework, which will most likely enhance the rock strength. Moreover, it can effectively protect the organic matter pores and intergranular pores in microcrystalline quartz from compaction, which is conducive to pore preservation.

Influence of developmental characteristics of clastic grains on physical properties of deep glutenite reservoirs in Chezhen Sag

shaoshuai Li[1*]
1. School of Geosciences, China University of PetroleumEast China, Qingdao, Shandong, CHINA
E-mail: 2268655012@qq.com

Keywords: reservoir, Shahejie Formation,detrital grains,pore evolution

The Chezhen Sag is an east-west extending fault basin in the north of the Jiyang Depression. The reservoirs in the lower sub-member of the third member of the Shahejie Formation are mainly of nearshore subaqueous fan origin and developed in a semi-deep lake-deep lake environment. Previous scholars have conducted detailed research on the provenance of the reservoir in this area. Lin Hongmei and other scholars divided the Chezhen area into three areas: felsic parent rock, carbonate parent rock and mixed parent rock according to the type of parent rock. In this study, a detailed comparative study of the reservoir physical properties of the two wells was carried out based on the data of logging, core scanning, and microscope observation data of the two wells Che 660 and Daxie 722 in the mixed parent rock area of the Chezhen Sag. The study found that although the types of debris in the two wells are generally similar, there are obvious differences in the type of pores and the degree of development. Therefore, in this study, the debris particles of the two wells are classified and counted in detail to analyze their differences and study their impact on the reservoir. physical influence.

Detrital sandstone is developed in Well Che 660, and the detrital particles are mainly detritus, among which the sedimentary rock detritus has the highest content, mainly dolomite detritus and limestone detritus; the second is metamorphic detritus, mainly metamorphic volcanic detritus and Metamorphic quartzite cuttings; the lowest content of magmatic rocks. In addition, the content of quartz particles is high, while the feldspar particles are few and almost invisible. In addition, the content of quartz particles is high, while the feldspar particles are few and almost invisible. The cements are mainly calcite and dolomite, and a small amount of iron calcite, iron dolomite and pyrite are also developed. Its pores are mainly developed by intergranular dissolution, sedimentary rock debris dissolution and a small amount of structural fractures, mainly secondary pores, and few primary pores, and the overall physical properties of the reservoir are poor.

Detrital sandstone is also developed in Well Daxie 722, and the debris particles are mainly debris, among which sedimentary rock debris and metamorphic rock debris have the highest content, sedimentary rock debris is slightly higher than metamorphic rock debris, magmatic rock content is the lowest, and the type of debris Similar to Che 660 well. However, both feldspar grains and quartz grains are developed in a certain amount, and the content of feldspar grains is relatively high. The cements are mainly calcite and dolomite, and basically no other minerals are cemented. The pore development type is mainly intergranular dissolution, feldspar dissolution pores, sedimentary rock debris dissolution and structural fractures are also developed, and the overall physical properties of the reservoir are relatively good.

4. Zichang Oil Production Plant, Yanchang Oilfield Co., Ltd., Zichang, Shaanxi, CHINA
E-mail: 869221614@qq.com

Keywords: Ordos Basin, Chang 6 low-permeability reservoir, Detrital components, Pore-throat structure,Fractal characteristics

Low and ultra-low permeability sandstone reservoirs are widely developed in the Upper Triassic Yanchang Formation in the Ordos Basin, and the microscopic pore structure characteristics are closely related to the reservoir quality and oil and gas distribution. The Chang 6 oil layer formation in the Xiaojiahe area has the problems of poor reservoir physical properties, strong heterogeneity, and high water content. Research on the microscopic pore structure of the reservoir is of great significance to the exploration and development of low-permeability-ultra-low permeability reservoirs. Utilizing core observation, thin section identification, scanning electron microscope observation, physical property test, and mercury injection analysis, combined with fractal theory, this paper studies the petrological characteristics, pore structure characteristics, fractal characteristics, and influencing factors of reservoir quality of Chang 6 reservoir in this area. The results show that : (1) The Chang 6 reservoir in the Xiaojiahe area is dominated by fine-grained feldspathic sandstone, which has the characteristics of low composition maturity, high structural maturity, and good sorting. The pore type is mainly intergranular pores, and feldspar dissolved pores and intergranular micropores are also developed. The reservoir is characterized by low porosity (average porosity is 8.95 %) and low and ultra-low permeability (average permeability is 1.14 mD). (2) There is a certain positive correlation between the content of quartz and feldspar in clastic components and reservoir physical properties. Among them, potassium feldspar is conducive to improving the magnitude of permeability, while plagioclase accounts for a small proportion, which has a weak impact on reservoir physical properties. The content of plastic components such as biotite and interstitial material is negatively correlated with physical properties. (3) Chang 6 sandstones can be divided into four types according to the characteristics of mercury intrusion curves, and the reservoir quality gradually deteriorates from type I to type IV. Parameters such as displacement pressure and pore throat radius in the pore structure parameters have a good correlation with reservoir physical properties. (4) Based on the pore fractal model of the capillary pressure curve, all sandstones can divide the $Lg(S_{Hg})$-$Lg(P_c)$ curve into two segments by the r_{apex} value (Pittman's plot apex radius) for fractal analysis. The first segment ($r>r_{apex}$) represents a relatively large pore-throat fractal characteristic, the calculated fractal dimension D_1 is greater than 3 and does not have a fractal characteristic. The rear segment ($r<r_{apex}$) represents a relatively small pore-throat fractal characteristic, and the fractal dimension D_2 is between 2.19 and 2.73. The weighted average algorithm was used to calculate the comprehensive fractal dimension D_{ave} and D_P. The correlation analysis between fractal dimension and physical parameters, pore throat structure parameters, and reservoir quality index (RQI) shows that D_2 and D_P are more suitable for characterizing the complexity and heterogeneity of microscopic pore structure. In conclusion, the quality of low and extra-low permeability sandstone reservoirs is controlled by the combination of clastic fraction, pore structure, fractal characteristics, and other factors.

Characteristics of new marine shale and new sedimentary model: Exploration of shale characteristics from Ordovician Wulalik Formation in Ordos Basin

Li Fengjiao[1], Dongdong Zhang[1*]
1. Department of Geology, Northwest University, Xi'an, shaanxi province, CHINA
E-mail: zhangdd@nwu.edu.cn

Keywords: the Wulalik Formation, sedimentary model, the deep-sea shelf facies

For a long time, marine shale gas in China has only been discovered in the Sichuan Basin on the Yangtze Plate. Until last year, a breakthrough was made in shale exploration in the Ordovician Wulalik Formation in the western Ordos Basin. This shale interval is all different from the well-known Wufeng Formation-Longmaxi Formation shale in the Upper Yangtze Platform in southern China and the Barnett shale in North America. Low-porosity, low gas content, low-pressure coefficient, and high brittleness index (higher carbonate content) are known as "new" marine shale.

The sedimentary environment is dominated by platform margin slope facies and deep-sea shelf facies. However, in the actual exploration and research, it is found that there are various lithologic combinations in the organic-rich interval of the Wulalik Formation, and there may be mixed deposits of different facies at the same time. This deposition also shows that the tectonic setting of the edge of the Ordos Basin was unstable in the Ordovician, and different types of miscible deposits will have an impact on the distribution and enrichment of shale oil and gas.

The study area has high clay mineral content (47.8% on average) and low carbonate content (7.1% on average), with quartz and feldspar content (44.9% on average) in the middle. There are siliceous mudstones and limestones at the bottom of the Wulalik Formation; from the middle to the upper part, the siliceous content gradually decreases, and the content of clay minerals gradually increases. The siliceous mudstone at the bottom of the Wulalik Formation has the highest organic carbon content (average: 0.82%) and hydrocarbon generation potential (average: 1.53 mg/g), and the upper Wulalik Formation has the organic carbon content (average: 0.29%) and hydrocarbon generation potential (average 0.24 mg/g) poor.

The mineral composition of the rock indicates typically mixed deposits. There is a positive correlation between TOC and Fe/Mn, indicating that the change of sea level may be an important factor controlling the enrichment of organic matter. There is a good correlation between TOC and the contents of redox indicator elements V and U, and there is a positive correlation between TOC and V/(V+Ni), V/Cr, U/Th. The relationship among redox conditions, the sea level and TOC content suggests that the hypoxic bottom water environment plays an important role in the sedimentation process of organic matter-rich black shale, or that water conditions are controlled by elevated organic matter fluxes, and therefore oxygen declines. There is a positive correlation between K2O, TiO2, Fe2O3 and Al2O3, indicating that clay minerals are mainly from terrigenous input.

The deep-sea shelf facies deposits of the Wulalik Formation are mainly siliceous and clay minerals and contain a small number of carbonate minerals, which are different from deep-water slope facies deposits with high carbonate minerals. This paper analyzes the sedimentary characteristics and organic matter occurrence conditions of the deep sea shelf facies of the Wulalik Formation and proposes an organic matter occurrence model, which complements the previous research on slope facies and broadens the space for shale gas exploration in northern China.

Spatial-temporal Distribution of Upper Ordovician-Lower Silurian Hydrocarbon Source Rocks around the Proto-Tethys Ocean

Shucan Zheng[1], Qinglai Feng[1*]
1. School of Architectural Engineering, Huanggang Normal University, Huanggang, Hubei, CHINA
E-mail: qinglaifeng@cug.edu.cn

Keywords: Upper Ordovician-Lower Silurian, Proto-Tethys Ocean, graptolite zones, spatial constraint, Spatial-temporal Distribution

Upper Ordovician-Lower Silurian strata are the research focus of biostratigraphy, mass extinction, paleoclimate and shale gas exploration. In this study, we review previous studies featuring the geographic and paleogeography locations, time-stratigraphic units, graptolite zones, palynological assemblages, and lithological characters of these hydrocarbon source rocks developed around the Proto-Tethys Ocean. A synthesis of the spatial-temporal characteristics of these organic-rich shales is presented. Although the results may be more or less modulated by a possible sampling bias, data were collected as completely as possible regarding the Wufeng-Longmaxi sediments in South China, Lower Silurian graptolite shales in Sibumasu and Indochina terrane (Western Yunnan in China, Shan State in Myanmar, Southern Thailand and Malaysia), Lower Silurian hot shale in North Africa, southern Iran, Arabian Peninsula and Turkey, Lower Paleozoic petroleum system in Baltic Basin (central and northern Europe), oil and gas deposits in Siberian platform, organic-rich deposit in Norwegian-Danish Basin, Anadarko basin in the US and Barrandian Basin in Czech Republic. Our compilation reveals the stratigraphic and chronological ranges of these strata based on graptolite zones. Spatial constraint of the organic-rich stratums concerning the eustatic sea level changes was also analyzed according to the graptolite zoning at the vertical direction and relevant characteristics.

Geochemical characteristics of gas source rocks and origin of shallow gas in the Hetao Basin, Inner Mongolia, China

Mingxuan Zhang[1*]
1. School of Earth Resources, China University of Geosciences (Wuhan), Wuhan, Hubei, CHINA
E-mail: zhangmx@cug.edu.cn

Keywords: Shallow gas,Gas origin,Stable isotope geochemistry,Biogenic,Hetao Basin

A large number of gas producing water wells were discovered in the Hetao Basin, Inner Mongolia, China. Understanding gas origin is vital for designing exploration and production strategies, in order to either shallow economic accumulation of biogenic gas. In this study, the Holocene, Pleistocene and Pliocene in Hetao Basin were divided into five sequences(SQ5-SQ1) and geochemical characteristics of gas source rocks and stable isotope composition of co-produced waters and gas were investigated. The results reveal that the gas source rocks are rich in organic matter, with kerogen type II2 and III as the main type. Methanogens have been detected in source rocks.The parent material is mainly from higher plants and mixed with lower aquatic organisms. The evolution of organic matter is in the stage of biochemical methane, which is very conducive to the formation of biogenic gas. Paleontological (palynological) data show that the characteristics of climate evolution lay the foundation for the formation of biogenic gas reservoirs. The sedimentary facies types of shallow lake facies, semi-deep lake facies and shore lake facies also have an intimate relation to biogenic gas. Methane, nitrogen, carbon dioxide and hydrogen are the main components of the gas, and the sum of the four is more than 97%, while the sum of ethane, propane, butane and pentane is less than 3%. The carbon isotope content of methane is -74.2~-78.‰, which has typical biogenic characteristics. Genetic diagrams of δ^{13}C-CH4 versus δ^{2}H-CH4 and additional parameters corroborated biogenesis as the main gas origin. Carbon isotopic differences between carbon dioxide and methane ($\Delta^{13}C_{H2O–CH4}$), as well as those of hydrogen isotopes in water and methane ($\Delta^{2}H_{H2O–CH4}$), also indicated a typical microbial CO2 reduction pathway. The gas produced by culture of methanogens has the same geochemical characteristics as the collected gas. The gas source rocks in Hetao Basin have strong potential for gas generation. SQ3 and SQ1 are the main gas generation horizon. The analysis of source rock and shallow gas shows that the gas is biogenic. This study is important for exploring the geological conditions and exploration potential of biogenic gas reservoirs in the Hetao Basin.

E-mail: hhchen@cug.edu.cn

Keywords: tight oil reservoirs, fluid inclusion, diagenesis, hydrocarbon charge event, ultra-low concentration U-Pb dating, Ordos Basin

As the second largest sedimentary basin in China, Ordos Basin is rich in oil and gas resources. Conventional and unconventional tight oil reservoirs have been developed together, among which Yanchang Formation of Mesozoic is rich in tight oil resources and has great exploration potential. However, the genesis of tight reservoirs in Yanchang Formation in Ordos Basin and its relationship with oil and gas charging remain controversial. Taking Chang 6, Chang 7 and Chang 8 Members of Yanchang Formation in the south of Ordos Basin as the main research object, combined with the study of sedimentary microfacies and strike-slip faults, this study investigated the reservoir diagenesis and hydrocarbon generation, migration and accumulation in the study area, so as to clarify the cause of reservoir densification and its relationship with the sequence of hydrocarbon charge events in this area. The reservoir diagenetic sequences were established by observing the thin sections with transmitted light, fluorescence and cathodoluminescence and stable oxygen and carbon isotopic ratios analysis. It is considered that compaction and carbonate cementation are the main reasons for the densification and porosity and permeability decline of the reservoir, and fracture and acidic-alkaline alternating dissolution are the fundamental reasons for the enhancement of reservoir quality. In the context of diagenetic sequences, fluid inclusions microthermometric measurement, and microscopic fluorescence spectrum analysis of single oil inclusion, combined with the one-dimensional basin modeling, the hydrocarbon charge history in the south of Ordos Basin were reconstructed. The results show that the study area has experienced three hydrocarbon charge events. The first charge event occurred in the early of Early Cretaceous (127.9-120.0 Ma); the second charge event occurred in the middle of Early Cretaceous (119.5-108.0 Ma), and the third charge event occurred in the late of Early Cretaceous (101.0-95.9 Ma). The hydrocarbon charging events are different, in which Chang 6 Member is only experienced with the third hydrocarbon charging event, Chang 7 Member is mainly experienced with the second and third hydrocarbon charging events, and Chang 8 Member have experienced all the three hydrocarbon charging events. In addition, combined with ultra-low concentration U-Pb dating technology, it provides a direct constraint on reservoir densification time. The results show that the two generations of calcite cementation happened from 185 ± 27 Ma to 159 ± 52 Ma in Yanchang Formation of the study area. This result clearly exhibits the reservoir densification time is earlier than that of the oil charging events. It reveals, therefore, the coupling relationship between reservoir densification and hydrocarbon charging events, which has important implication for tight reservoir evaluation in Ordos Basin.

Genetic mechanism of low resistivity shale and their implications on reservoir quality: A case study in the Southern Sichuan Basin, China

Tianqi Zhou[1*]
1. Institute of Unconventional resources, Research institute of petroleum exploration and development, Beijing, CHINA
E-mail: zhoutianqi@petrochina.com.cn

Keywords: shale gas reservoir, low-resistivity, Sichuan Basin, reservoir qualitygravity flow deposited

Genetic mechanism of low-resistivity shale and its impact on reservoir quality are currently hot topic on a world- wide scale. Shale with resistivity lower than 20 Ω· m is widely developed in the Wufeng-Longmaxi formation of the Southern Sichuan Basin and these low-resistivity shales really created barriers for making reservoir prediction using the electromagnetic method. This paper discussed the genetic mechanisms and reservoir qualities of three types of low-resistivity shale reservoirs in the Southern Sichuan Basin (Changning block and Luzhou block). With results derived from mineral composition, organic geochemistry and petrophysical properties, three main reasons controlling the distribution of low-resistivity shales in the Southern Sichuan Basin have been deduced: extensive development of gravity flow deposits, poor structural preservation conditions and the graphitization of shale caused by the Emeishan basalt(1) The distribution of shale reservoir with resistivity < 12 Ω•m is uniform with that of gravity flow deposits in the southern Sichuan Basin. High clay mineral contents (especially illite) in gravity flow deposits increase cation exchange capacity and irreducible water saturation of shale reservoir, resulting in the decrease of electrical resistivity. (2) Resistivity of shale close to complex fault-fracture zone is generally lower than 20 Ω•m, indicating that poor structural preservation conditions led to the wide distribution of low- resistivity shale. The resistivity of shale near the NE trending fault in the Changning block is significantly lower than that in other areas. (3) The Emeishan basalt caused extensive graphitization of shale in the west of the Changning block, while the graphitization degree of shale in the Luzhou block was limited. The resistivity of shale in the Luzhou block was not affected by graphitization. Among three types of low-resistivity shale, type III low-resistivity shale is characterized by high quartz content, high TOC, high porosity, high gas content and low degree of graphitization. Although the resistivity of type III is often lower that 20Ω•m, it is still a favorable exploration target of Wufeng- Longmaxi Formation in the southern Sichuan Basin.

Reservoir characteristics and formation mechanism of high-quality reservoirs in Ledong Area, Yinggehai Basin

Nan Jiameng 1,Qiu Longwei 1*

1.School of Geoscience and Techology,CHINA UNIVERSITY OF PETROLEUM, QINGDAO,SHANDONG province,CHINA

Abstract

Yinggehai basin is located in the northwest of the South China Sea. It is an extension conversion Cenozoic petroliferous basin controlled by the dual mechanism of lithospheric extension and Honghe fault strike slip. The basin includes three first-order structural units: Yingdong slope, Yingxi slope and central depression. Yinggehai basin is the main battlefield of natural gas exploration in the western South China Sea. The field of medium and deep temperature and overpressure has gradually become the main direction of natural gas exploration.The content of quartz in the sandstone of Ledong area is 8%-92.5% (average 63.84%), followed by feldspar (content 1%-19%, average 11.41%) and rock debris (content 0.5% - 74%, average 7.89%). The sorting of clastic particles in Ledong area is mainly medium to poor. The reservoir porosity in Ledong area is 0.89% ~ 20.4% (average 10.33%), and the permeability is (0.05 ~ 26.38)×10-3 μm2 (average 0.82×10-3 μm2). The reservoir is low porosity and ultra-low permeability, ultra-low porosity and ultra-low permeability. Ledong area has high compaction intensity, less primary intergranular pores, and the contact relationship between clastic particles is mainly linear contact. The reservoir cement in Ledong area is mainly carbonate cement and less siliceous cement. Carbonate cements are mainly calcite and iron calcite, with less dolomite, iron dolomite and siderite.Higher carbonate cement is an important reason for the poor connectivity between pores and throats and poor overall physical properties in Ledong area. The reservoir pores in Ledong area are mainly dissolution pores, and feldspar and other minerals are corroded.The formation mechanism of high-quality reservoir: (1) sedimentation controls the structural characteristics of the original components of sediments and is the internal factor controlling the development of primary and secondary pores. For example, the clastic rock reservoir formed in the traction flow sedimentary environment with strong hydrodynamicforce after long-distance transportation has the characteristics of high content of rigid particles, high composition maturity, good sorting and rounding, strong anti compaction ability, low content of matrix and high content of primary pores. It can still preserve well connected primary pores and good original physical properties before undergoing dissolution modification. (2) The formation of secondary pores by dissolution is an important factor to improve reservoir physical properties. Dissolution can be divided into different mechanisms, typically including thermal evolution dissolution mechanism of organic matter, biodegradation dissolution mechanism of hydrocarbons, TSR dissolution mechanism, transformation dissolution mechanism of clay minerals, deep hydrothermal dissolution mechanism, alkaline dissolution mechanism, etc. (3) Hydrocarbon filling occupies pore space, which can hinder the flow of formation water, inhibit diagenesis such as cementation and compaction, and protect reservoir pores; (4) The abnormal high pressure reduces the effective stress of the formation, slows down the compaction and effectively preserves the primary and secondary pores.

Pore-System Evolution and Dynamic Digital Rocks of Shale Samples during Pyrolysis: Considering Various Diagenesis Events

Yuqi Wu[1*], Keyu Liu[1], Chengyan Lin[1], Chunmei Dong[1]
1. School of Geosciences, China University of Petroleum (East China), Qingdao, Shandong, CHINA
E-mail: wuyuqi@upc.edu.cn

Keywords: Shale, Pore system, Organic matter, Thermal maturation, Dynamic modeling

Accurate characterization of shale samples is of great importance for predicting and evaluating their intrinsic properties as they undergo various geological processes and diagenesis events. As such, constructing shale models not only entails accounting for the numerous components and pores, but also requires considering the effects of thermal maturation and diagenesis on the evolutions of the pore systems and components. In this study, a dynamic and diagenesis-based modeling method that integrates the discrete element modeling, quartet structure generation set, and morphological operation algorithms was developed to simulate the diagenesis events and pore-system evolutions which occurred during pyrolysis of shale samples. In the new method, the compaction, cementing, dissolution, and variation of organic matter are simulated. In addition, three types of pores, including organic matter (OM), interparticle (interP), and intraparticle (intraP) pores, and other components including kerogen, pyrite, clay minerals, globigerinids, calcite, feldspar, quartz, and petroleum products, are all considered in our process-based modeling. Also, In order to demonstrate the performance of our diagenesis-based modeling method, dynamic shale models of multiple cases with different geological processes are constructed. Then, to characterize the constructed samples, the occurrences and distributions of all components are studied using a two-point correlation function. Aside from statistical comparisons, the gas flow in these shale models is also simulated to exhibit the permeability variations produced in the process-based models. Moreover, the degree of cementation, the fractions of interP, intraP, and OM pores are varied to mimic new geological scenarios, which aims to further evaluate the performance of the proposed technique. The results indicate that our diagenesis-based modeling method presents an excellent performance. Furthermore, the presented modeling technique can be extended to investigate the effects of various components and pores on the intrinsic properties of shales in the future.

A large-scale mudstone fan in an Eocene rift lake basin in China

Zaixing Jiang[1*]
1. Energy, China University of Geoscience, Beijing, CHINA
E-mail: jiangzx@cugb.edu.cn

Keywords: mudstone,lake,shale oil

Mudstone accounts for about 70% of sedimentary rocks. It widely spreads from fluvial, lacustrine, coastal, shelf, slope to deep sea depositional environments. It occurs in a form of drape or sheet in most cases. Muddy fans have been found in modern semi- to deep sea, e.g., the Quaternary Mississipi fan(Galloway and Hobbday,1996). But their ancient analogues have rarely been identified. In this study, we report a discovery of a large-scale mudstone fan, the Minfeng fan with abundant hydrocarbon that distribute in an Eocene rift lake basin in China. This is achieved by investigating 3-D seismics, well loggings and tests, drilling cores, as well as organic and inorganic laboratory analyses.

The Minfeng fan is about 25km wide, 15km long, and 1.5km thick. Several seismic facies can be identified, i.e., besom-like, mounded, wedged and sheeted. As a whole besom-like seismic facies is distributed on the fault slope, and therefore makes up a slope fan of a fan-delta origin. While the mounded and wedged seismic facies occurs in the deep-lake floor in the front of the besom-like facies. The mudstone fan is thick and mounded in the center, wedged in the margin, and thins out and becomes sheeted southward, eastward and westward. It is interfingered with the fan-delta in the north. There are two channels feeding muddy sediments across the fan delta to the basin floor, resulting in the muddy sublacustrine fan. The muddy sediments were transported in density flow, and deposited with wanning dynamics in a succession: besom-divergent thin bedded conglomerates, sandstone and mudstone(inner fan)—mounded and concave mudstone(middle fan)—wedged mudstone(outer fan)—sheeted mudstone(suspended muds with autochthonous sediments in deep lake plane) .

The mudstone fan is abundant in organic matter. TOC ranges from 1.71%-5.47% with average 2.95%. The organic matter types are II1 and II2 in inner fan, and type I in mid and outer fan.

In addition to the Minfeng mudstone fan, other three mudstone fans have been found to have great potential for shale oil in Lijin, Boxing and Guangli. The size and thickness of a mudstone fan is controlled by topographic gradients and lake-margin canyons. The larger the gradient and lake-margin canyon, the fan’s size and thickness get larger. A steep slope is liable to generate and help sediment gravity flows moving farther to the basin. And a fixed and incised canyon focused the density flow to transport sediments basinward.

Reservoir Development Characteristics of Yudong 1 Gas Field in Tabei Uplift, Tarim Basin

Rui Wang[1], Xiuxiang Lv[1*]
1. School of Geosciences, China University of PetroleumBeijing, Beijing, CHINA
E-mail: luxx_cup@163.com

Keywords: Tabei uplift,Meso-Cenozoic,lithologic gas reservoirs,reservoir characteristics

Yudong 1 gas field is located in the Kalayuergun structural belt of the Tabei uplift of the Tarim Basin, and it belongs to a large area of lithologic gas reservoirs. Two sets of reservoirs are mainly developed in the Yudong 1 gas field, which are distributed in the lower Paleogene sandstone member and the Cretaceous Bashijiqike Formation. By analyzing the core data, logging data, casting thin section data and scanning electron microscope data of the two sets of Meso-Cenozoic reservoirs in the Yudong 1 gas field, the author studies the characteristics of the Meso-Cenozoic reservoirs in the Yudong 1 gas field. The following understandings have been obtained: the lithology of the Paleogene reservoirs in the Yudong 1 gas field is mainly fine-grained feldspar lithic sandstone, with a small amount of dolomite and anhydrite cements, and the pore types are mainly intergranular pores, with a small amount of intergranular pores. Dissolved pores, intragranular dissolved pores and argillaceous micropores, the total surface porosity is 0.1%~21.6%. Through three-dimensional quantitative fluorescence and nuclear magnetic resonance analysis, the porosity is 6.78~26.27%, the average is 14.47%, and the permeability is 0.11~402.38× 10^{-3}μm^2, with an average of 402.38×10^{-3}μm^2, according to the evaluation standard, its physical properties are medium to good; the lithology of the Cretaceous Bashijiqike Formation is dominated by fine sandstone, with a small amount of siltstone and argillaceous cementation. The porosity is 17.4~22.6%, and the average porosity is 21.4%. According to the evaluation standard, its physical properties are the best. The sandstone is extremely developed, the size of the cuttings is moderate, the reservoir is concentrated vertically, and the horizontal distribution is relatively stable.

Lithofacies types and characteristics of shale reservoir: A case study from Jurassic Shale of the Da'anzhai Member in Yuanba area, northern Sichuan Basin

Qianwen Li[1*], Zhongbao Liu[1]

1. Petroleum Exploration and Production Research Institute, Sinopec , Beijing, CHINA

E-mail: liqw2018.syky@sinopec.com

Keywords: Reservoir, Lithofacies, Shale, Da’anzhai, Jurassic, Yuanba

The continental shale strata in the Jurassic Da'anzhai Member have complex lithology and strong heterogeneity, which restrict the selection of optimal intervals and exploratory deployment. To find out the reservoir characteristics and gas-bearing capacity of different lithofacies types of Da'anzhai Member in Yuanba area, experimental methods including TOC measurement, whole-rock mineral composition, thin section analysis, FIB-SEM, mercury injection, N2 adsorption experiment, CH4 isothermal adsorption and physical property test were carried out. Then the lithofacies types of shale and interlayers were identified and divided, and optimal lithofacies were selected based on the comparison of physical properties, pore types and structure, gas content and occurrence status for different lithofacies types. Results show that the shale reservoir of the second sub-member of Da'anzhai can be identified and divided into three types and six categories of shale lithofacies, two types and six categories of interlayer lithofacies, which further combined into three macro-lithofacies assemblage types. Shale pore types of Da'anzhai Member are mainly inorganic pores dominated by clay mineral pores, while fewer organic pores mainly developed in clay shale facies, providing storage space for shale gas. The total shale gas content is calculated to be 2.59~4.38 m3/t, in which the free gas content accounts for about 67%, showing a good gas potential. However, the brittle mineral content of the shale reservoir is only 50%, indicating a poor fracturing performance. It is concluded that, lithofacies assemblages type AB-I has developed good stratification and lamination, pretty hydrocarbon generation potential, high gas content and free gas ratio, as well as widespread limestone interlayers with better fracturability, which is thought the most favorable exploration intervals of the Da’anzhai Member.

Study on the organic matter evolution and nano-scale pore occurrence characteristics of organic- rich shale

1*

1. , , , , CHINA
E-mail: 913714801@qq.com

Keywords: Nano-pore, Pore evolution, Frenkel-Halsey-Hill Model, Shale

Abstract

In order to explore the characteristics of nanopores in different maturity shale, the shape and characteristics of shale pores under different maturity were studied by scanning electron microscopy (SEM) and low temperature nitrogen experiment (LP-N2-GA) based on FHH fractal model. The results show that the intergranular pores and organic pores in the shale of the Upper Yangtze area are most developed, and the pore size is distributed from a few nanometers to several tens of micrometers, providing the main reservoir space for shale gas occurrence; SEM gray scale by pseudo color enhancement technology After image processing, the pore development characteristics of shale can be observed more intuitively; the average organic matter face rate in shale is between 16.7% and 23.8%, and with the increase of maturity, the organic matter face rate in shale is gradually increased; The results of low temperature nitrogen adsorption test, using FHH fractal model to calculate the fractal dimension D of nanopores between 2.499 and 2.860, with an average of 2.713, the fractal dimension of shale is positively correlated with TOC and quartz, clay minerals and feldspar and fractal dimension. The number is negatively correlated, but the correlation is not obvious. Combined with the fractal dimension of nanopores in low-mature shale, it indicates that with the increase of maturity, the fractal dimension of nano-pore shows a trend of decreasing first and then increasing gradually. When Ro is less than 0.7%, the mechanical compaction caused by the increase of buried depth causes the pore volume and specific surface area of the mesopores to decrease rapidly; when Ro is between 0.7% and 1.3%, the secondary pores formed by the evolution of kerogen hydrocarbons It supplements the reduction of pore volume and pore specific surface area caused by mechanical compaction. The total pore volume and specific surface area of shale remain basically unchanged at this stage; when Ro is between 1.3% and 2.6%, hydrocarbons cannot be transported effectively. Removal or elimination of reservoir overpressure and the transformation of organic pores between organic nanopores and organic acid groups with hydrocarbon formation leads to a transient increase in shale pore volume and specific surface area; when Ro is greater than 2.6%, the hydrocarbon generation process At the end and the release of pressure, the pore evolution gradually returns to the normal compaction trend, and the pore volume and specific surface area of the shale decrease, but the degree of reduction is limited.

The mechanism of organic pores formation in lacustrine shales of China and its effect on reflectance measurement

Peng Pang[1*], Hui Han[1,2], Guang Hu[1], Chen Guo[1]
1. School of Geoscience and Technology , Southwest Petroleum University, Chengdu, Sichuan, CHINA
2. Natural Gas Geology Key Laboratory of Sichuan Province, Southwest Petroleum University, Chengdu, Sichuan, CHINA
E-mail: pangpenggeology@163.com

Keywords: Lacustrine shales, Organic pores, Macerals, Differential developmental characteristics, Reflectance

Shale oil and gas are unconventional resources with great development potential and are gradually being produced commercially by various countries. Shale pores as the main storing space for shale gas and oil have been studied extensively, which can be divided into organic matter (OM) pores, interparticle pores and intraparticle pores (Loucks et al., 2012). And, OM pores are generally considered to be primary storing space for hydrocarbons in shales (Ma et al., 2015).

Previous studies have found that the pore developments of various macerals were very different with each other (Curtis et al., 2012; Sanei et al., 2015). The pore characteristics of dominant macerals in marine shales have been relatively well investigated. It is well known that macerals in lacustrine shales are much more complex than marine shales. However, the pores of various macerals and their influences on reflectance measurement remain poorly understood.

This study explored the mechanism of OM pores formation in lacustrine shales and its effect on reflectance measurement from the perspective of macerals. 80 Typical lacustrine shales with various maturities and TOC contents were selected from the Qingshankou Formation of Songliao Basin, the Shahejie Formation of Bohai Bay Basin, the Yanchang Formation of Ordos Basin, and the Badaowan Formation of Junggar Basin in China. OM pores of different macerals were characterized using integrated correlative light and electron microscopy (iCLEM) and Low-pressure gas adsorption (LPGA) experiments. And the relative contributions of macerals to organic pores were estimated. On the basis of the geochemical parameters, the thermal evolution law of organic pores in macerals was analyzed. Finally, the influence of organic pores on reflectance of vitrinite and solid bitumen was discussed by performing reflectance measurement experiment. Main conclusions of this research are as follows.

(1)The organic pores of lacustrine shale are mostly circular or elliptical in morphology, usually aggregated in a honeycomb shape. The organic pores are mainly distributed in the range of 100—400 nm, and the average plane porosity of macerals is 10.13 %.

(2)Among various macerals, sapropelinite preserved a certain amount of pores, but almost no pores existed in exinite. There was a small amount of microcracks and pores in vitrinite, and a large number of primary pores that retained plant structure can be seen in fusinite. Due to the process of hydrocarbon generation and expulsion, solid bitumen formed amounts of organic pores and microcracks.

(3)The order of organic pore diameter from small to large is solid bitumen, bituminite, alginite, vitrinite, fusinite and exinite, and the order of pore development degree from high to low was alginite, fusinite, bituminite, solid bitumen, vitrinite and exinite. The contribution of organic pores mainly comes from bituminite, solid bitumen and fusinite. As for the controlling factors of organic pore development, thermal maturity is not the only factor, and maceral type also has a significant influence on the formation of organic pores.

(4)The development of organic pores (an increase in pore size and pore number) enhances the surface roughness of vitrinite or solid bitumen, resulting in an underestimate of their reflectances.

Reservoir lithofacies architecture patterns and its controlling effect on sweet spots of terrestrial mixed fine-grained rocks:A case study of Permian Lucaogou Formation shale oil in Jimusaer Sag, NW China

Senlin Yin[1], Leli Cheng[1*]
1. Research Institute of Mud Logging Technology and Engineering, Yangtze University, Yangtze University, Jingzhou , Hubei, CHINA
E-mail: 190273515@qq.com

Keywords: mixed fine-grained rock,lithofacies architecture,shale oi,UAV, mixed shallow lacustrine deposits zone, sweet-spot

In the process of shale oil development, lacustrine mixed fine-grained rocks lithofacies controlling effect of the sweet-spot can be quite complex. Based on the core, outcrop, logging, testing and production data, the classification, 3D prototype model and combination pattern are carried out through lithofacies architecture analysis, UAV and 3D geological modeling technology. The research shows that: (1) Combining traditional fieldwork with UAV photography to characterize the 3D spatial distribution characteristics of the lithofacies architecture of the outcrop section of the Lucaogou Formation. The stratigraphic-structural models and three-dimensional lithofacies prototype models are presented from well setting and lithofacies types quantitatively characterizing. It is believed that its lithofacies architecture has relatively stable but vary locally. (2) The lithofacies architecture combinations of mixed fine-grained rocks are mainly divided into three types: gradient type, mutation type and special type. The graded types characterized by symmetrical lithofacies architecture and a superposition of multiple similar cycles, are widely developed. The reservoir in the graded types is a high-quality reservoir with developed dissolution pores, and is a mixed beach-bar microfacies in a mixed rock belt. The mutant type can be subdivided into two types. The development degree of the sand body is average, characterized by asymmetric lithofacies architecture and a superposition of multiple similar cycles. And the reservoir is a thin reservoir with high-quality hydrocarbon generation. The special type belongs to the thick clastic rock with a high degree of sand body development. It is a relatively reservoir with tight reservoir properties and superimposed by a single cycle of sand bodies. (3) The lithofacies architecture controls the distribution of sweet spots and development strategies. The graded type reservoir shows weak heterogeneity and well-developed sand. This type of reservoir has the best development effect and is suitable for large-scale deployment of horizontal well platform operations. Mutant type reservoirs are well developed, but it shows strong heterogeneity and average development effect. And they are the follow-up succession area. The special type reservoir is distributed with poor continuity, strong heterogeneity, and good development effect. The deployment of horizontal wells requires meticulous research on the lithofacies architecture and NMR oil bearing saturation.

Porosity evolution of Minhe oil shale under a rapid heating open system and the carbon storage potentials

Daming Niu[1], Pingchang Sun[1*]
1. Earth Science Institute, Jilin university, Changchun, Jilin province, CHINA
E-mail: sunpingchang711@126.com

Keywords: Oil shale, Thermal simulation, Reservoir physical property evolution, Open system, Carbon storage

Oil shale has been recognized as an important oil source with great advantages in reserves and development prospects (Han et al., 2014; Pan et al., 2016; Zhao et al., 2017; Liu et al, 2017). When depleted, the pore system can be acting as excellent storage space (Ma et al., 2021). Fracture and pore evolution during in situ pyrolysis of oil shale is crucial to understanding the complex petrophysical changes to enhance the oil extraction (Ma et al., 2021). Meanwhile the increased porosity will provide enough space for carbon sequestration to balance the carbon emission generated by oil consumptions (Oldenburg et al., 2001; Godec et al., 2014; Ma et al., 2019). This paper focuses on porosity evolution and reservoir physical properties changes of oil shale samples at different heating stages from the macro to microscale. The comprehensive analysis was performed based on the results from a wide range of characterizing techniques. During 3 artificial thermal evolution stage, the size, volume, type, geometry, connectivity of pores and fractures were quantitively measured and imaged at mm-scale, μm-scale and nano-scale to understand the evolution comprehensively. These results indicate in the low-temperature heating stage (185~350°C), the volume of fractures and micropores began to increase slowly. The pores are predominately consisting of micropores and transition pores in cylindrical geometry. Organic pores showed a gradual and slow increase, and the change in inorganic pores were increased slightly. In the medium-temperature heating stage (350~440°C), the number and width of fractures increased significantly. Micropores increased rapidly and became largely medium pores in slit geometry. Organic pores show a trend from a rapid increase to a slow increase, whereas the inorganic pores did not change significantly. In the high-temperature heating stage (440~520°C), the micro- and macrofractures of the sample continued to widen and extend slowly, and the adjacent microfractures became connected to form larger fractures. The rate of volume increases in organic pores and fractures and inorganic pores slowed. The pores primarily formed large pores and micropores in cylindrical and slit geometries. The heated oil shale reseroivs of these three stages are classied as Class III, Class II and Class I reservoir respectively with reservoir physical properties poor, good and excellent. The the carbon dioxide storage potential were then accessed based on the above results. These results indicate After in situ conversion, the carbon release of oil shale reservoirs is around 0.014 t, far less than that of carbon dioxide storage (0.2 t), which suggest a possible feasibility of in-situ pyrolysis development and subsequent in-situ carbon storage.

Dynamic evolution of shale gas occurrence state over geological time

Min Li[1,2], Xiongqi Pang[1,2*]

1. State Key Laboratory of Petroleum Resources and Prospecting, China University of Petroleum (Beijing), Beijing, CHINA
2. College of Geosciences, China University of Petroleum (Beijing), Beijing, CHINA
E-mail: pangxq@cup.edu.cn

Keywords: Gas-generated amount, Gas storage capacity, Adsorbed gas, Free gas, Dynamic evolution

The occurrence state of shale gas is significant to shale gas resource evaluation and productivity prediction, and its dynamic evolution needs to be further studied. This paper presents a method to study the dynamic evolution of shale gas occurrence state during burial. This method has two advantages: One is considering the coupling effects of external factors (temperature, pressure) and internal factors (organic matter content and maturity, porosity) on the shale gas occurrence state in geological evolution; The second is determining the actual content and occurrence state of shale gas by matching the gas generation and gas storage capacity in geological evolution. This method is applied to studying the evolution of shale gas occurrence state in the Longmaxi Formation in Sichuan Basin. The results showed that the actual gas content of was 0 in the shallow burial. When the buried depth was 1900-4100 m, the gas-generated amount was less than the gas content capably stored, and the actual gas content depended on the gas-generated amount. With the increase of the gas-generated amount, shale gas first existed in the form of adsorbed gas. After the adsorbed gas was saturated, free gas appeared and gradually increased, exceeding the adsorbed gas content. As the burial depth increased from 4100 m to the maximum burial depth, the gas-generated amount was greater than the gas content capably stored. The actual gas content depended on the gas content capably stored. The adsorbed gas and free gas existed together, the content of adsorbed gas and free gas gradually decreased, but the proportion of free gas was always higher than that of adsorbed gas. To sum up, the dynamic evolution process of the shale gas occurrence state is mainly divided into three stages: the gas-free stage, the stage dominated by adsorbed gas, and the stage dominated by free gas. And there is a depth point corresponding to the highest actual free gas content during the burial, and the shale at this depth point is the “sweet point” for shale gas development.

Wettability of different clay mineral surfaces in shale: Implications from molecular dynamics simulations

Kanyuan Shi[1,2], Junqing Chen[1,3*], Xiongqi Pang[1,2]

1. State Key Laboratory of Petroleum Resources and Prospecting, China University of Petroleum, Beijing, Beijing, CHINA
2. College of Geosciences, China University of Petroleum, Beijing, Beijing, CHINA
3. College of Science, China University of Petroleum, Beijing, Beijing, CHINA

E-mail: cjq7745@163.com

Keywords: Shale, Molecular dynamics, Nanoscale, Wettability, Clay minerals

Nanoscale organic and inorganic pores in shale reservoirs are important oil and gas reservoir spaces. Also, the surface wettability of clay minerals significantly affects the oil and gas-bearing capacity of shale reservoirs. Therefore, studying the surface wettability of common clay minerals in shale at the nanoscale is of great significance for shale oil and gas exploration and development. Molecular dynamics (MD) can avoid the limitations of complex mineral composition, strong heterogeneity, difficult sampling, and the high cost of relevant experiments in shale reservoirs. Also, it can analyze the surface wettability from a micro perspective. In this study, the wetting behavior of water in different oil phases (n-hexane and toluene) on different clay mineral surfaces (montmorillonite, kaolinite, chlorite, and illite) at the nanoscale was systematically studied using MD simulation. The results show the following order of inherent water wettability on the surfaces of common clay minerals: montmorillonite > chlorite > kaolinite > illite. The main interactions between water and oil and the mineral surfaces were van der Waals force and electrostatic force. In addition, the temperature, liquid hydrocarbon type, and mineralization of water affected the wettability of clay mineral surface. By comparing the experimental results with the MD simulation results, similar wetting characteristics were obtained, and the reliability of the simulation results was verified. MD simulation was used to explore the water wetting of the surfaces of four clay minerals in a shale reservoir from the micro level. This makes up for the lack of experimental means for clarifying the flow and production mechanisms of shale oil and gas and effectively improves the evaluation technology of shale.

Characterization on differences in pore systems heterogeneity for organic-rich laminated shales and organic-poor layered shales of Chang 7 Formation in the southwestern Ordos Basin, China

Hao Lu[1,2], Qing Li[1,2], Dali Yue[1,2*], Shenghe Wu[1,2], Wurong Wang[1,2]
1. College of Geosciences, China University of Petroleum Beijing, Beijing, CHINA
2. State Key Laboratory of Petroleum Resources and Prospecting, China University of Petroleum Beijing, Beijing, CHINA
E-mail: yuedali@cup.edu.cn

Keywords: organic-rich laminated shale, organic-poor layered shale, pore system heterogeneity, fractal dimension, multifractal spectrum

Organic-rich laminated shale and organic-poor layered shale are two vital types in shale stratigraphic systems of Chang 7 Formation in the southwestern Ordos Basin, China, and it is of great meaning to clarify the heterogeneity and difference of their pore structures for the exploration and development of shale oil and gas. By integrating the digital image processing, fractal and multifractal theory, and various experimental methods, the geometric, topological and fractal heterogeneity of pore systems of organic-rich laminated shales (ORLS) and organic-poor layered shales (OPLS) were quantitatively characterized.

Intergranular pores, organic pores and intercrystalline pores of pyrite minerals with higher plane porosity form the main storage space of ORLS. Microfractures and intercrystalline pores in clay minerals play an important role in the pore system of OPLS. Multifractal spectrums show that the wider size range of intercrystalline pores and the discontinuous size distribution of microfractures with stronger holistic distribution heterogeneity, which contribute to the more heterogeneous pore system of ORLS. The wider range and discontinuity of the pore size distribution for intergranular pores and organic pores, and the instability of the morphological structure for microfractures, which all lead to the heterogeneity of the pore system in OPLS. The petrophysical and pore structure parameters indicate that ORLS has better storage and permeability than OPLS. The pore composition of ORLS is dominated by micropores and macropores. Mesopores account for the highest proportion in OPLS. The micropore structure of ORLS is more complex, while pore structure complexity of mesopores is weaker than that of OPLS. The porosity positively correlates with the macropore volume controlled by quartz and pyrite content, and the average pore-throat size affects the fractal characteristics of mesopores and macropores in ORLS. The porosity of OPLS displays a positive correlation with the macropore surface area; the mesopore and macropore volume impact the mesopore and macropore structural complexity, respectively, which are related with feldspar and clay mineral content. This study shows prominent theoretical significance for enriching the research of fine-grained sedimentology, and provides theoretical support for the fine exploration and efficient development of shale oil and gas.

Sedimentary model of lacustrine fine-grained sediments: a case study from the Holocene Qinghai Lake, China

Zhijie Zhang[1*], Chuanmin Zhou[1], Xuanjun Yuan[1], Wonsuck Kim[2], Dawei Cheng[1]
1. Research Institute of Petroleum Exploration and Development, PetroChina, Beijing, CHINA
2. Department of Earth System Sciences, Yonsei University, Seoul, KOREA, SOUTH
E-mail: zhzhijie@petrochina.com.cn

Keywords: Fine-Grained Sediments, Qinghai Lake, Flocculation, Sedimentar Model

The increasing interests in unconventional petroleum resources has led to an advanced research of lacustrine fine-grained sediments. The Qinghai Lake, situated on the Northeast Qinghai-Tibet Plateau, is the largest saline lake in China with fine-grained Holocene sediments. A sedimentary model is proposed for the Holocene Qinghai Lake by integrating short cores, petrographic and geochemical data, satellite images, and physical modeling results. The littoral zone of Qinghai lake basin is dominated by reworked sandstone, oolite sand, and siltstone, with a typically low total organic carbon (TOC). Littoral sediment (siliciclastics) is mainly from delta, with little from wind and coastal erosion. The sublittoral zone, is dominated by organic-poor muddy siltstone and silty mudstone. In contrast, the profundal zone is dominated by organic-rich mudstone associated with fallout biological debris both of autochthonous and allochthonous origins. Satellite images show Buha River discharges flow into the lake like splashiag with sediment plume, which can capture algae by flocculation processes. The algae-containing flocculated particles usually are not deposited in situ but reworked and transported following lake current to sublittoral and profundle zones. Mudstone rich in allochthonous organic matters is commonly deposited by hyperpycnal flow, and typically accumulates in proximity to river mouth. They tend to interbed with thick hyperpycnal sandstone that forms favorable petroleum reservoir. Mudstone rich in autochthonous organic matters is commonly deposited by flocculation of algae and clay particle induced by hypopycnal, meopycnal and homopycnal flows and typically accumulate far away from river mouth. In Qinghai Lake, when moderate salinity meets flood that generates homopycnal and/or hypopycnal flows, mud grains flocculate and capture algae available in the lake, depositing more organic matter in the proximal area. As long as flocculation continues to sediment to aggregate with each other, deeper part of the lake should have higher TOC concentration. The accumulation of such deposits are mainly controlled by concentration of sediment plume, lake current, characteristic of clay mineral, and biological productivity. The proposed sedimentary model is supposed to provide a better understanding on evaluation of hydrocarbon potential of source rocks and identification of target zones for unconventional resources.

Keywords: Thin sandstone reservoirs,Deep strata, Hydrocarbon enrichment mechanism,Tarim Basin,Karashayi Formation.

Thin sandstone oil and gas reservoirs are an important oil and gas resource and are widely distributed in China. Its reservoir has the characteristics of thin thickness, deep burial depth, vertical sand and mud interbedding, and rapid lateral change (Zhang et al., 2014; He et al., 2014). So, it is difficult to accurately identify and predict the reservoir during the process of oil and gas exploration and development. However, in recent years, with the development of exploration technology and the application of new methods (Chen et al., 2002; Ning et al., 2006; Huang et al., 2009; Wang et al., 2018), this problem is gradually overcome. At present, the unclear oil and gas enrichment mechanism of thin sandstone reservoirs are one of the main problems restricting the exploration and development of thin sandstone oil and gas. Therefore, the research on the oil and gas enrichment mechanism of deep thin sandstone reservoirs have important practical significance. In this paper, the Carboniferous Karashayi Formation thin sandstone hydrocarbon accumulation in Tahe Oilfield, Tarim Basin is taken as an example to analyze and study. Through comprehensively use the data of core, well logging, mud logging, oil testing and analytical testing in the study area to carry out research on the hydrocarbon enrichment conditions and main controlling factors in the thin sandstone reservoirs of the Carboniferous Karashayi Formationand establish the hydrocarbon enrichment mechanism of deep thin sandstone reservoirs. The research results show that the hydrocarbon enrichment of the Carboniferous Karashayi Formation is mainly controlled by three geological elements: sedimentary facies, fluid potential difference and oil source faults. Oil and gas are mainly enriched in medium-fine sandstone reservoirs in the delta front. The surrounding rock capillary force is 8 times greater than the reservoir capillary force, and the distance between the reservoir and the oil source fault is less than 1 km. The formation and distribution of thin sandstone oil and gas reservoirs are controlled by the combination of sedimentary facies, fluid potential difference and oil-source fault. Based on this, a ternary coupled reservoir control model of "premium facies-low potential-near source" was established for deep thin sandstone reservoirs, in order to provide guidance for the exploration and development of thin sandstone reservoirs.

Geochemistry characteristics and paleoenvironmental significance of trace elements and rare earth elements in late Paleozoic mudstone in the Qinyuan area

Chunlan Yu[1], Nana Mu[1*], Wenhui Huang[1], Jintong Liang[2]
1. School of Energy Resources, China University of Geosciences (Beijing), Beijing, CHINA
2. Institute of Sedimentary Geology, Chengdu University of Technology, Chengdu City, Sichuan, CHILE
E-mail: munn@cugb.edu.cn

Keywords: Trace elements,rare earth elements, occurrence state, sedimentary environment,provenance,Qinyuan area

Trace elements and rare earth elements in mudstone, as sensitive indicators of sedimentary background changes, are of great significance for reconstructing the paleoenvironment, paleoclimate and provenance attributes of sediments [1,2]. In this study, the contents and distribution of trace elements and rare earth elements, paleosalinity, paleoclimate and provenance characteristics of Upper Paleozoic mudstone in the Qinyuan area were discussed, using X-ray diffraction whole-rock analysis technology and inductively coupled plasma–mass spectrometry. The study showed that the contents of trace elements are relatively enriched in B, Mn, Sr and Zn compared with the average value of the crust. Compared with clay rock, Mn and Zn contents are relatively high. The average content of REY is 306.38 ug/g, higher than the average ∑REY in North American shale and the upper crust. The average values of δEu and δCe are 0.56 and 1.06, respectively. Except for WY001-6 and WY001-15, which are Medium-type of REY enrichments, the REY distribution patterns of the remaining samples are similar, showing the characteristics of light rare earth elements (LREY) enrichment and heavy rare earth elements (HREY) depletion. According to the content of element B and the ratios of B/Ga and Sr/Ba, it is considered that during the late Paleozoic sedimentary period in the Qinyuan area, it was mainly fresh brackish water, and occasionally, there was a direct injection of salt water. The V/(V+Ni), V/Cr, Ce_{anom}, δEu/δCe, Ce/La and Sr/Cu ratios show that the sedimentary medium is in a reduced state, mainly in a dry and hot climate. The mudstone source rocks of the late Paleozoic in the Qinyuan area come from granite and sedimentary rocks and a small amount of alkaline basalt, which has the sedimentary characteristics of the passive continental margin and a continental island arc. Yinshan Upland is the sediment-source region for the Late Paleozoic strata of the Qinyuan area, according to the distribution pattern of rare earth elements normalized by chondrite. HREY has a high positive correlation with B(r=0.95) and Ga (r=0.98), indicating that the occurrence of HERY, Ga and B are the same. Warm and humid environment was conducive to the preservation of light rare earth elements. An acid reduction and relatively high salinity environment can promote the enrichment of heavy rare earth elements in late Paleozoic mudstone in the Qinyuan area.

Keywords: Delta-shallow sea sedimentary system, Deep Water Area, Terrestrial organic matter, Hydrodynamic conditions

The delta-shallow sea sedimentary system is a special sedimentary system with both terrestrial and marine organic matter. It is generally believed that the distribution of terrigenous organic matter in deep water is limited. However, more and more oil and gas exploration practices in deep water have discovered the contribution of terrigenous organic matter, which proves that terrigenous organic matter exists in deep water areas and is of great significance to oil and gas generation. Therefore, on the basis of a large number of investigations on the control factors of terrigenous organic matter distribution, the flume experiment technology was used to explore the control of different factors on terrigenous organic matter, and the key factors for the enrichment of terrigenous organic matter in deep water areas were clarified. Through a large number of investigations and flume experiments, it is clear that the distribution of organic matter mainly has the following characteristics: (1) Organic matter is more easily adsorbed by fine-grained sediments, and the pre-delta area where argillaceous sediments are enriched is also the enrichment area of terrigenous organic matter; (2) Terrigenous organic matter is distributed near the estuary, and the abundance of organic matter increases first and then decreases towards deep water; (3) In the coastal-shallow sea areas with active biological action, the transformation of terrestrial organic matter by biological action may become the main controlling factor affecting its distribution; (4) The stronger the river action, the farther the terrestrial organic matter can be transported, and the peak area of the organic matter abundance tends to migrate to deep water; (5) The retransportation of terrigenous organic matter by large hydrodynamic forces such as waves, tides, and coastal currents may be the key factor for its occurrence in deep water. This has important guiding significance for the prediction of dominant source rocks in deep-water areas with less drilling.

Provenance analysis of Badaowan Formation of Lower Jurassic in dachanggou basin, Xinjiang

Lei Xingxuan[1], Sun Pingchang[1*], Wang Junxian[1], Li Yuanji[1]
1. School of Earth Sciences, Jilin University, Changchun, Jilin, CHINA
E-mail: sunpingchang711@126.com

Keywords: Dachanggou Basin ,lower Jurassic,Badaowan formation,geochemistry,detrital zircon U-Pb dating,source analysis

Dachanggou basin is a Mesozoic coal-bearing and oil shale basin in northwest China, located in the northern Junggar basin(Wang J X et al.,2021).In this paper, the Lower Jurassic Badaowan Formation of Dachanggou Basin in northern Xinjiang was selected as the research object. The main provenance types of sediments in the Badaowan Formation of Dachanggou Basin were analyzed by thin section identification, geochemical characteristics analysis and detrital zircon LA-ICP-MS U-Pb age test.It is found that the roundness and sorting of rock particles reflect the low compositional maturity and structural maturity, which are characterized by near-source deposition.The content of SiO_2 (average 47.48 %) in the sample is low, and the variation range is large, indicating that the quartz content is low(Sircombe,1999). Al^2O_3 (average 15.18) content is higher, indicating that clay minerals and feldspar content is higher ; the chemical alteration index (CIA) ranged from 32. 60 to 86. 95, with an average of 72. 99. Combined with the comprehensive analysis of ICV value and Th / U ratio, it shows that the material source area has experienced strong weathering and weak weathering, revealing that there are certain fluctuations in the paleoclimate.The characteristics of clastic components show that the sandstone of the Badaowan Formation is mainly from the source area of the recycled orogenic belt and a small amount of magmatic arc tectonic background. The lithic types are mainly felsic exhalative rocks, andesite, granite and a small amount of metamorphic lithic fragments. Further combined with geochemical characteristics, it is shown that the source rocks of the clastic rocks in the source area are mainly felsic volcanic rock assemblages, and a small amount of neutral rocks and felsic sedimentary rocks are mixed.Further combined with zircon age test, the U-Pb age of detrital zircon generally presents an obvious main peak age of 282~376 Ma, a secondary peak age of 478~542 Ma and two weak peak ages of 858~922 Ma and 1122~1270 Ma.The zircons of the strongest peak age (282~376 Ma, Devonian-Permian) are mainly magmatic zircons, accounting for 88 % of the peak age of zircons, which are consistent with the Carboniferous, Permian andesite and volcanic lava in the study area(Liu G et al.,2017).Detrital zircons in the peak period of 478~542 Ma (Cambrian) accounted for 10 % of all zircons, indicating that there was still a supply of continental crust materials formed during the deposition of Badaowan Formation.The zircons of 6 grains at 880 Ma and 2 grains at 1300 Ma show that there is still a supply of material sources for the Palaeozoic metamorphic rocks in the study area. At the same time, a series of geochemical parameters and diagrams show that the tectonic background of the provenance area is mainly continental island arc and has the characteristics of oceanic island arc.

Source rock characteristics of Cretaceous organic rich black shales in the Mid-Atlantic passive continental margin basins

Xin Zhan[1*], Hongyan Zhao[1], Lingwu Kong[2], Lin-An Pang[1], Wei Du[1], Zheng Liu[1]
1. Global Technology Supporting Center, CNOOC International Limited, Beijing, CHINA
2. Exploration Department, CNOOC International Limited, Beijing, CHINA
E-mail: zhanxin@cnoocinternational.com

Keywords: Source rock, black shale, paleotropical Mid-Atlantics, Cretaceous, the ITCZ, paleoclimate

The Cretaceous marine source rocks are mainly mudstones and carbonate rocks, accounting for 30% of the source rocks in geological history. Cretaceous Neocomian, Albian, and Cenomanian-Turonian source rocks have been well developed in the Mid-Atlantic passive continental margin basins. However, the understanding of the quality, quantity, and spatial distribution of these source rocks and their controlling factors are limited. This study reveals the source rock characteristics of Neocomian, Albian, and Cenomanian-Turonian in the Mid-Atlantic passive continental margin basins, on the basis of the IHS, DSDP, ODP, and IODP data, as well as other published data.

In total, 22 deep sea drilling wells have been used to reveal Neocomian, Albian, and Cenomanian-Turonian deposits. The Neocomian source rocks are predominantly deep water mudstone and shale, with limestone and marl on the shelf, whereas the Albian and Cenomanian-Turonian source rocks are principally thick deep water black shale and mudstone, with interbedded black shale, mudstone, and marl. The Neocomian source rocks have a average TOC value of 1.5%, in the range of 0.5%-60%, and a average HI value of 126 mg/g, in the range of 22-768 mg/g. The TOC value of the Albian source rocks ranges from 0.5%-36.5%, with an average value of 2.2%, and the HI value ranges from 30-720 mg/g, with an average value of 207 mg/g. The Cenomanian-Turonian source rocks have a average TOC value of 4.4%, in the range of 0.5%-56%, and a average HI value of 322 mg/g, ranging between 66-687 mg/g.

The results show that the Cenomanian-Turonian mudstones are excellent source rocks, the Albian mudstones are good-excellent source rocks, and the Neocomian mudstones are fair-good source rocks. In terms of the location, each of the Neocomian, Albian, and Cenomanian-Turonian source rocks are well developed in the northwest Africa, the northeast South America, and the Mexico Gulf Basin, whereas they are poorly developed in the southwest Europe and eastern North America. From the perspective of paleolatitude, the maximum average TOC and HI values of Albian and Cenomanian-Turonian source rocks are generally observed in the paleotropical regions, with the minimum standard deviation of TOC and HI values. Significantly, the average TOC and HI values and their standard deviation values of Albian and Cenomanian-Turonian source rocks decrease as the increase of paleolatitude, within the paleosubtropical Mid-Atlantics. This suggests that the deposition of organic-rich black shale and its internal heterogeneity, and ultimately the distribution and hydrocarbon generation potential of source rocks, may have been controlled by large-scale ocean circulation, which was primarily driven by the subtropical trade winds, and hence directly linked to the position of the ITCZ and the dynamics of the Hadley Cell.

E-mail: 957576033@qq.com

Keywords: Storm deposition, tempestite, shale oil, Qingshankou Formation, Gulong Sag

Qingshankou Formation in Gulong Sag has attracted much attention because of its rich shale oil. But up to now, some basic geological problems of Qingshankou Formation shale are not clear. Therefore, it is necessary to make clear these basic geological problems. It is generally believed that Gulong Qingshankou Formation is a set of deep-lake and semi-deep-lake fine-grained deposits mainly composed of mud shale. Recent studies have found that storm rocks and storm deposits are commonly developed in Qingshankou Formation. The mud shales in the formation mostly have a sandy structure and the grain size is mainly fine sand, indicating that the environment is affected by undercurrent and the flow velocity is 0.25-0.65 cm/s. Small liquefaction veins are often developed at the bottom of tempestite, which indicates that storm shaking liquefaction is common in Gulong sag. It is also found that the water depth in Gulong sag may be 20-30 meters. These phenomena have a certain significance for understanding the formation environment of qingshankou Formation mud shale, and thus have a certain reference for oil and gas exploration and development.

Dikes in shale oil reservoir of Qingshankou Formation in Gulong Sag Geometry characteristics and their causes

Jianhua Zhong[1*], Jianbo Gap[1], Ningliang Sun[2]

1. Northeastern University at Qinhuangdao, School of resources and material, Qing Huangdao, HeBei, CHINA
2. Key Laboratory of Ministry of Education on Safe Mining of Deep Metal Mines, Northeastern University, Shenyang, Liaoning, CHINA

E-mail: 957576033@qq.com

Keywords: sand veins, liquefaction, formation dynamics, gravity subsidence, shale oil, Gulong sag

Gulong shale oil is an important replacement resource in Songliao Basin, with estimated geological reserves of up to 15 billion tons. In terms of sedimentary and petrological characteristics, the Gulong Qingshankou Formation shale is characterized by extensive sand veins, which are not found in other basins. The sandstone veins in the shale oil reservoirs of the Gulong Qingshankou Formation can be divided into five types according to lithology: (1) siltstone veins, (2) mud veins, (3) ostracoda and ostracoda debris veins, (4) pyrite veins and (5) Tuff veins. According to the form can be divided into three kinds: (1) linear; (2) the intestines; (3) mass; (4) lamellar or lamellar and (5) irregular; According to the output mode, it can be divided into (1) bedding or horizontal and (2) bedding or oblique bedding and vertical. According to the nature of the surrounding rock can be divided into three kinds: (1) mud shale; (2) siltstone and (3) dolomite. The overall size is small, with a width of 1-2 mm and a length (or height) of 1-2 cm, but large ones can be seen as wide as 10 cm and can even run through the entire core. Visible length up to 12 cm; Most curved as intestine, few slightly curved. Multi tilt output, tilt direction has a certain rule, 180 degrees of symmetry. Generally developed in gray black shale, a small amount of siltstone and dolomite (nodules). According to the preliminary study, the dikes in the shale oil reservoir of Gulong Qingshankou Formation are formed by gravity subsidence caused by density inversion: the storm rapidly transported sand-grade particles to the newly deposited clay, and the silty sand was deposited into the clay due to the low density of clay and the high density of silty sand, which resulted in the formation of sand-veins. The study of sand veins in Gulong shale oil reservoir has three significations. First, we can know the sedimentary environment, sedimentary process and sediment state when the sand veins were formed. Second, we can know the diagenetic compaction rate of mud shale. Third, it can assist reservoir evaluation.

Petrology and microscopic pore structure characteristics of shale oil reservoir in the Palaeogene Shahejie Formation of Dongpu Sag

NingLiang Sun[1*], Kun Lv[2]

1. Key Laboratory of Ministry of Education on Safe Mining of Deep Metal Mines, Northeastern University, Shenyang, Liaoning, CHINA

2. Exploration and Development Research Institute, Zhongyuan Oilfield Company, Puyang, Henan, CHINA

E-mail: 296182073@qq.com

Keywords: shale oil, fine-grained rock, petrological characteristics, microscopic reservoir, Dongpu sag

The petrology and microscopic pore structure of shale are the key indexes to evaluate the shale oil and gas reservoir performance. The petrological characteristics, lithofacies types, pore-fracture types, pore-throat distribution and oil content characteristics of the Shahejie Formation shale oil reservoir in the Dongpu Sag were studied using core observation, thin section analysis, scanning electron microscopy, mercury injection-liquid nitrogen adsorption and 3D reconstruction of micro-CT. The result shows that the main mineral components of shale oil of Dongpu Sag are clay minerals and carbonate minerals, with less felsic minerals. The main lithofacies includes laminated limestone, laminated clay stone, laminated calcareous fine-grained mixed rocks, laminated argillaceous fine-grained mixed rocks, massive clay stone, massive dolomite. The main reservoir porosity includes intergranular pores, intragranular dissolution pores, clay mineral intergranular pores and organic pores, the microfractures can be divides into diagenetic fractures and tectonic fractures, laminated limestones and laminated calcareous fine-grained mixed rocks possess more types of reservoir space, and the reservoir spaces are relatively large. Lithofacies and bedding structure are important factors that influences pore development and quality. Laminated calcareous fine-grained mixed rocks, laminated limestone and laminated argillaceous fine-grained mixed rocks possess large pore size, well pore connectivity and relatively developed microfractures as well as good shale oil content and mobility, among them, laminated limestone is the most favorable lithofacies, they are the key shale oil exploration targets in Dongpu sag.

Pore structure characterization of lacustrine shale in the Jurassic Da'anzhai member in Yuanba area, Sichuan Basin

Jiang Daiqin[1], Zou Huayao[1*]
1. College of Geosciences, China University of Petroleum-Beijing, Beijing, CHINA
E-mail: huayaozou@cup.edu.cn

Keywords: Lacustrine shale, Pore structure characteristics, Da'anzhai member; Yuanba area, Sichuan Basin

The lacustrine shale in Da'anzhai member of Yuanba area is the key research target in the exploration of continental shale oil and gas. We focused our research on well YY2 to research organic geochemistry, petrology, porosity and pore structure characterization. A combination of field emission scanning electron microscopy (FE-SEM), low pressure N2/CO2 adsorption and mercury intrusion porosimetry (MIP) measurements were conducted to characterize the pore structure and the effects of organic matter and inorganic minerals on porosity and the pore structure were discussed. Organic geochemical and petrography analysis shows that the study shale samples contain total organic carbon (TOC) that ranges from 0.70% to 1.68% with an average of 0.98%, and average vitrinite reflectance value (Ro) being 1.42%, that three organic macerals of vitrinite, inertinite and solid bitumen were identified and computed with vitrinite being the uppermost macerals. The dominant minerals in Yuanba area are clay minerals, quartz and calcite. The porosity of shale samples ranges from 2.7% to 5.0% with an average of 3.8%. FE-SEM images have provided relevant information on shale pore morphology, including OM-hosted pores, clay-mineral pores and pores of framework minerals. The Combination of CO2, N2 adsorption and MIP can effectively reveal information pertaining to micro-meso-macro pores up to a limit of 10μm. Mesopore volumes are dominant in the continental shale in the study area, followed by micropores and macropores, and the pore size distribution ranges mainly from 0.3nm to 20nm. The pore specific surface areas range from 12.76 m2/g to 21.24 m2/g with an average of 17.43 m2/g, with the CO2 micropore specific surface area by DFT model and the N2 meso-macro pore specific surface area by BET model accounting for 48.7% and 51.3%, respectively. The micro-nano pore structures in shale matrix are related to clay minerals and organic matter. Micropores, mesopores and macropores all occur in clay minerals, and the mesopores are dominant. Clay-mineral pores contribute most of the specific surface area in shale. OM-hosted pores are mainly micropores and macropores, with relatively smaller specific surface areas. OM-hosted pores are mainly associated with vitrinite, followed by inertinite. Although pores occur within the solid bitumen, the solid-bitumen pores are not mainly contributed to OM-hosted pores. The fractures parallel to bedding are common in Da'anzhai shales, some of which are Calcite-filled and solid-bitumen-filled in, indicating that they belong to natural fractures, once have been opened underground. The unfilled fractures are not necessarily artificial induced fractures. Microfractures observed on FE-SEM images are also considered as macropores to store shale gas. This study has important significance in gaining a comprehensive understanding of continental shale pore structure and the shale gas storage-seepage mechanism.

Analysis of Difference of Pore Structure between Lacustrine and Marine Shales

Houjian Gong[1*], Zhenxue Jiang[1], Tingwei Li[2]
1. Unconventional Petroleum Research Institute, China University of Petroleum (Beijing), Beijing, State/Province, CHINA
2. Guangzhou Marine Geological Survey, China Geological Survey, Guangzhou , Guangdong , CHINA
E-mail: gonghoujian@126.com

Keywords: lacustrine facies,marine facies,shale reservoirs,pore structure

The key factor influencing oil and gas enrichment is the pore structure of shale reservoirs. Influenced by different depositional environments, the pore structure of lacustrine shale and marine shale is significantly different. Applying the method of gas adsorption, scanning electron microscope and high-pressure mercury injection, as well as taking the lacustrine shale of Shahejie Formation in Jiyang Depression and the marine shale of Longmaxi formation in Sichuan Basin as examples, the thesis deeply analyzes the difference of pore structure between lacustrine and marine shale reservoirs. The results show that there are two kinds of organic matter pores in lacustrine shale reservoirs. The one is complex formed by organic matter and inorganic minerals through adsorption, wrapping or filling. Numerous organic matter pores developed in the interior or edge of the complex in irregular multilateral shape or slit shape. The other one is massive organic matter, which is distributed in inorganic minerals in an isolated form, and developed inside the organic matter in circular or oval shape. The marine shale reservoirs develop densely distributed and interconnected honeycomb-shaped organic pores. The pore volume of marine shale is mainly provided by micropores and mesopores, and the specific surface area is provided by micropores and mesopores. The degree of pore development of marine shale is sorted from large to small, which are micropores, mesopores and macropores respectively. The pore volume of lacustrine shale is mainly provided by mesopores and macropores, and the specific surface area is provided by micropores and mesopores. The pore development degree of lacustrine shale is sorted from large to small, which are macropores, mesopores and micropores respectively. Micropores control the adsorbed gas volume of marine shale reservoirs through large specific surface area, and is of great importance in the contribution of movable gas, which can provide a large adsorption surface and reservoir space for shale gas, beneficial to the occurrence of shale gas. Macropores of lacustrine shale determine the enrichment of movable hydrocarbons through large pore volume, which can provide a large reservoir space and seepage channels for shale oil, beneficial to the occurrence and flow of shale oil.

Spatiotemporal distribution of major source rocks in the transition from depressed to rifted basin: A case study of the Guyang to Linhe Formations in the Linhe Depression, Hetao Basin, China

Chenxi Li[1,2], Zhen Liu[1,2*]
1. State Key Laboratory of Petroleum Resource and Prospecting, China University of Petroleum (Beijing), Beijing, CHINA
2. College of Geoscience, China University of Petroleum (Beijing), Beijing, CHINA
E-mail: 1552818282@qq.com

Keywords: Depressed-rifted transition, Organic facies, Velocity-lithology model, Source rock,Differential superposition, Linhe Depression

Source rock prediction in the Linhe Depression is exceptionally difficult owing to inadequate data, while the process by which depressed-rifted conversion influences source rock distribution remains unclear. Thus, this study aimed to predict source rock distribution and demonstrate its influencing factors. Based on outcrop, geochemical, well log, and seismic information, a seismic methodology involving the prediction of organic facies distribution using seismic facies analysis and mudstone thickness via a seismic velocity-lithology model was applied to predict source rocks. Our study showed the suitability of this method for early exploration in basins with inadequate data. The correlation coefficient between the predicted and borehole values of mudstone was 0.94, and the relative error was < 14.6%. The optimal source rocks in the second member of the Guyang Formation were encountered in new wells JHZK9, LHC1, and JH14 and accurately predicted, thereby validating our methodology. Furthermore, optimal source rocks transitioned from broad to limited distributions, moved closer to the boundary fault, and transferred from gentle slopes to deep sags during the depression to rift period. This transition dominated the distribution of source rocks. The basin type restricted the location of source rocks, and the transfer of lacustrine centers played a leading role in the distribution and differential superimposition of source rocks. Additionally, differential compression influenced source rock thickness in the second member of the Guyang Formation, while segmented variations in the boundary fault style and activity rate influenced the thickness in the second member of the Linhe Formation. This study effectively predicted the distribution and thickness of the main source rocks in the Linhe Depression, which was confirmed by new drilling wells, further analyzed the controlling effect of depressed-rifted transition on the distribution of source rocks, which has great reference significance for the study of source rocks in similar superimposed basins.

Main controlling factors and genetic mechanism of effective reservoir development of deep clastic rocks --- A case study of the Xujiahe Formation in the Northwest Sichuan Basin

yiqing Su[1*], Zhuangzhuang Bai[1]
1. Institute of Oil and Gas Geology, Research Institute of Petroleum Exploration and Development, Beijing, CHINA
E-mail: 949996315@qq.com

Keywords: Northwestern Sichuan, deep layer, high-quality reservoir, sedimentary microfacies, diagenesis, fracture

The deep clastic rock of Xujiahe Formation in the northwest of Sichuan Basin is an important field of natural gas exploration, and the reservoir is one of the key factors controlling the development of gas reservoir. The main controlling factors and genetic mechanism of reservoir development are studied by using core, outcrop, seismic and logging data, and four new understandings are obtained. First, the deep effective reservoir of Xujiahe formation is a low porosity and permeability reservoir, which is mainly developed in delta underwater distributary channel, estuarine bar and other microfacies. The lithology is mainly coarse sandstone and pebbly fine sandstone. The reservoir space mainly includes primary pores, intragranular and intergranular dissolution pores and fractures. The average porosity is 5.90%, which belongs to ultra-low porosity, and the average reservoir permeability is 12.9 × 10-3 μm2, belonging to extra low-ultra low permeability. Second, the development degree of effective reservoir is mainly controlled by sedimentary microfacies, diagenesis and fracturing. The medium coarse sandstone in underwater distributary channel is a favorable sand body; The dissolution pores formed by dissolution and the transformation of primary pores effectively improve the porosity and permeability of sand body; The structural fractures produced by fracturing play an important role in the reservoir. Third, The genetic mechanism of deep effective reservoir in Xujiahe formation is as follows: underwater distributary channel sand body in delta front was buried rapidly in the early stage and retained a large number of primary pores; Under high temperature and high pressure, feldspar dissolves rapidly, which is conducive to the formation of a large number of secondary pores; The widely developed chlorite cementation can effectively protects the primary poresThe abnormal high pressure in the foreland depression is conducive to the preservation of reservoir space; The tectonic stress during the formation of foreland basin forms a large number of fractures, which is conducive to the formation of large-area effective reservoirs. Fourth, combined with sedimentary microfacies, lithology, reservoir thickness, porosity, pressure coefficient and other factors, comprehensively evaluate four effective scale reservoir development areas in Northwest Sichuan, including Zitong-Laoguanmiao-Wenxingchang, Zhongtaishan, Weicheng, Zhebachang-Bailongchang- Jianmenhe. The results have important reference significance for enriching the genetic theory of deep clastic rocks and guiding natural gas exploration.

Diagenetic alteration in Carboniferous mudstones, UK: insights from integration of 2D and 3D imaging

Jingyue Hao[1*], Lin Ma[2], Cathy Hollis[1], Kevin Taylor[1]

1. Department of Earth and Environmental Sciences, The University of Manchester, Manchester, Greater Manchester, UNITED KINGDOM

2. Department of Chemical Engineering, The University of Manchester, Manchester, Greater Manchester, UNITED KINGDOM

E-mail: jingyue.hao@manchester.ac.uk

Keywords: Bowland Shale, Mudstone, Diagenesis, XCT

The characterisation of mudstones is challenging owing to their fine-grained and heterogeneous nature, and complex microstructure. Mineral composition, and the diagenetic evolution of this, is an important control on mudstone properties, porosity and permeability. As well as traditional 2D microscopic imaging techniques, mineral distribution and microstructures can be visualised in 3D at the micro- to nano- scale with the use of synchrotron-derived x-ray tomography. This study integrates 2D and 3D imaging to provide a unique perspective on the spatial distribution and texture of minerals in the Carboniferous Bowland Shale Formation, UK, looking at mudstones with both early and burial diagenetic histories.

Early to intermediate diagenetic processes observed include shell dissolution, pyrite precipitation, the precipitation of barite, calcite, kaolinite, dolomite, ankerite and quartz and the replacement of kaolinite by illite. 3D images show that the orientation of kaolinite, barite and anhedral pyrite is preferentially parallel to the bedding, which is related to the presence of laminations and the distribution of shell material. The Bowland Shale samples having undergone deeper burial diagenesis contain kaolinite, illite, chlorite, pyrite, silica nanospheres, micron-sized quartz, quartz overgrowths, non-ferroan and ferroan dolomite, ankerite and calcite (including oscillatory zoned ankerite, non-ferroan and ferroan dolomite). 3D images show that ankerite was precipitated in space created by the dissolution of ferroan dolomite. Ankerite dissolution was also observed in the studied samples, and occurred prior to the formation of calcite-filled veins. Pores are present within and around pyrite and silica nanospheres and the presence of these minerals limited compactional loss of porosity during diagenesis. Three types of carbonate-related pores were observed, namely (i) intra-, (ii) inter-, and (ii) intra- and inter- mineral jointed pores, which are partially within the mineral and partially bounded to the mineral. These jointed pores are interpreted to have formed through the dissolution of carbonate grains during burial diagenesis.

The integration of 2D and 3D imaging data obtained within this project has provided uniquely comprehensive evidence on the mineral-pore and mineral-mineral relationships, allowing the diagenetic histories much better understood from both planar and spatial perspectives.

Shale lithofacies characteristics and reservoir differences of Wufeng Formation-Longmaxi Formation in southeastern Sichuan-northwestern Guizhou

Guanbao Ren[1], Lei Chen[1*]

1. School of Geoscience and Technology, Southwest Petroleum University, Chengdu, Sichuan, CHINA

E-mail: cl211@126.com

Keywords: lithofacies,shale reservoir characteristics,Wufeng Formation-Longmaxi Formation,Southeast Sichuan-Northwest Guizhou

As the basis of shale gas geological research, shale lithofacies control the hydrocarbon generation capacity, reservoir performance and fracturing performance of shale, and affect the distribution of "sweet spots" in shale reservoirs. Based on the test data of thin section identification, X-ray diffraction analysis, total gas content and TOC content, this paper finely divides and analyzes the shale lithofacies of Wufeng Formation-Longmaxi Formation in the southeast Sichuan-northwest Guizhou. It is demonstrated that: (1) the study area develops twelve lithofacies, namely, calcareous shale lithofacies (C-1), mixed calcareous shale lithofacies (C-2), clay-rich calcareous shale lithofacies (C-4), mixed clayey shale lithofacies (CM-2), silicon-rich clayey shale lithofacies (CM-4), mixed siliceous shale lithofacies (S-2), calcium-rich siliceous shale lithofacies (S-3), clay-rich siliceous shale lithofacies (S-4), calcareous/siliceous mixed shale lithofacies (M-1), mixed shale lithofacies (M-2), clayey/calcareous mixed shale lithofacies (M-3) and clayey/siliceous mixed shale lithofacies (M-4). (2) There are differences in reservoirs among various lithofacies. Among them, the TOC content of mixed siliceous shale lithofacies (S-2), calcium-rich siliceous shale lithofacies (S-3) and calcareous/siliceous mixed shale lithofacies (M-1) is more than 3%, the gas content is more than 2m3/t, and the content of brittle minerals is more than 70%; The TOC content of mixed shale lithofacies (M-2) is 2~3%, the gas content is about 2m3/t, and the content of brittle minerals is 64%; The TOC content of mixed calcareous shale lithofacies (C-2), clay-rich calcareous shale lithofacies (C-4), clay-rich siliceous shale lithofacies (S-4), clayey/calcareous mixed shale lithofacies (M-3) and clayey/siliceous mixed shale lithofacies (M-4) is less than 2%, the gas content is less than 2m3/t, and the content of brittle minerals is 60%~70%; The TOC content of mixed clayey shale lithofacies (CM-2) and silicon-rich clayey shale lithofacies (CM-4) is 2%~3%, the gas content is more than 2m3/t, but the content of brittle minerals is less than 30%. (3) Based on the entropy method and the actual geological conditions of the study area, the division standard of advantageous lithofacies is established, and three advantageous lithofacies are divided into class I, class II and class III. Among them, calcareous/siliceous mixed shale lithofacies (M-1), mixed siliceous shale lithofacies (S-2) and calcium-rich siliceous shale lithofacies (S-3) are class I lithofacies (the most advantageous lithofacies); mixed shale lithofacies (M-2), clayey/siliceous mixed shale lithofacies (M-4) and clay-rich siliceous shale lithofacies (S-4) are class II lithofacies; calcareous shale lithofacies (C-1), mixed calcareous shale lithofacies (C-2), clay-rich calcareous shale lithofacies (C-4), clayey/calcareous mixed shale lithofacies (M-3), mixed clayey shale lithofacies (CM-2) and silicon-rich clayey shale lithofacies (CM-4) are class III lithofacies.

Mechanism of super-organic matter rich in Triassic Chang 7 shale of Ordos Basin, China

Weiwei Yang[1*], Yi Yang[1]

1. Experimental Research Center, Petroleum Exploration and Development Research InstituteChangqing Oilfield Company, CNPC, Xi'an, Shanxi, CHINA

E-mail: yww1_cq@petrochina.com.cn

Keywords: super organic-rich shale, fresh and brackish water,high rates of production,volcanic events,hydrothermal activity,Ordos Basin

Bulk geochemical data indicate that Triassic Chang 7 shale is super rich in organic matters while it was formed in a fresh and brackish water, which is not usually the case for high TOC sediments. So there must be some special conditions favorable for organic matter (OM) enrichment in Chang 7 shales, and systematic petrographic and geochemical analyses were performed. It was shown that the Chang 7 super organic-rich shales are abundant in organic laminae, framboidal pyrites, collophanes, and some elements including iron (Fe), diphosphorus pentoxide (P2O5), copper (Cu), vanadium (V), molybdenum(Mo), and uranium(U). In addition, the organic carbon contents increase as the Fe, P2O5, Cu, V, Mo, and U element contents increase and the ratios of U/Th and V/(V+Ni) are growing. Therefore, high productivity (algae blooming) and anoxic depositional environments are critical for OM enrichment. Many geochemistry data demonstrate that the water is oxic, while the environment under the sediment-water interface is anoxic as a result of a high organic supply that sufficiently consumes oxygen. Combined with the geological settings and our previous studies, we propose that the frequent volcanic events and hydrothermal activity, which were caused by the collision of the North China landmass with the Yangtze landmass and the formation of the Qingling Mountains, are significant in the OM enrichment in the fresh and brackish lacustrine shales. Deposition of volcanic ash into aqueous environments may lead to the increase of some key nutrients, such as Fe and P2O5, which may enhance primary productivity. New evidence for hydrothermal activity, the reddingite, was demonstrated in this study. Not only can the hydrothermal activity provide elements necessary for life, but also it is favorable for anoxic settings. The deposition of the Chang 7 lacustrine organic-rich shales can be explained using the High-Productivity-Driven Model, which is related to volcanic events and hydrothermal activity as a consequence of regional tectonic movement. An anoxic depositional setting is beneficial for OM preservation and slow sedimentation rates in the deep lacustrine are favorable for OM enrichment.

Great breakthroughs have been made in shale oil exploration of Fengcheng Formation in Mahu depression, Junggar Basin, but the reservoir characteristics and internal shale oil occurrence characteristics of fine-grained sedimentary rocks of Fengcheng Formation need to be further studied. Based on the core observation of MY1 well and combined with macro-micro scale analysis, this study comprehensively reveals the characteristics of various types of fine-grained rock reservoirs and oil-bearing properties.

The fine-grained sedimentary rocks of Fengcheng Formation in well MY1 are mainly deposited in semi-deep lake to deep lake, with thin-layer event deposits such as gravity flow and hydrothermal solution. Based on the classification scheme of felsic carbonate clay minerals and X-ray diffraction data, the main fine-grained rock types and research units are determined as siliceous rock, mixed siliceous mudstone, siliceous carbonate mudstone and carbonate siliceous mudstone. Combined with microscopic identification argon ion polishing scanning electron microscope observation, except that siliceous carbonate mudstone develops a large number of dissolution pores and more intergranular pores, other fine-grained rocks generally develop intergranular pores, intergranular pores and dissolution pores, and each fine-grained rock contains a small amount of organic pores and fractures.Based on the combined analysis of low-temperature nitrogen adsorption high-pressure mercury injection ct-fib-sem and other means, each fine-grained rock type contains nano-sized pores and micron sized pores. According to the fractal theory of nitrogen adsorption and high-pressure mercury injection, the pore structure of siliceous rock is the simplest, which is followed by siliceous carbonate mudstone, carbonate siliceous mudstone and mixed siliceous mudstone.S_1, TOC and OSI parameters of fine-grained rocks show that Fengcheng Formation has good oil bearing property. The oil bearing property of siliceous rock is the best, the oil bearing property of siliceous carbonate mudstone is poor, and the oil bearing property of mixed siliceous mudstone and carbonate siliceous mudstone is medium.

Generally speaking, the shale oil reservoirs are siliceous rock, carbonate siliceous mudstone, siliceous carbonate mudstone and mixed siliceous mudstone from excellent to poor. This achievement will provide a target for further exploration and evaluation of shale oil in Fengcheng Formation.

Microfacies analysis and mapping of the late Ordovician-early Silurian Wufeng–Longmaxi shelf shale in southern Sichuan Basin, China

Zhensheng Shi[1*]

1. Unconventional oil and gas, PetroChina Research Institute of Petroleum Exploration Development, Beijing, CHINA
E-mail: shizs69@petrochina.com.cn

Keywords: microfacies analysis, microfacies mapping, shelf shale, southern Sichuan Basin, Wufeng–Longmaxi shale

Microfacies analysis and mapping of shelf shale are a hot spot in shale sedimentology. Based on shale thickness and X-ray diffraction whole rock data, microfacies and their distribution are analyzed and mapped systematically. The results show that: (1) Shale thickness and contents of carbonate, quartz, and clay minerals are closely related to topography, water depth, and transportation pathways and can be used to indicate microfacies. Commonly, the lower the topography, the thicker the shale; the deeper the water depth, the higher the quartz content; the shallower the water depth, the lower the carbonate content; the closer to transportation pathways, the higher the clay mineral content. (2) Shelf shale can be subdivided into five microfacies based on shale thickness and contents of carbonate, quartz, and clay minerals, namely, shallow shelf, subaqueous slope, subaqueous plain, subaqueous sag, and turbidite. Shallow shelf has the highest carbonate content above 20%, subaqueous sag has the highest quartz content above 55%, and turbidite has the highest clay mineral content above 35%. (3) Distributions of shale thickness and contents of carbonate, quartz, and clay minerals can be used comprehensively to identify microfacies distribution for the Wufeng–L11 shelf shale. As a result, two highs, one slope, one plain, four sags, and eight turbidite are shown in the southern Sichuan Basin, China.

Geological controls on the pore structure of the lacustrine Triassic Chang 7 Shale in the Ordos Basin, China

Guanping Wang[1*], Zhijun Jin[2], Qian Zhang[2]
1. School of Energy Resources, China University of Geosciences, Beijing, Beijing, CHINA
2. Institute of Energy, Peking University,, Beijing, CHINA
E-mail: wangguanping@cugb.edu.cn

Keywords: Pore structure,fractal dimensions,thermal maturity,mineral composition, lacustrine Chang7 Shale.

The complex pore system of lacustrine organic-rich shales poses challenges to the evaluation of shale oil and gas resources. To improve our understanding of the pore structure and its controls of the lacustrine Chang 7 Shale in the Ordos Basin, 12 samples at the oil window stage with varying organic matter contents were analyzed using total organic carbon (TOC), vitrinite reflectance (Ro), X-ray diffraction (XRD), field emission-scanning electron microscopy (FE-SEM), low-temperature N2 and CO2 adsorption experiments and fractal method. The results showed that macro- and meso-pores contribute to the main pore volume in the lacustrine Chang 7 Shale. Pore diameter peaks are dominantly distributed around 0.7 and 37 nm. The intragranular pores in clays and intergranular pores between minerals and OM are well developed, while the pores in OM are rarely observed. The fractal dimensions of the Chang 7 Shale's pore structure suggest that D2 is better than D1 in reflecting the pore heterogeneity. OM shows negative effects on the total pore volume, while quartz promotes the development of macro- and meso-pores. The relationship between clay minerals and total pore volume shows a reversed U-shape curve (pore volume increases first up to 45% clay content and decreases thereafter). Both quartz and clays show negative effects on the heterogeneity of meso- and macro-pores, and positive effects on the micro-pore heterogeneity. A new abrupt change of the pore system in lacustrine shales happens at the critical maturity value of 0.8% Ro. Both the pore structure parameters and fractal dimensions show the inverse trends before and after this critical value. This observation is closely related to the compaction processes coupled with hydrocarbon generation and expulsion, which helps better understand the pore system evolution in the lacustrine shales.

Characteristics and diagenetic evolution of fine-grained sedimentary rocks in the first member of Qingshankou Formation in central depression of northern Songliao Basin

Lianxin Tao[1], Pingchang Sun[1*]
1. College of Earth Sciences, Jilin University, Changchun, Jilin, CHINA
E-mail: sunpingchang711@126.com

Keywords: Songliao Basin, section 1 of Qingshankou Formation, fine sedimentary rock characteristics, diagenesis, hydrocarbon evolution

The fine-grained sedimentary rock of the upper Cretaceous Qingyi Member in the central depression area of northern Songliao Basin is an important source rock series in this area. In order to determine the characteristics and diagenetic evolution of different types of fine-grained sedimentary rocks, the rock types and fine characteristics of fine-grained sedimentary rocks in the first member of Qingyi Formation in the study area were studied by means of rock thin section, scanning electron microscope, X-ray diffraction and organic geochemical analysis. The diagenetic evolution stages of different burial depths were divided. The burial history, thermal history recovery and hydrocarbon generation evolution characteristics were analyzed, and the relationship between diagenetic evolution and potential unconventional oil and gas types was revealed.

According to core observation and X-ray diffraction analysis, with TOC, felsic minerals, clay minerals and carbonate minerals as parameters, the rock types of the first member of Qingyi Formation are finely divided into eight rock types : high organic clay shale, high organic felsic shale, high organic mixed shale, medium organic felsic shale, medium organic mixed shale, low organic felsic shale, low organic siltstone and low organic carbonate rock.

Through the analysis of TOC, rock pyrolysis analysis, biomarkers and other data, the average TOC of Qingyi Member is 2.59 %, indicating that the overall abundance of organic matter is high. Ro,Tmax, CPI and OEP data show that the Qingyi Member is distributed in the immature-high mature stage. Based on the intersection diagram of S2 and TOC, it is shown that among the eight rock types in the first member of Qingyi Formation, clay shale, feldspar shale and mixed shale with high organic matter have good hydrocarbon generation potential, followed by feldspar shale and clay shale with medium organic matter, and feldspar shale, siltstone and carbonate rock with low organic matter have poor hydrocarbon generation potential.

Through the observation of thin section and light section, scanning electron microscope and energy spectrum analysis, it is found that the diagenesis of Qingyi Member mainly includes compaction and pressure dissolution, cementation, dissolution and clay mineral evolution. The felsic minerals increased with the increase of depth, while the clay minerals decreased gradually. In clay minerals, as a whole, kaolinite gradually disappears, chlorite gradually decreases, and illite-montmorillonite mixed layer gradually transforms to illite with the decrease of depth. Overall, the study area is in the early diagenetic B-middle diagenetic B diagenetic stage.

Through fluid inclusion temperature measurement, combined with previous tectonic uplift data and paleogeotemperature curve in this area, the burial history and thermal history of wells in different regions and different depths are restored. It shows that in the shallow buried area (2150 m), the organic matter has carried out large-scale hydrocarbon expulsion stage in the early stage, and then entered the thermal cracking stage. Based on the organic geochemical characteristics, a thermal evolution hydrocarbon generation model was established. In the immature-low maturity stage , most organic matter hydrocarbon generation basically ended, and the crude oil formed earlier showed light optimization and humidification.

Orbital and sub-orbital pacing of mudstones in Dongying Depression, eastern China: Implications for Middle Eocene East Asian climate evolution

Xiangxin Kong[1*], Zaixing Jiang[1]
1. School of Energy Resources, China University of Geosciences (Beijing), Beijing, CHINA
E-mail: kongxiangxin@cugb.edu.cn

Keywords: Obliquity, semi-precession, Middle Eocene Climate Optimum, East Asian monsoon, Dongying mudstones

The Middle Eocene was a key stage in East Asian and global climatic evolution. A 390 m thick mudstone succession in the Dongying Depression (eastern China) contains a continuous continental sedimentary record that can be used to investigate key climate variations during the Middle Eocene in East Asia. The deposition of the Dongying mudstones extended from ~43.48 Ma to ~39.24 Ma and can be divided into five climate stages based on pollen and mineral compositions. The Middle Eocene Climatic Optimum, which was characterized by a hot humid climate unlike other stages recorded by the Dongying mudstones, was recorded in a stage that contains organic-rich claystones. This study is the first characterization of the Middle Eocene warming event in eastern China. We also found that the orbital and sub-orbital cycles recorded by the Dongying mudstones drove the climatic changes and influenced carbonate enrichment. Based on the relationship between astronomical signals and climate parameters, the obliquity signal may represent variations in cold and dry airflow from high latitudes, while the semi-precession signal may represent changes in warm and wet airflow from low latitudes. These two orbital cycles may have played roles similar to the winter and summer monsoons in the present East Asian monsoon system, respectively. Therefore, the Dongying mudstones not only recorded global temperature fluctuations during the Middle Eocene, but also recorded the early evolution of the East Asian monsoon. This study further indicates that astronomical cycles played a critical role in the onset and strengthening of the East Asian monsoon.

Sedimentary and Reservoir Characteristics of lacustrine shale in Jurassic Lianggaoshan Formation, Fuling Area, Sichuan Basin, China

Yanji Li[1], Qingshao Liang[2*]

1. College of Earth Sciences , Chengdu University of Technology, Chengdu, Sichuan, CHINA
2. Institute of Sedimentary Geology, Chengdu University of Technology, Chengdu, Sichuan, CHINA

E-mail: liangqs@cdut.edu.cn

Keywords: Fuling area,Lianggaoshan Formation,Sedimentary environment,Reservoir space

In order to explore the oil and gas potential of Jurassic lake shale in Sichuan Basin, the lacustrine shale of Lianggaoshan Formation in the Fuling Area is taken as the research object, and the lacustrine shale sedimentary and reservoir characteristics of Lianggaoshan Formation are systematically analyzed based on core observation, thin section analysis, Ar-ion polishing scanning electron microscope and gas content measurement. The Lianggaoshan Formation in the Fuling Area is dominated by delta-lake sedimentary system, in which the semi-deep Lake is a favorable environment for the development of organic shale. The reservoir space of shale in Lianggaoshan Formation is dominated by micro-fractures with high gas content, and the lacustrine shale in the Fuling area is widely distributed, with large continuous thickness and well developed reservoir space, which provides a good preservation condition for shale gas. The study on lacustrine shale sedimentary environment and reservoir characteristics of Lianggaoshan Formation can guide the exploration of lacustrine shale gas in the Fuling Area.

Study on sedimentary environment of fine-grained sedimentary rocks of the Lower Cambrian Qiongzhusi Formation in Sichuan Basin and its periphery

Kaixuan Cao[1], Dong Wu[1*], Zhaoheng Liu[1], Meiyan Fu[1], Wang Xu[1], Haoxiang Lan[1], Guanghui Duan[1]
1. College of Energy, Chengdu University of Technology, Chengdu, Sichuan Province, CHINA
E-mail: lisandpw@163.com

Keywords: Sichuan Basin, Qiongzhusi Formation, Fine-grained sedimentary rocks, Sedimentary environment, Sedimentary microfacies

The exploration and development practice shows that the shale of the Lower Cambrian Qiongzhusi Formation in Sichuan Basin and its periphery shows a good shale gas exploration prospect. However, due to many factors such as deep burial, complex tectonic sedimentary background and limited research data, the understanding of the rock characteristics and sedimentary environment of this set of shale is relatively weak, which limits the exploration and development of shale gas to a certain extent. Based on the habit that the division of shale sedimentary environment generally depends only on water depth and lithofacies in the previous research, this paper systematically studies the sedimentary environment of Qiongzhusi Formation based on the field outcrop, core and logging data of Qiongzhusi Formation in Sichuan Basin and its periphery, combined with geochemical parameters, paleontological species and other identification marks. In the shelf environment with combined influence of ocean and ancient land, medium water depth and strong reduction, four sedimentary microenvironments are further identified: oxygen-rich wave tide disturbing, oxygen-rich weak evaporation mixing, oxygen-poor limited still water and anoxic upwelling current disturbing. The study of sedimentary microenvironment of Qiongzhusi Formation can effectively help to understand the sedimentary evolution of this set of marine shale and provide reference for the next oil and gas exploration direction.

4. Research Institute of petroleum exploration and exploitation, PetroChina Xinjiang Oilfield Company, Karamay, Xinjiang, CHINA

E-mail: zhangjingyalx@163.com

Keywords: Mixed sedimentation, Source rocks, Shale oil, Organic geochemistry, Lucaogou Formation, Junggar Basin

The Permian Lucaogou Formation (P_2l) in the Jimusaer Sag, Junggar Basin in China is considered as a promising target for shale oil exploration and exploitation. It is an essential source rock as well as a shale oil producing layer, characterized by mixed sedimentation of three end-member components of siliciclastics, carbonates, and tuffaceous materials, which is significantly different from the conventional source rocks (e.g., mudstones or carbonates). Methods including core and thin section analysis, X-ray diffraction, Soxhlet extraction, TOC measurements, Rock-Eval pyrolysis, organic maceral analysis, organic carbon isotope analysis and Gas chromatography−mass spectrometry were used to investigate the mixed sedimentation process, hydrocarbon potential and depositional environment characteristics of the fine-grained mixed rocks in the Lucaogou Formation. The P_2l mixed rocks were divided into terrigenous-, carbonate-, and tuffaceous-dominated mixed rocks, formed through the mixing processes of facies mixing, source mixing, punctuated mixing and in-situ mixing. They were highly abundant of organic matter (OM) at the thermally low mature to mature stage, which mainly originated from the mixture of planktonic organisms, bacteria, and terrigenous higher plants. The lithofacies association, OM material source and hydrocarbon generation potential of mixed rocks in the early (lower section) and late (upper section) depositional stages of P_2l showed some differences. Compared with the lower section, there were less terrigenous supply influx during the upper section deposition, which was demonstrated by less terrigenous- and tuffaceous-dominated mixed rocks, as well as terrestrial OM input, but more carbonate-dominated mixed rocks, and sapropelic kerogen of bacterial, algal and planktonic source. Besides, the hydrocarbon potential of the upper section was higher than that of the lower section, proved by higher values of TOC, $S_1 + S_2$, and hydrogen index (HI) parameters in the upper section samples. The mixed source rocks in the lower and upper sections of P_2l were deposited in different environment as well, which was mainly controlled by climatic change, and thus indicative of lake basin evolution. During the lower section deposition, the climate was warm and humid, and the depositional environment was deeper, dysoxic−anoxic and brackish, with a more balanced-filled scenario dominating. Whereas during the upper section deposition, the climate became semiarid and hot with greater evaporation. The lake basin indicated an under-filled setting, with shallow, saline, and evaporative environment. Overall, the fine-grained mixed rocks in the Lucaogou Formation were source rocks of high quality, offering favorable resource potential for shale oil exploration.

Keywords: lacustrine organic-rich laminated shales, aragonite, paleoenvironmental

Lacustrine organic-rich laminated shales are often varves representing annual rhythmic deposition, potentially preserving information about the tectonic setting, paleoaltimetry, paleoenvironments, variations in lake water conditions (evaporative concentration, source waters, temperature) and biological activity. Aragonite lamina, which was found from the first member of Shahejie formation, Eocene strata in Bonan Sag, Bohai Bay Basin, provide significant paleolake signatures. Mineralogical and geochemical analyses were conducted on alternating yellowish and greyish aragonite lamina. The yellowish layers are mainly composed of aragonite crystals and algae skeleton, while the greyish layers contain less aragonite and fewer organic remnants that accumulate among debris with sporadic framboidal pyrite. The δ13C values of yellowish layers are remarkably positive, while the δ18O values are slightly negative. Consequently, in the warm season, due to the high salinity and evaporation effects, Mg/Ca ratios are elevated. And the algae bloom causes a decrease in the CO2 content, leading to high pH values, which are favourable for the precipitation of aragonite instead of other carbonate minerals. Moreover, slightly negative δ18O values in yellowish layers are interpreted as the result of intense inflow during warm seasons, which leads to less precipitation of organic matter and debris. The greyish layers in cold seasons are the opposite. The results from this study show that understanding the lacustrine lamina origin of Bonan Sag is essential for paleoenvironmental and paleoclimate interpretations.

Sedimentary and geochemical characteristics of marine-continental transitional shale gas in the eastern margin of Ordos Basin

Dexun Liu[1*], Leifu Zhang[1], Qun Zhao[1], Yuanjiang Yu[1], Xiaobo Li[1]
1. Unconventional Department, Research Institute of Petroleum Exploration and Development, PetroChina, Beijing, CHINA
E-mail: liudexun@petrochina.com.cn

Keywords: shale gas, marine-continental transitional, lagoon deposits, geochemical characteristics

A systematic study was conducted using intensive sampling, core analysis, rock thin sections and drill logging data to identify sweet spot in the Daning-Jixian region of the Shanxi Formation. The first Marine and continental transitional shale gas iron pillar well in China has been established, and the Shan32 sub-member is proposed as the sweet spot of development target.

The vertical variations of sedimentological and geochemical characteristics suggest that the Benxi, Taiyuan, and Shanxi formations were deposited under different environment conditions. The Upper Carboniferous Benxi Formation was dominated by marine environment, and then changing to transitional facies. The Lower Permian Taiyuan Formation is a sedimentary system with alternating marine and transitional facies. Marine limestones are characterized by abundant marine fauna and flora, along with the lowest detrital influx input among the three formations. In contrast, transitional shales are characterized by higher detrital influx input and oxic sedimentary environment. The Shanxi Formation is a typical marine-continental transitional depositional system. Ten types of lithofacies were identified. In additionten lithofacies were classified into four associations that reflect four depositional environments: tidal flat depositssupratidal to intertidal zones, lagoon deposits, tidal channel to tidal flat deposits and lagoon-tidal flat deposits. The lithofacies association in the deep lagoon are favorable for the development of a high-TOC shale gas reservoir.

The Lower Shanxi Formation is characterized by complex interbed-ding of shales, sandstones and coals. Sandy intervals are resulted from mouth bar and tidal channel deposition, which are characterized by no organic matter enrichment, high Ti and Al content, showing influence, but limited, of seawater. Shale intervals with high TOC, Sr/Ba, U/Th, and trace elemental proxies values (U/Th, MoEF, and UEF) were deposited in a lagoonal environment. Shale intervals were deposited in a lagoonal environment with high TOC (0.94–40.64%, avg. 5.43%), Sr/Ba and trace elemental proxies values (U/Th, 0.18–3.27%, avg. 0.44%; MoEF, 0.95–32.3, avg. 8.56; UEF, 0.67–15.17, avg. 2.53).

This study shows that high-resolution geochemical characteristics of elements could be reliable indicators for sedimentary microfacies analysis, and hence could provide implications for marine - continental transitional shale gas favorable sedimentary facies belt in which sedimentary environment changes frequently and organic-rich sediment accumulated under varied conditions. Marine and continental transitional shale gas opens a new field for shale gas development in China in the future. Large shale gas field is expected to be built i in the eastern margin of Ordos Basin. It is estimated that the production of Marine and terrestrial transitional shale gas will reach more than 10 billion cubic meters in 2035.

E-mail: muchang503@126.com

Keywords: Shale gas, Laminae, Reservoir quality, Longmaxi formation, Sichuan Basin

Widely developed in shale strata, laminae are the most typical shale sedimentary structure. To investigate their influence on shale gas reservoir quality, this study of the marine Silurian Longmaxi Formation in the Sichuan Basin used microscopic observations on standard-size thin sections and larger polished thin sections (7.6 cm × 4.8 cm), X-ray diffraction whole rock mineral analysis, field-emission scanning electron microscopy (FE-SEM) imaging, nitrogen adsorption testing, and mercury intrusion capillary pressure (MICP) techniques. The microscopic observation of thin sections enabled us to detect the laminae characteristics, including the density and maximum thickness of individual lamina, and four types of lamina development were identified: silica-rich lamina, carbonate-rich lamina, clay-rich lamina, and organic-rich lamina. The total organic carbon (TOC) content, mineral composition, natural fracture, pore type, pore size distribution, porosity, permeability, and tortuosity were investigated in these different laminae types using FE-SEM, MICP and geochemical analysis. Within their relatively small lateral extent, laminae mainly present as planar, discontinuous and parallel(Shi et al., 2018). The thickness of laminae ranges from 0.08 mm to 2.2 mm. The silica-rich laminae develop natural fractures(Guan et al., 2019 & 2021). And there are three types of laminasets: silica-organic laminaset, silica-clay laminaset, and carbonate-organic laminaset, the reservoir property and fracability of silica-organic laminaset are better than other laminasets. The silica-organic laminaset is the priority exploration target in the Longmaxi Formation. Combining the laminae and laminaset characteristics, and their pore structure, we concluded that the organic pores and total pore area are mainly affected by the TOC content, whereas the development of the laminae controls the inorganic macropore scale and affects the pore size distribution. Future research should focus on the hydrodynamic background of laminae formation and its influence on organic matter enrichment and reservoir stimulation. Relevant knowledge can provide an important reference and technical support for increasing the optimization and evaluation of favorable reservoirs in the Longmaxi Formation, Sichuan Basin.

E-mail: lincs58@126.com

Keywords: coal,lakeside swamp,highstand system tract,Kuqa depression

Three sets of coal seam assemblages are mainly developed in Jurassic in Tarim Basin, which are located in the lower and upper members of Yangxia formation and the lower member of Kezilenuer formation. Due to the different accommodation space required for coal seam accumulation in different system tracts of different sequences and different periods of the same system tract, the development degree of coal seam (peat) and sedimentary environment, the coal accumulation is also quite different, which may be developed in each system tract of the sequence. By analyzing, it is found that Jurassic coal seams are mainly developed in transgressive system tract and highstand system tract of the sequence. The highstand system tract after rapid transgression occurs in shallow and is easy to form thick coal seams with continuous distribution. In addition, the effect of coal formation in the early stage of transgression is general during rapid transgression; When the transgression speed is slow, coal is easy to form in the early stage, and the coal seam is thick. The Jurassic coal sedimentary environment is the plain swamp of Yangxia formation and the lakeside swamp of Kezileinuer formation. The single sedimentary coal seams of flood plain swamp and lakeside swamp are limited in scope and thickness. However, in the early stage of kezileinuer formation, due to silting up of lake, the plain swamp and lakeside swamp were connected together, forming a huge thick coal seam with continuous distribution.

Integrated studies of neutron scattering and nitrogen physisorption for nano-scale pore structure changes during artificial maturation of a shale sample from Shanxi Formation from Ordos Basin in China

Xiaofei Liang[1], Qinhong Hu[2*], Guagnqing Yao[1]
1. Key Laboratory of Tectonics and Petroleum Resources, China University of Geosciences, Wuhan, Wuhan, Hubei, CHINA
2. Department of Earth and Environment Sciences, University of Texas at Arlington, Arlington, State of Texas, UNITED STATES
E-mail: maxhu@uta.edu

Keywords: Shale,Pyrolysis,Small-angle neutron scattering,Nanopore,Mesopore connectivity

The pore structures of shales, including pore volume, specific surface area (SSA), pore size distribution (PSD), and pore connectivity, are important factors that control petroleum storage and migration. However, due to the lack of comprehensive research on the pore structure of accessible and inaccessible pores during the thermal maturation of shale samples, it is difficult to objectively evaluate the pore structure changes during the hydrocarbon generation process of an immature shale. In order to study the nano-scale pore system of shale during thermal maturation, a series of water-containing pyrolysis experiments (pyrolysis temperatures at 250°C-550°C) were carried out on an organic-rich shale from the Shanxi Formation in the northern Ordos Basin of China. By using (ultra) small-angle neutron scattering [(U)SANS] and low-pressure N2/CO2 adsorption (LNA/LCA) methods to test the residual solids after pyrolysis, we quantitatively assessed the evolution of accessible and inaccessible pores. The pore properties obtained by integrating results from these two methods fully cover the entire nano-sized pore range (0.35-1000 nm), with mesopores (2-50 nm) and macropores (>50 nm) as major contributors to pore volume. Both pore volume and specific surface area decreased firstly, then increased and decreased with increasing maturity, reaching their peaks at 340℃ and 500℃, respectively. The inaccessible pore percentage of mesopores, defined as (SANS mesopores – LNA mesopores / SANS-mesopores), is shown to increase first, then decrease and again increase. According to the oil generation contents and calculated EasyRo, the results from eight pyrolysis temperatures are divided into four evolutionary stages: 250℃-340℃ (“bitumen generation”), 340℃-380℃ (“oil generation”), 380℃-460℃ (“oil cracking”), and 460℃-550℃ (“wet gas cracking”). In the 1st stage, the inaccessible pores of 2-18 nm increase due to a possible bitumen filling. For the 2nd stage, the inaccessible pores of 2-50 nm increase due to the likely filling of generated oil. In the 3rd stage, the inaccessible pores at 9-50 nm are reduced maybe due to the discharge and cracking of residual organic matter. These findings help to characterize the dynamic pore structure changes during petroleum generation process of organic-rich shale, and provide theoretical support for shale petroleum exploration and development.

Typical Characteristics and Indicative Significance of Continental Shale Reservoir in Luanping Basin, Yanshan Tectonic Belt, China

Xiaodong Yuan[1], Yuanfu Zhang[1,2], Zaixing Jiang[1,2*]
1. School of Energy Resources, China University of Geosciences , Beijing, CHINA
2. Institute of Earth Science, China University of Geosciences, Beijing, CHINA
E-mail: jiangzx@cugb.edu.cn

Keywords: Shale oil and gas, Reservoir characteristics, Volcano lake, Sedimentary environmentXiguayuan Formation, Luanping Basin; Yanshan Tectonic Belt

Luanping Basin is a typical faulted basin in Yanshan tectonic belt and there has been no breakthrough in oil and gas exploration for a long time. Our team discovered shale oil and gas in Luanping Basin through a lot of research work, and made the first exploration breakthrough on this basis. Compared with the typical shale reservoirs at home and abroad, the shale reservoirs in Luanping Basin have three typical differences, namely, the source of shale material, the brittleness characteristics of reservoir and the composition of oil and gas. According to the particularity of the material source of shale, core, thin section, main and trace elements, reservoir test, geochemical index and other data were used for analysis. According to the particularity of the brittleness characteristics of the reservoir, X-ray diffraction method is used to analyze it. Gas chromatography-mass spectrometry (GC-MS) was used to analyze the particularity of oil and gas components.

Results: Based on core and thin section observation, it is concluded that there are terrigenous, volcanic and hydrothermal sources in the mud shale of Xiguayuan Formation. By X-ray diffraction analysis, the brittleness index is up to 81.5%. In terms of oil and gas composition, the average saturated hydrocarbon content of crude oil is 87.46%, showing the characteristics of high maturity and medium light oil; the average methane content of natural gas is 75.44%, and the average value of hydrocarbon gas is up to 96.21%, showing the characteristics of low maturity dry gas.

On the one hand, the multiple sources of volcanic and terrigenous materials not only affect the type and development degree of reservoir space, but also affect the hydrocarbon generation potential and other conditions of the source rock, so that the corresponding intervals have better reservoir physical properties and hydrocarbon generation potential. On the other hand, the participation of volcanic and hydrothermal activities provides more brittle minerals such as quartz, feldspar and carbonate for the lacustrine deposits, which not only forms rich reservoir rock types, but also makes its brittleness index better than that of most continental lacustrine reservoirs and has better fracturing performance. In addition, the kerogen macerals in the semi-arid sedimentary environment with volcanic activity are characterized by high vitrinite content. Combined with the catalytic action of trace elements, the source rocks at low to medium maturity stage can form shale reservoirs with oil and gas production and high gas production, and the oil and gas composition is also characterized by high saturated hydrocarbon content and dry gas.

Based on the analysis of the typical characteristics of shale material source, brittleness and oil and gas composition of shale reservoir in Luanping Basin, it is shown that high quality source rock, high quality reservoir and high saturated hydrocarbon reservoir can be formed in the complex semi-arid lake affected by volcanic activities. It provides important theory and support for the follow-up exploration of other similar basins at home and abroad.

Development Characteristics and Control Factors of Shale Lithofacies Assemblages in Es4cs formation of Dongying Sag

Zhengwei Fang[1], Liqiang Zhang[1*]

1. School of Geosciences/Research Institute of Exploration and Development , China University of Petroleum/Shengli oilfield of Sinopec, Dongying, Shandong, CHINA

E-mail: zhanglq@upc.edu.cn

Keywords: Dongying sag,Shale, Lithofacies assemblage,Development characteristic, Control factor

Es_4^{cs} formation in Dongying sag is the key member of shale oil exploration in Shengli Oilfield. At present, the lack of systematic and regular understanding of shale lithofacies assemblages in this member restricts the search for shale oil sweet spots. Based on the geological data such as core scanning image, thin section and geochemistry, the shale lithofacies and their assemblages were systematically analyzed, and the typical lithofacies assemblages, vertical variation and their controlling factors were identified. Studies suggest that controlled by ancient lake level and climate change, lithofacies assemblage development with regularity, from bottom to top: during the deposition of $Es_4^{cs}{}_4$ layer, lake level high amplitude and high frequency shifted, the ancient climate was relatively dry, water salinity was higher, the typical lithofacies assemblage was grain layer dolomitic argillaceous aphanitic limestone/grain layer argillaceous dolomite clamping block chip grain dolostone; during the deposition of $Es_4^{cs}{}_3$, the lake level maintained high amplitude and high frequency change, the paleoclimate alternated between dry and wet, the lake salinity decreased, and the lake stratified obviously, mainly developed the lithofacies assemblage of laminated argillaceous limestone interbedded with laminated silty limestone; during the deposition of $Es_4^{cs}{}_2$, the lake level changed with low amplitude and low frequency, the paleoclimate changed from dry and wet frequently to wet gradually, and the lake water was relatively unstable, the lithofacies assemblage of lenticular laminated argillaceous limestone interbedded with calay-bearing mudstone was mainly developed, and the lithofacies assemblage of mesoclastic argillaceous cryptocrystalline limestone and silty mudstone was locally developed. during the deposition of $Es_4^{cs}{}_1$, the paleoclimate was mainly humid, the lake level was relatively stable, the lake salinity increased slightly, and the lithofacies assemblage of massive argillaceous cryptocrystalline limestone mixed with lenticular laminated argillaceous limestone were mainly developed. The results have important guiding significance for paleogene shale oil exploration in Jiyang Depression of Shengli Oilfield.

Comparative study on reservoir characteristics of organic rich shale in different sedimentary microfacies of Late Permian Longtan Formation in western Guizhou, China

Xiao Ma[1*]
1. School of Geosciences and Information Physics, Central South University, Changsha, Hunan, CHINA
E-mail: 691601310@qq.com

Keywords: Late Permian Longtan Formation, sedimentary microfacies, shale reservoir characterization

Marine-continental transitional shales are widely distributed in coal measure strata in western Guizhou with large cumulative thickness, high organic matter content and high maturity, leading to a certain exploration potential. Though organic petrological analysis, X-ray diffraction experiment, high-pressure mercury injection, N_2 and CO_2 adsorption, argon ion polishing scanning electron microscope observation and other analysis techniques, the geological development characteristics and pore structure characteristics of Longtan shales in different sedimentary microfacies are studied, and the influence of sedimentary microfacies on shale gas generation and reservoir is revealed. Results show that shales have the characteristics of high TOC (generally greater than 2%), low porosity and complex reservoir pore structure.

The sedimentary facies in the west of the study area are mainly delta plain, and the lithology is the interbedding of dark shale, silty shale and coal seam. Due to the turbulent sedimentary environment, the vertical lithology changes of well Y and H are relatively complex. The average TOC of shales reaches 5.87%, while the maturity ranges from 0.99% to 1.16%, which suggested a low maturity stage. The clay mineral occupies a dominant position in the mineral composition (with an average of 69.5%). The sedimentary facies in the middle of the study area where well J and X located is mainly lagoon. The lithology is sandstone, silty mudstone, dark shale and coal seam, which show a typical coal bearing structure of transitional facies. The TOC (2.49-3.25%) is lower than that of shale deposited from delta , while the kerogen has evolved to the high maturity (R_o, 2.64-2.93%). The average content of clay is 26.52%, which is far lower than that of well Y and H. The east of the study area is a carbonate platform, mainly composed of dolomite, basalt and gray mudstone. Compared with other areas, the TOC, maturity and clay content of L are in the middle stage (TOC is 3.07%, R_o is 1.93%, clay is 48.50%).

In the shale deposited in the delta and carbonate platform, the average pore volume is 0.029cm^3/g and 0.026cm^3/g, respectively, and the average specific surface area is 21.63m^2/g and 19.12m^2, respectively. Mesopores are the main contributor to the pore structure, macropores are the second, while micropores contribute less. The pores are mainly wedge-shaped mineral intergranular pores and intragranular pores. A small amount of organic matter pores are developed in kerogen. The pore volume and surface area of shales deposited in lagoon facies are 0.025cm^3/g and 19.89m^2/g. The pore structure is dominated by the ink bottle-shaped micropores. In the samples with high maturity, organic matter pores are developed and can be observed in kerogen or asphaltene in the form of bubbles or sponges. The comparison shows that sedimentary microfacies mainly affect the hydrocarbon generation and storage capacity of source rocks by affecting the abundance of organic matter and mineral composition. The shale deposited in lagoon facies has good hydrocarbon generation potential and reservoir performance, suggesting a greater development potential.

Sedimentology and geochemistry of the Lower Permian Shanxi Formation Shan 23 Submember transitional shale, Eastern Ordos Basin, North China

Yifan Gu[1*]
1. School of Geoscience and Technology, Southwest Petroleum University, Chengdu, Sichuan, CHINA
E-mail: xnsygyf@126.com

Keywords: Permian, transitional facies, geochemistry, organic-rich shale, Shan 23 Submember, Ordos Basin

Shanxi Formation Shan 23 Submember transitional shale in Eastern Ordos Basin is characterized by high TOC value, wide distribution, and large single-layer/cumulative thickness. In this study, based on section division of Shan 23 Submember, petrographic, mineralogical, high-resolution geochemical analyses were intergrated to reveal sedimentary environment, detrital influx, paleoclimate, paleosalinity, and paleoredox conditions. Results indicate that Shan 23 Submember is divided into four sections (Shan 23-1, -2, -3 and -4). The upper part of Shan 23-1 section is dominated by bay facies, which is characterized by high TOC value (2.75%-10.96%, avg. 6.98%), low detrital influx proxies (Zr, 97ppm-527ppm, avg. 310ppm; Ti, 1985ppm-7591ppm, avg. 3938ppm), relatively dry paleoclimate condition (CIA*, 41.96-92.58, avg. 75.55; Sr/Cu, 6.23-14.49, avg. 8.87), high paleosalinity proxies (Sr/Ba, 0.39-1.29, avg. 0.62), and relatively anoxic reduction condition (UEF, 0.83-3.00, avg. 1.67; MoEF, 3.95-27.00, avg. 15.56). By comparison, the other three sections are dominated by combination of transitional facies, including barrier island, lagoon, tidal flat and swamp. In this interval, shale is deposited in lagoon facies. The paleoclimate gradually tends to be warm and humid, which result in increasement of chemical weathering intensity. Meanwhile, the detrital influx increases, and the paleoredox condition tends to be oxic. The above conditions are not conducive to the preservation of organic matter in lagoon facies shale.

Depositional controls on lithoface and mineral assemblage of lower Cambrian shale in the upper Yangtze region, China

Wanle Liang[1*], Detian Yan[1], Zixuan Liu[1], Lin Li[1]
1. School of Earth Resources, China University of Geosciences, Wuhan, Hubei, CHINA
E-mail: liangwanle@cug.edu.cn

Keywords: depositional environment, lithoface, mineral assemblage, lower Cambrian shale, upper Yangtze

Paleozoic marine organic-rich shale is widely developed in southern China, of which the lower Cambrian Niutitang Formation is one of the most potential shale formations. The multiscale sedimentary structure, diagenetic pathway and geochemical characteristics of organic-rich shale in two continuous cores in western Hubei and southern Shanxi were studied by X-ray diffraction, major and trace elements, optical microscopy and FE-SEM imaging. The controlling effect of depositional environment on the lithofacies changes and mineral assemblages of the lower Cambrian Niutitang shale in the upper Yangtze region of South China is discussed. The Niutitang shales are mostly siliceous mudstones deposited under anoxic conditions. Six lithofacies types and three laminar associations (banded silt, sand-mud gradient and sand-mud thin interbedding) have been identified. The mineral grain assemblages are mainly extra-basin grains, including detrital quartz, potassium-rich clay minerals, albite, potassium-feldspar, mica and debris. Organic mineral aggregates, clay complexes, etc. The diagenetic characteristics of authigenic components mainly include grain metasomatism, cementation and hydrothermal action. Quartz in shale includes clay and silt grades, with extra-basin and intra-basin sources, and authigenic clay-sized microcrystalline quartz exists.

Layered argillaceous siliceous mudstone facies, layered siliceous mudstone facies, and layered carbonaceous mudstone facies mainly occur in the lower part of the Niutitang Formation, with high TOC content (2.78wt%) and abundant bio-quartz. Organic-clay minerals are enriched in the form of aggregates or fecal pellets, and the interface of organic-rich laminae is not clear. The content of silty laminae is low, pyrite layers appear, and bioturbation is absent. This is attributable to anoxic conditions and high primary productivity due to rapid sea level rise and increased aeolian fluxes. The TOC content of massive silty mudstone facies and layered dolomitic mudstone facies decreases, and silty laminae and clay laminae are interbedded, indicating that the deposition rate increases and the paleohydrodynamic conditions changed periodically. Higher eolian input during this process resulted in increased primary productivity of surface water, while intermittent anoxic conditions favored organic matter preservation. The upper layered mixed siliceous mudstone facies has low TOC content (1.34wt%) and high calcite content. The carbonate minerals are generally angular, and silt-grade grains and silty laminae increase, indicating the enhanced paleohydrodynamics. It is not conducive to the accumulation of organic matter, because of the reduced primary productivity, strong oxidized water body, and the high dilution of terrigenous debris. Regional tectonics, sea level, sedimentation and climate changes lead to the evolution of the depositional environment, resulting in changes in shale lithofacies and mineral assemblages. A comprehensive study of the lithoface and mineral assemblage under the control of the depositional environment of the lower Cambrian Niutitang shale in the upper Yangtze region of South China reveals the driving mechanism of the shale diagenetic pathway and provides a theoretical basis for shale gas exploration.

Characteristics and types of fine-grained sedimentary rocks microfacies in Triassic Chang 9: A case study of centimeter-level core description of two wells in the Ordos Basin, China

Ziye Wang[1*]

1. Petroleum Geology and Experiment Research Center , Research Institute of Petroleum Exploration and Development, PetroChina, Beijing, CHINA

E-mail: wangzy58cn@163.com

Keywords: Fine-grained Sedimentary Rocks, Interdistributary, Semi-deep Lacustrine, Yanchang Formation, Ordos Basin

With the exploration and development of shale oil and gas, fine-grained sedimentary rocks has become an important research object in sedimentology. Previous studies show that the lacustrine fine-grained sedimetary rocks are developed both in Chang 7 and Chang 9 members. Chang 7 was deposited in the maximum lake flooding period of Yanchang Formation with large thickness and wide distribution; Chang 9 was deposited in the first lacustrine flooding period with relatively thin thickness. Many scholars have carried out researches on Chang 7 Member and obtained a large number of relatively mature understandingsLu et al., 2006Yang et al., 2010WU et al., 2015Li et al., 2017Zhang et al., 2017Hou et al., 2017, while few researches have been carried out on Chang 9.The whole interval coring wells (Well C22 and Well Y84) with fine-grained sedimentary rocks of Chang 9 were selected to carry out centimeter-level core description, and analyze the lithology, microfacies characteristics and vertical sedimentary evolution. The analysis shows that the lithology of Chang 9 is mainly black and gray-black mudstone with thin layer of siltstone and local sandstone. The thickness of single layer of mudstone is 0.1-1.1m, with a maximum thickness of 2.6m, accounting for up to 40% of the thickness of the Chang 9 Memberthe single siltstone layer is 0.1-1.2m, with a maximum thickness of 3.0m, accounting for about 29% of the thickness. The main types of sedimentary facies include interdistributary and underwater distributary channel in braided deltaic front and semi-deep lacustrine. The lithology of the interdistributary microfacies is mainly gray-black silty mudstone,containing a small amount of siltstone, with horizontal bedding, slow wave bedding and common plant debris; the lithology of the underwater distributary channel microfacies is mainly medium and fine sand characterized by fine upper and coarse normal grain sequence, with massive bedding, parallel bedding and cross bedding; the lithology of the semi-deep lacustrine is mainly black and gray-black mudstone, with tens of centimeters thick upward thickening reverse grain order in which the proportion of siltstone increased significantly upwards, mixed with multiple thin-layer sandstones. It should be noted that there are many small scour structures and cross-beddings in the argillaceous siltstone deposited in semi-deep lacustrine of some layers, indicating that the sedimentary conditions is not settling in hydrostatic suspension, likely to be transported and deposited in the form of high-density flow. Although the above sedimentary facies types are distributed throughout the whole Chang 9 Member, overall the proportion of dark mudstone increases from bottom to top, which is consistent with the geological background of lake transgression. In conclusion, the fine-grained sedimentary rocks of Chang 9 are mainly mudstone and siltstone with frequently interbedded deposited in deltaic front and semi-deep lacustrine, which is different from Chang 7 with relatively thick layer. The analysis of Chang 9 is a supplement to the study of fine-grained sedimentary rocks, and provides a sedimentological basis for the exploration of shale oil in the whole Yanchang Formation.

Pore characteristics of shale oil reservoir of Jurassic Da 'anzhai member in central Sichuan Basin ,China

Shengyang Xie[1*], Xingzhi Wang[1]
1. School of Geoscience and Technology, Southwest Petroleum University, Chengdu, Sichuan Province, CHINA
E-mail: xsy_time@163.com

Keywords: Pore characteristics,Shale oil,thermal simulation experiment,Da'anzhai member,Sichuan Basin

Lacustrine shale in Da 'anzhai member of Jurassic system in central Sichuan Basin is the key exploration target of shale oil and gas resources in China in the future. In this paperthe characteristics of shale rock types and components, pore types and structures, and pore evolution under thermal simulation were studied in detail by field emission scanning electron microscope(FESEM), petrophysical test, X-ray diffraction(XRD), organic carbon testing(TOC), low-pressure N2 adsorption experiments and thermal simulation experiment. The results indicate that: (1) The mineralogy of shale in Da 'anzhai member are mainly clay minerals, quartz and calcite, with a small amount of feldspar, dolomite and pyrite. And the shales can be divided into two types: calcite rich mixed shale and clay mineral-rich mixed shale. (2) The storage spaces of shale oil reservoirs in Da 'anzhai Member are mainly intergranular pores of inorganic minerals, and the proportion of organic pores is relatively low. The specific surface area of the reservoir ranges from 1.064 m2/g to 9.227m2/g, with an average of 4.949m2/g. The pore volume ranges from 0.003 to 0.016cm3/g, with an average of 0.010cm3/g. The mesopores contribute mostly to the total pore volume and total specific surface area.(3) There is a positive correlation between clay minerals and specific surface area and total pore volume in the mixed shale of Da 'anzhai member, and the content of clay minerals has an obvious control on porosity development. (4) With rising thermal simulation temperature, the degree of thermal evolution and porosity of shales increase, and the organic porosity is the main contributor to the added porosity. In the light of the above results, inorganic pores, especially intergranular pores of clays, are the main types of pores in Da 'anzhai Shale oil reservoir, and organic matter evolution degree, burial duration and depth obviously enhance quality of the organic pores.

Keywords: Oil fractionation, Residual oil, Retention mechanism, Saline lacustrine shale, The Dongpu Depression

Halite and gypsum minerals in saline shale makes the retention mechanism and chemical fractionation of residual oil unique. Shale samples with different gypsum mineral contents were used in organic geochemical experiments, showing that the high total organic matter (TOC) content and type II kerogen leads to a high residual oil content, as shown by high values of volatile hydrocarbon and extractable organic matter. XRD and FE-SEM date indicate that the existence of gypsum in saline shale contributes to an enhanced pore space and a higher residual oil content in comparison to non-gypsum shale. Additionally, the increase in the gypsum mineral content leads to an increase in the saturated hydrocarbon contents and a decrease in polar components contents (resins and asphaltene). Furthermore, thermal simulation experiments on low-mature saline shale show that the content of saturated hydrocarbons in the residual oil is high and remains stable and that the storage space is mainly mesoporous (>20nm) in the oil expulsion stage. However, in the gas expulsion stage, the content of saturated hydrocarbons decreases rapidly, and oil exists in mesopores (>20nm and <5nm). In general, gypsum is conducive to the development of pore space, the adsorption of hydrocarbons and the occurrence of saturated hydrocarbon, leading to large quantities of residual oil. The data in this paper should prove to be reliable for shale oil exploration in saline lacustrine basins.

Microscopic morphological characteristics and controlling factors of shale oil reservoirs in Da 'anzhai member, central Sichuan basin

Lin Chen[1], Haihua Zhu[1*], Benjian Zhang[2], Qinfan Yi[1], Yucong Li[2], Minglei Wang[3]
1. , , , , CHINA
2. , , , , CHINA
3. , , , CHINA
E-mail: zhhswpu@163.com

Keywords: Sichuan Basin,Da 'anzhai Member,shale oil,pore morphology,controlling factor

Lacustrine facies shale in Da 'anzhai Member is the key strata for shale oil exploration in Sichuan Basin.Pore characteristics are crucial to occurrence and flow of shale oil.In order to understand the microscopic pore characteristics, argon ion dissection, scanning electron microscopy and image processing software were used to extract the pores from high-resolution electron microscopy images, obtain the size and morphology parameters of different types of pore, such as pore diameter, circularity and aspect ratio,clear the microscopic pore morphology characteristics, in-depth analysis of the influencing factors of pore morphology change.The results show that :the pore types of black shale in Da 'anzhai are divided into two types (organic pores and inorganic pores) and seven kinds (organic pores, clay pores, grain edge pores, calcite intracrystalline pores, pyrite intercrystalline pores, feldspar intragranular pores and quartz intracrystalline pores), among which clay pores, quartz / calcite intracrystalline pores, grain edge pores and organic pores are the most common.The morphological characteristics of different types of pores are different,The pore diameter of organic matter is small, the circularity and the solidity values approaches 1. The aspect ratio is small. The the characteristics of interparticle of clay and particle margin pores are low circularity/solidity and high aspect ratio.Quartz/calcite intraparticle pore size is largecircularity/solidity is big . The aspect ratio is small. Shale components have a controlling effect on pore size and shape : pore size sorting shows inorganic pores (brittle minerals) > inorganic pores (plastic minerals) > organic pores ; the morphology of organic pores is close to that of brittle mineral-related pores (pores in calcite crystals), but it tends to be round ; clay pores show strip shape; statistics show that clay pores, grain boundary pores and organic pores have a trend of smaller pore size and better pore circularity.The difference of pore size and shape between undercompaction and compaction of brittle mineral-related pores is small,the pore size of clay pores and organic pores in undercompacted section is larger,and the directionality of clay pores in undercompacted section is poor, which tends to be disorderly arranged.

Pore structure and wettability of Bossier Shale, East Texas, United States: Insights from integrated porosimetry, scattering, and imbibition approaches

Yang Wang[1*]
1. School of Earth Science and Resources, Chang'an University, Xi'an, Shaanxi, CHINA
E-mail: yang.wang@chd.edu.cn

Keywords: Pore geometry, wettability, (U)SAXS, spontaneous imbibition, Bossier Shale

Ascertaining the pore geometry and its wettability characteristics of tight shales is of great significance to reveal the mechanisms of occurrence, migration, and production of oil and gas in shale resources. Taking the core samples of Bossier Shales collected from Well A, East Texas, USA, as examples, the pore geometry and its wettability behavior in a broad nm-μm-scale pore spectrum were characterized based on the integrated techniques, including water immersion porosimetry (WIP), mercury intrusion porosimetry (MIP), (ultra)small-angle X-ray scatting [(U)SAXS], contact angle measurement, and liquid spontaneous imbibition (SI). Due to differences in sample size used, data interpretation, the detectable pore type (e.g., connected or not) and pore diameter ranges among different methods, sample porosities derived from WIP, MIP, and (U)SAXS are different, which range from 7.70-13.34%, 5.12-9.52%, and 2.48-6.44%, respectively. Therefore, a comparison of porosity derived from different methods needs to be handled with utmost care. Additionally, although (U)SAXS is an effective technique to detect both connected and non-connected pores, the fraction of non-connected pores could be underestimated by directly comparing the pore size distribution derived from (U)SAXS and MIP tests. Since sample sizes used for and pore information reflected by these two methods are different. Furthermore, the studied Bossier Shales exhibit various contact angle values and imbibition behaviors when using differently polarized liquids, revealing their mixed-wet characteristic. Comprehensively considering the differences in contact angle, imbibition slope, and imbibed liquid volume, three sub-categories of wettability behavior, with respect to more oil-wet (Samples B-12321, B-12360, B-12370, and B-12393), more water-wet (Sample B-12341), and intermediate mixed-wet (Samples B-12403 and B-12422), were qualitatively identified.

Classification of fine-grained sedimentary rocks in lacustrine basins and its petroleum geological significance

Xiaojun Wang[1], Qiusheng Chang[1], Menglin Zheng[1*]
1. Exploration and Development Research Institute, Xinjiang Oilfield Company, Karamay, Xinjiang, CHINA
E-mail: zhengmlbasin@163.com

Keywords: classification of fine-grained sedimentary rock, lacustrine basin, continental basin, rock classification, rock nomenclature, petroleum geology

Fine-grained sedimentary rock, as the most common type of rock in the surface of the earth's crust, is rich in oil and gas resources, which recently has become a research hotspot in the field of oil and gas industry. Because fine-grained sedimentary rocks are mainly composed of grains or crystals with a grain size less than 0.0625 mm, their composition is diverse and complex, leading to confusion in the use of rock type terms. This problem is particularly prominent in the fine-grained sedimentary rocks of the terrigenous lacustrine basins. In order to build a clear and consistent communication platform between researchers, this paper proposes a set of three-level naming and classification schemes, which are sedimentary structure, texture and composition, and salt component, respectively. First, it can be divided into laminated fine-grained sedimentary rock and massive fine-grained sedimentary rock based on the sedimentary structure. Secondly, it can be divided into seven main rock types based the sedimentary texture and composition. Finally, according to the salt composition, it can be divided into different rock types in different evolution stages of the continental lake basin. Based on the descriptive attribute as the standard of classification, the scheme is progressively described, which has the genetic significance of reflecting the provenance, hydrodynamic conditions and the evolution of saline lacustrine basin. The petrological classification of fine-grained sedimentary rocks in continental lacustrine basin is not only helpful to understand the stratigraphic attribution and evolution of source rock types and abundance in fine-grained sedimentary rock systems, but also helpful to predict the spatial distribution of geological "sweet spots". It is significant in theory and practice of petroleum geology such as oil and gas resource evaluation, scientific targets optimization, and improving the overall efficiency of petroleum exploration and development.

The pore structure of shale oil reservoir of Jurassic Daanzhai member analyzed by low-pressure N2 adsorption experimentsnortheast Sichuan Basian:A case study of Well-LA1

Yi Qinfan[1], Zhu Haihua[1*], Zhang Tinshan[1]

1. School of Geosciences and Technology, Southwest Petroleum University, Chengdu, Sichuan, Sichuan, CHINA

E-mail: zhhswpu@163.com

Keywords: Pore structure,Shale oil,Da'anzhai member,Sichuan Basin

To gain pore structure characteristics and controlling factors of lower Jurassic Da'anzhai shale oils reservoirs in Northeast Sichuan Basinthe samples from LA1 well were systematically analyzed by organic carbon (TOC) testing, field emission scanning electron microscope, X-ray diffraction (XRD) analysis and low-pressure N2 adsorption experiments. The results show that the shale mainly consists of clay minerals, quartz and calcite, with a small amount of dolomite, feldspar and pyrite. The pore types are dominated by clay intergranular poresfollowed by calcite intragranular pores, quartz intergranular pores, and minor organic pores. Low-pressure N2 adsorption experiments shows that the specific surface area of studied samples are 1.064 to 9.227 m2/g with an average of 4.949 m2/g. The pore volume is 0.003 to 0.016 cm3/g, and average 0.010 cm3/g. The contribution of mesoporous to the pore volume and specific surface area was slightly higher than macroporous. The pore volume and specific surface of shale are mainly contributed by clay intergranular pores, and positive correlation with clay minerals and quartz content. Organic matter has limited influence on pore volume and specific surface area of shale. Fractal characteristics of pore were mainly determined by clay minerals and the fractal dimension (D)ranges from 2.521 to 2.667, the average value is 2.586. The increase of quartz makes the pore structure complicated and resulting the increase of the fractal dimension. The selective filling of intergranular pores or intragranular pores by organic matter makes the pore structure simplified and the fractal dimension decreases with the increase of organic matter.

Diagenesis Types of Fine-grained Sedimentary Rocks in the Ek2 of Cangdong sag and Their Influence on Reservoirs

Lingzhi Yin[1], Shiyue Chen[1*]
1. School of Geosciences, China University of Petroleum(East China), Qingdao, Shandong, CHINA
E-mail: chenshiyue@vip.sina.com

Keywords: Fine grained sedimentary rocks, Diagenesis, Reservoir, Second section of Kongdian Group, Cangdong sag

Cangdong sag is an important oil-rich sag in Bohai Bay Basin, eastern China. Organic-rich fine-grained sedimentary rocks with a thickness of 400m are developed in the second member of Paleogene Kongdian Formation, which have good shale oil resource potential. However, there are few studies on diagenesis of fine-grained sedimentary rocks in Kong-2 member of Cangdong sag, especially the study on pore-increasing and pore-reducing mechanism based on diagenesis is insufficient, which restricts the fine evaluation of shale oil reservoir performance in different lithofacies and stratigraphic units.

Based on the qualitative analysis of core observation description, rock thin section analysis and scanning electron microscopy of Well G108-8 , Well GD12, and Well GX12X1 in Cangdong sag, combined with quantitative characterization techniques such as XRD whole rock analysis, XRD clay mineral analysis and energy spectrum analysis, it is clear that the diagenesis of fine-grained sedimentary rocks in the second member of Kong in Cangdong sag includes compaction, cementation, dissolution, metasomatism, clay mineral transformation and thermal evolution of organic matter. Because of the widespread development of cristobalite in Cangdong sag, a large number of cristobalite cements are filled in cracks or intergranular pores. The thermal evolution of organic matter is mainly characterized by internal hydrocarbon generation pores and marginal contraction joints. Under the scanning electron microscope, it is observed that the organic matter in the second member of Kong Formation in Cangdong sag is easy to combine with clay minerals to form 'organic matter-clay aggregate'. The conversion process of clay minerals can catalyze the hydrocarbon generation of organic matter, thus promoting the development of organic pores in the aggregate. Corrosion is common in the second member of Kong in Cangdong sag, mainly developed feldspar and carbonate rock corrosion. Under the influence of organic acids released from hydrocarbon generation of organic matter, corrosion pores formed by dissolution are more likely to be seen in unstable minerals in carbonate or clastic lamina adjacent to organic matter.

According to the data of porosity and permeability, pressure porosity and permeability, gas adsorption, high pressure mercury injection and nuclear magnetic resonance, the reservoir characteristics of Kong 2 member in Cangdong sag are analyzed. The results show that the porosity of the fine-grained sedimentary rock reservoir in Kong-2 member of Cangdong sag is between 0.24% and 9.35%, with an average of 2.95%. The permeability is between (0.01-25.3) × 10^{-3}μm^2, with an average of 0.613 × 10-^{3}μm^2, and the overall reservoir is ‘ultra-low porosity and ultra-low permeability’. Pores include inorganic pores, organic pores and micro cracks. The pore size is small, mainly micro-nano pores.

The influence of diagenesis on the reservoir of the second member of Kong Formation in Cangdong sag is complex, including the mechanism of increasing porosity and reducing porosity. The pore-increasing mechanism includes thermal evolution of organic matter, dissolution and clay mineral transformation;compaction and cementation are the main factors affecting the porosity and permeability of the reservoir, which belong to porosity reduction for the reservoir of Kong 2 member in Cangdong sag.

E-mail: zhangph@hhu.edu.cn

Keywords: micro-CT, 3D pore characterization, fluid-flow simulation, tight-gas sandstones, Lower Cretaceous Denglouku Formation, reservoir quality

The development of High-resolution X-ray computed tomography (micro-CT) as a complementary tool to laboratory core tests has been widely applied to the study of petroleum geology. Micro-CT has been widely used as a non-destructive technique, allowing 3D imaging and analysis of internal features of various object such as tight-gas sandstone reservoirs. Reservoir quality controls the storage, distribution, and flow of fluids within tight-gas sandstone reservoirs, however, it remains difficult to predict. Micro-CT is performed on representative tight sandstone samples from the Lower Cretaceous Denglouku sandstones in the southern Songliao Basin to quantify the internal architecture in 3D and to carry out fluid-flow modelling. These sandstones are mainly fine- to medium-grained, braided fluvial and braid-delta feldspathic litharenites with the dominant diagenetic regime corresponding to mesodiagenesis. The quantitative 3D imaging and modelling by means of micro-CT provides a better insight of pore network connectivity and pore preservation characteristics at the pore scale. The pore-scale imaging and modeling provide information on volume of pore space and effectiveness of pore connectivity and, consequently, are likely to investigate the control of pore-lining clay minerals on pore preservation effectiveness and the role of pore network on reservoir quality of the studied sandstones. A combined integration of 3D pore characterization and fluid-flow visualization is compared with pore characteristics predicted by textural, depositional and diagenetic variations, and it can be found that these results are in good agreement, and may be useful for pore-to-core prediction of reservoir quality in tight-gas sandstones.

Lithology and its influence on physical properties of silurian L1 member shale reservoirs in Zhaotong area, China

zhenyu Liu[1], yixiu zhu[1,2*]
1. College of Geosciences, China University of Petroleum, Beijing, China University of Petroleum, Beijing, Beijing, CHINA
2. State Key Laboratory of Petroleum Resource and Prospecting, China University of Petroleum, Beijing, Beijing, CHINA
E-mail: zhuyixiu@cup.edu.cn

Keywords: shale reservoir, fine-grained sedimentary rock, clay mineral,Silurian Longmaxi formation, Zhaotong demonstration area

A set of black shale sequence formed by marine shelf environment is developed in L1 member of Silurian Longmaxi formation in Zhaotong area, which is the key exploration and development section of shale gas in this area. In order to deeply and systematically understand the characteristics of organic shale reservoir in L1 member of Longmaxi formation in this area, the lithology and physical properties of shale reservoir were characterized by core and field specimen observation, thin section identification, scanning electron microscope analysis, x-ray diffraction element analysis (XRD), nuclear magnetic resonance experiment and nitrogen adsorption experiment. The study shows that the main mineral composition of L1 member fine-grained rock consists of quartz and feldspar, clay minerals, carbonate minerals and pyrite, the content of clay minerals is higher with an average value of 33.8% and the content of quartz is up to 30.5%.Fine-grained rock has developed texture, thick color depth, stable lithology and continuous thickness of 30 meters or more;The high quality shale reservoirs are mainly black thick layered organic-rich mixed shale, followed by organic-rich ash mixed shale and organic-rich siliceous shale.The shale develops nano scale organic pores, the average porosity of the shale reservoir is 2.437%, the average permeability is 0.00314mD, and the heterogeneity is strong. The low-porosity and low-permeability reservoirs are mainly composed of micropores and mesopores whose pore sizes are less than 10nm, in which micropores are the most developed.The organic-rich mixed shale in the L1 member is characterized by relatively high content of clay minerals, and the increase of clay mineral content makes the physical properties of fine-grained reservoir deteriorate.Quartz enrichment enhances the compaction resistance of fine-grained rocks and is beneficial to the preservation of micro nano pores.Authigenic chlorite and illite produce a certain amount of intercrystalline micro nano pores in clay minerals, which makes the pore throat curved and changeable and the pore structure complex.The large flake kaolinite and nano scale honeycomb imemonite mixed layer gradually transformed into curved flake illite. The edge of the flake became filamentous, which made the micro and nano scale pores more complicated and the overall physical properties deteriorated.

Analysis of pore characteristics and lithofacies characteristics of Qingshankou Formation Unit 1

Cao Yong Qiang[1*]
1. School of Earth Sciences and Resources, China Univerity of Geosciences, Beijing, CHINA
E-mail: caoyongqiang@cugb.edu.cn

Keywords: Qingshankou Formation, shale oil, lithofacies

As a new energy source, shale oil has attracted great attention in China. The study of pore characteristics and controlling factors of shale can help to understand the pore system and its evolution of lacustrine organic-rich shale, which has guiding significance for the exploration and development of continental shale oil and gas in China.

In this study collect predecessors about late cretaceous the Qingshankou Formation Unit 1 of Songliao Basin on the basis of research results, the integrated use of geochemical data, core observation and micro of the microscopic observations of the Qingshankou Formation Unit 1 of Songliao Basin shale pore characteristics and its control factors were studied, and the pore evolution are discussed.

According to the average pore size, the lithofacies of the Qingshankou Formation Unit 1 of Songliao Basin is classified into massive medium-grained mudstone(MMM), discontinuous laminated medium-grained mudstone(DLM), discontinuous laminated fine-grained mudstone(DLF), continuous laminated fine-grained mudstone(CLF), continuous laminated medium-grained mudstone(CLM) and massive fine-grained mudstone(MFM). From the perspective of sedimentary structure and grain size structure, the average pore size of continuous lamellar and fine-grained mudstone is larger, which is the most favorable for oil and gas storage and migration. However, there is only one block fine-grained mudstone sample, so the conclusion may not be representative and this lithofacies is ignored. The lithofacies with the largest average pore size is CLM, followed by CLF.

The content of clay minerals in the Qingshankou Formation Unit 1 does not change obviously with depth. According to the clay mineral content, the lithofacies of the Qingshankou Formation Unit 1 is classified into MMM, CLM, CLF, DLF, MFM and DLM. From the perspective of sedimentary structure and grain size structure, the massive structure and fine grain structure are more favorable to the development of clay minerals. The influence of sedimentary structure on clay mineral content is less than that of grain size structure.

According to the quartz content, the lithofacies of the Qingshankou Formation Unit 1 is divided into DLF, DLM, MFM, CLF, CLM and MMM. From the perspective of sedimentary structure and grain size structure, the massive structure and medium-grain structure are favorable to the development of quartz.

Therefore, it can be preliminarily concluded that the average pore size of the CLM is the largest, and the corresponding quartz content is second only to that of the MMM. It can be concluded that the CLM is a lithofacies conducive to oil and gas storage and migration.

Temporal distribution of black shale in the geological past: sourcing from a global Deepdive knowledge base

Chunmei Su[1], Zhong-Qiang Chen[1*], Xiaobo Zhang[2], Yuangeng Huang[1], Zhenhua Li[2]

1. State Key Laboratory of Biogeology and Environmental Geology, China University of Geosciences (Wuhan), Wuhan, Hubei, CHINA

2. School of Computer, China University of Geosciences (Wuhan), Wuhan, Hubei, CHINA

E-mail: zhong.qiang.chen@cug.edu.cn

Keywords: Information Extraction, Deepdive, Knowledge base construction, Black Shale

The black shale, comprised of dark-colored, organic-rich sediment, is one of the most common sediments in the depositional systems of Earth through the geological time. Black shales usually deposited in relatively low-energy settings and represent important carbon burials that link with global climate changes. They are also important source rocks for conventional petroleum and gas as well as unconventional shale gas. Spatiotemporal distributions of black shales therefore have attracted increasing interests for sedimentologists and petroleum geologists. Here, we construct a high-resolution knowledge base of global black shales using a novel deepdive approach from published literatures worldwide. All PDF documents recording black shales are first collected and converted into text using an OCR method. Then, an NLP (Natural Language Processing) software-labeled glossary of terminology and tags is employed to recognize all possible candidate pairs from each sentence in these 7237 papers collected. Each pair and its features represent a factor graph model, and a series of heuristic procedures is operated to score the weights of each pair's features in order to test each candidate's likehood. The deepdive datasets achieve 92%/1004, 97%/1688, and 84%/1420 of accuracy/distinct pairs on location, age, and strata, respectively, with probability >90%. The global dataset deciphers that black shale units are commonly present from the Archean to Cenozoic. Of these, the Cretaceous records the highest occurrence frequency of black shale, followed by the Devonian and Cambrian. Geologically, most of the deep-time black shales deposited in the North America, Europe, and China.

Sequence Stratigraphy and Reservoir between the Organic-rich Fine-grained Siliciclastic and Carbonate System

Shu Jiang[1*]
1. School of Earth Resources, China University of Geosciences at Wuhan, Wuhan, Hubei, CHINA
E-mail: jiangsu@cug.edu.cn

Keywords: Fine-grained deposits, shale, reservoir, sequence stratigraphy

Fine-grained deposits are characterized by a particle size of less than 1/16 mm (62.5 μm), including mudstone, shale, marl, siltstone, and other deposits with fine-grained composition. Mineral components mainly include clay minerals, feldspar, quartz, carbonate minerals, and organic matter. According to the carbonate presence, the organic-rich fine-grained system can be divided into siliciclastic-rich and carbonate-rich deposits. In order to better predict the reservoirs associated with the depositional processes in time and space. We identified the 5th to 3rd order sequence boundaries in the typical lacustrine to marine fine-grained rocks in China, North America, and South America based on the detailed core description, geochemical, mineral, and petrophysics analysis, logging curve motif, and seismic data. The rock properties in the sequence stratigraphic framework show that the transgressive systems tract (TST) and the early highstand systemS tract (EHST) of the lacustrine to marine siliciclastic fine-grained deposits are characterized by high uranium gamma value, high organic matter content, and high biogenic quartz content, with the highest value corresponding to the maximum flooding surface (MFS). For the carbonate-rich fine-grained deposits, the TST and EHST intervals are characterized by low gamma, low organic matter content, low detrital quartz content, and high carbonate content. The common feature of both types of fine-grained deposits is the condensed section corresponding to the maximum flooding surface is characterized by the lowest content of clay minerals. Both the TST and EHST for the siliciclastic and carbonate-rich fine-grained systems have the best reservoir quality with highest fractability index. Common high-quality reservoirs include heterogeneous organic-rich and siliceous shale and organic-poor fine-grained carbonate rocks.

5. Research Institute of Exploration and Development, Xinjiang Oilfield Company, PetroChina, Karamay, Xinjiang, CHINA

E-mail: jinzj1957@pku.edu.cn

Keywords: shale oil, reservoirs, tectonic fractonics

The maximum burial depth of the alkaline lacustrine shale of the Lower Permian Fengcheng Formation in Mahu Sag of Junggar Basin is more than 5000m, which has great potential for shale oil exploration and development. Tectonic fractures are widely developed in continental shale, which can provide important storage space and main seepage channels for shale oil reservoirs. In order to guide the exploration and development of this area, the genetic types and development characteristics of tectonic fractures were analyzed by comprehensively utilizing various data of outcrops, drilling cores, thin sections and imaging logging. On this basis, combined with the evolution of tectonic stress field in the Mahu Sag and formation sequence of fractures, using fluid-inclusion analysis of fracture filling, calcite U/Pb dating, and burial history analysis, the formation mechanism of tectonic fractures is clarified. The result shows that tectonic fractures in the study area can be divided into transformational shear fractures, bed-parallel shear fractures and intraformational open fractures according to their origin. High dip-angle tectonic fractures with dip-angles of nearly 90° are the most abundant in shale oil reservoirs. Due to the small thickness of rock mechanical stratigraphy of shale, the scale of tectonic fractures is generally small with the height of mostly less than 25cm. The density of tectonic fractures is mostly distributed below 2/m. Tectonic fractures with high density appear around faults because of stress concentration disturbed by fault movements. Tectonic fractures were determined to be formed at the end of the Permian and the end of the Triassic. In the late Hercynian movement, the fractures with the strike of NW-SE and NNW-SSE were formed due to NW-SE compression, with fluid-inclusion homogenization temperatures approximately 70 to 100°C. During the Indo-China movement, the fractures with the strike of NNW-SSE and NNE-SSW were formed by the near south-north compression, with fluid-inclusion homogenization temperatures approximately 110 to 130°C. It is observed in cores and thin sections that the unfilled tectonic fractures have good oil-bearing property, and the filled tectonic fractures are reopened due to late dissolution or tectonic activity, which has good effectiveness. The formation time of the two-stage structural fractures coincides with the charging time of shale oil, which is the key factor for the enrichment of shale oil.

Evolution of pore structures during the entire hydrocarbon generation process of Marine Carbonate-rich shale: the inspiration from thermal simulation experiments

WANG TONG[1], Liu wen hui[1*]
1. Geology, Northwest University , Xi'an, Shaanxi, Shaanxi Province, CHINA
E-mail: lwh@nwu.edu.cn

Keywords: Carbonate-rich shale,pore evolution,thermal simulation experiment

The immature marine Carbonate-rich shale(TOC=6.13%,VRo=0.59%) is selected for s series of thermal simulation experiments in a Semi-enclosed pyrolysis system from immature to overmature stages.CO2 adsorption and N2 adsorption tests were carried out on rock samples at different evolution stages, quantitatively characterized their pore structure characteristics, and studied the coupling relationship between the evolution process of organic matter hydrocarbons and the evolution of pores.The results show that with the increase of the simulated experimental temperature and pressure, the yields of total oil, expelled oil, retained oil and hydrocarbon gas showed different evolutionary characteristics, and the total oil yield reached a peak at Ro=0.97%, which was also the maximum storage period of retained oil.The organic matter hydrocarbon generation-rentention-expilsion and diagenesis interacted with the pore evolution of the organic shale from beginning to end and the mechanism of action at different stages of thermal evolution was different. Mesopore and macropore have a greater influence on the total pore volume, more than 70% of the total specific surface area is contributed by micropores and mesoporous.And there is a certain degree of transformation between different scale pores in the organic matter diagenesis-hydrocarbon formation process. The research results are helpful to understand the formation and evolution characteristics of carbonate-rich shale oil and gas, and can provide simulation experimental theoretical support and guidance for the exploration and development of deep shale oil and gas.

Characteristics and enrichment mechanism of Platinum group elements in black shale of Early Silurian Longmaxi Formation in southwestern Sichuan Basin

Jiawei He[1*]

1. Institute of Sedimentary Geology, Chengdu University of Technology, Chengdu, Sichuan, CHINA
E-mail: 469788362@qq.com

Keywords: Longmaxi formation,PEG,Enrichment mechanism

In order to explore the content characteristics and enrichment mechanism of platinum group elements in the black shale of Longmaxi formation of Early Silurian in the southwest margin of Sichuan Basin, the content of platinum group elements in the black shale of Longmaxi formation of Silurian in YNP section and MCP section was measured by HR-ICP-MS, and its enrichment mechanism was discussed in combination with the characteristics of major elements, trace elements and petrology. The study shows that the black shale PGE of Longmaxi formation in the southwest margin of Sichuan Basin shows a Pt Pd distribution model with relatively strong enrichment of Pd and Pt and relatively strong loss of Ir. According to the analysis of Ir content, Pd/PtPd+Pt/Os+Ru+Ir and It/Pt-Pd/Pt parameters, it is considered that the black shale PGE in the study area does not have extraterrestrial material sources. According to the content characteristics of rare earth elements, the enrichment coefficient of trace elements, Pd/IrAl_2O_3-SiO_2Pt-PdIr/Pd-Pt/Pd and other parameters, combined with the comparison of PGE distribution patterns of black shale platinum group elements and typical hydrothermal geological bodies in the study area, it shows that PGE in the study area is closely related to submarine hydrothermal activities. According to the correlation between PGE and environmental parameters in the study area, it indicates that redox state is the main controlling factor of PGE enrichment. The difference of sedimentary facies and sea level fluctuation are the main reasons for the difference of PGE main controlling factors between YNP section and MCP section. In addition, TOC in the study area has a good positive correlation with redox parameters, and PEG can be used as a discriminant parameter for redox state of water and enrichment of organic matter.

Source rock characteristics and sedimentary environment of Qingshankou Formation outcrop in the southeast of Songliao Basin

Mingyu Jin[1*]
1. regional geological research, Daqing oilfield company, Daqing, Heilongjiang , CHINA
E-mail: 77025183@qq.com

Keywords: Songliao Basin, Qingshankou formation, Source rock

The research results of source rocks of Qingshankou Formation based on core analysis in Songliao basin are rich, but few people pay attention to the characteristics of field outcrop source rocks and sedimentary environment. The characteristics and sedimentary environment of field outcrop source rocks of Qingshankou Formation in the southeast of Songliao basin are analyzed using geochemical research methods based on field outcrop, such as lithology fine description, whole rock microscopic examination, rock pyrolysis analysis, constant and micro analysis, etc . The results show that the thickness of Qingshankou Formation exposed in Songliao basin is 10-35m. It is a set of lacustrine stratigraphic unit rich in biological fossils, with gray black mud shale as the main framework and thin argillaceous dolomite, ostracod and stromatolite dolomite as the secondary framework. The lithology is mainly grayish green and grayish black mud shale, with relatively developed foliation, rich in biological fossils such as ostracods, leaflimb media and plant debris; The source rocks are dominated by planktonic algae, followed by sapropel amorphous body, type I kerogen, followed by type II 1, with medium poor hydrocarbon generation potential. The pyrolysis parameter w (TOC) of Qingshankou Formation source rock is 6.8-7.6%, Tmax is 430-441 ℃, S1 is 0.95-1.26mg/g, S2 is 32.68-69.17 mg / g, RO is 0.49% - 0.55%, which is located near the oil generation window and has good hydrocarbon generation potential. The paleoclimate index parameter w (SR) / w (Cu) of the common trace element combination parameter is between 3.5-11, the paleosalinity index parameter w (SR) / w (BA) is between 0.25-0.61, and the redox environment index parameter w (V / (V + Ni)) is between 0.76-0.79, indicating that the set of source rocks was formed in the freshwater brackish water reduction environment under the warm tidal and humid climate. The research results can effectively guide the exploration deployment of Gulong shale oil in Songliao basin.

Salinization origin and paleoenvironment conditions of the Permian Lucaogou Formation in the southern Junggar Basin, NW China

Dongdong Liu[1*], Qingqing Fan[1]
1. Unconventional Petroleum Research Institute, China University of Petroleum, Beijing, Beijing, CHINA
E-mail: liudd@cup.edu.cn

Keywords: Early Permian, paleoclimate, arid, salinization, Central Asian Orogenic Belt

The Early Permian is regarded as a critical period for marine to continental transition of the Junggar Basin. Lacustrine organic-rich shale successions were deposited in the Lucaogou Formation in the southern Junggar Basin (SJB) at that time. Although the paleoenvironmental reconstruction of the Lucaogou Formation has been discussed from diverse perspectives, the genesis of lacustrine salinization remains controversial. Revealing its depositional environment and salinization origin are vital for shale oil exploration in this succession. This study investigated the Lucaogou Formation in three sags from the SJB, namely the Chaiwopu Sag, the Fukang Sag, and the Jimsar Sag. Paleoclimatic indicators (i.e., CIA values and Sr/Cu ratios) show that the Lucaogou Formation was generally deposited under semiarid to arid conditions, among which the Jimsar Sag was more arid than the other two sags. Meanwhile, V/Cr and V/(V+Ni) ratios illustrate dysoxic-anoxic conditions prevailing during its deposition. Sr/Ba and B/Ga ratios suggest brackish-marine salinity levels in the three sags, among them the Jimsar Sag exhibited saltier conditions than the other two sags. Provenance indicators suggest that samples from the Fukang and Chaiwopu sags were mainly derived from felsic to intermediate igneous rocks, while samples from the Jimsar Sag were mainly derived from felsic rocks with a certain sedimentary recycling process. We propose that the lacustrine salinization of the Lucaogou Formation is attributed to marine transgression, which both explain the increasing of paleosalinity and deepening of lake basin during its deposition. The SJB was composed of a cluster of lakes which were relatively independent and rarely connected with each other. However, seawater inpouring and lake levels rising rapidly may have coalesced to form a giant paleo-lake when marine transgressions took place.

The influence of Cretaceous climate change on organic matter enrichment in the Cote d'Ivoire Basin

Li Li[1*], Quan Li[1], Songling Yang[1]
1. Global Technology Supporting Center , CNOOC International Limited, Beijing, CHINA
E-mail: lili76@cnoocinternational.com

Keywords: Palynology, elemental and organic geochemistry, organic sources, paleoenvironment, marine source rocks

The Cote d'Ivoire Basin is a typical transform margin basin in the northern Gulf of Guinea in West Africa. After the marine incursion caused by the separation between South America and Africa, marine source rocks of the Cote d'Ivoire Basin began to develop from the Late Albian. Based on the evaluation of source rock quality and thermal maturity of organic matter, the Upper Albian-Turonian organic-rich marine shales were suggested as important marine source rocks in the studied area. Data of palynology, elemental geochemistry, and organic geochemistry were used to figure out the main controlling factor on the organic matter enrichment and the development of high-quality marine source rocks during the Late Albian-Turonian. The variations of the chemical index of alteration (CIA) and the relative abundances of *Ephedripites* pollen and *Classopollis* pollen demonstrate that the climate was relatively arid during the Late Albian, and predominantly warm and humid but intermittently arid during the Cenomanian-Turonian. The element ratio (Calcium /(Calcium+Iron) and biomarker parameters (Pristane/Phytane and Gammacerane / C_{30} αβ hopane) suggest that the Upper Albian-Turonian high-quality source rocks were deposited under anoxic environments with salinity stratification. The high values of Phosphorus / Aluminum and (2-methylhopane + C_{25} highly branched isoprenoids) / C_{30} αβ hopane indicate high primary productivity due to the flourishing of cyanobacteria and diatoms in the marine environment. In addition, marine dinoflagellate input is indicated by a detailed investigation on calcareous phytoplankton. The low values of Titanium / Aluminum and (C_{19}+C_{20})/C_{23} tricyclic terpanes reflect decreased terrigenous detrital matter (TDM) input during the deposition of high-quality source rocks. Therefore, low TDM input, reducing environment, and high productivity were controlling factors on the organic matter enrichment. According to the synchronous variations of climate, TDM input, salinity and reducing condition of the water column, and bio-productivity, it is proposed that climate change played an important role in organic matter enrichment by influencing the freshwater supply and TDM input. Under the relatively arid climate, less rainfall could lead to less freshwater influx and decreased TDM input. Therefore, inorganic nutrients and organic matters were less diluted, thus boosting the flourishing of aquatic organisms. The small amount of freshwater inflow and TDM input in combination with the stronger evaporation could facilitate the salinity stratification of the water column. This was beneficial for organic matter preservation.

Effective parameters for the redox condition of high thermal maturity black shale: A case study of Sinian–Cambrian fine–grained sediments in the Sichuan Basin, SW China

Qiang Li[1,2], Guangdi Liu[1,2*], Zezhang Song[1,2], Yushun Cao[1,2]
1. College of Geosciences, China University of Petroleum, Beijing, Beijing, CHINA
2. State Key Laboratory of Petroleum Resources and Prospecting, China University of Petroleum, Beijing, Beijing, CHINA
E-mail: guangdiliucupb@gmail.com

Keywords: High thermal maturity, fine–grained sediments, redox conditions, Sinian–Cambrian system

The redox conditions during the formation of the fine–grained sediments comprise one of the factors affecting the content of organic matter. The Sinian–Cambrian system in the central Sichuan Basin has experienced unusually high thermal maturity, with equivalent vitrinite reflectance exceeding 3.0% (Wei *et al*., 2017; Qiu *et al*., 2021). For fine–grained sediments (such as the QZS and DY–3 Fm.), it is an important research topic to evaluate which parameters remain effective for the redox condition. Many studies have shown that the redox backgrounds of the QZS and DY–3 Fm. are significantly different (Gao *et al*., 2017). Based on organic geochemistry and inorganic geochemical analyses (trace elements, TEs), the parameters of Pristane (Pr) and Phytane (Ph), Ph/nC18, Pr/nC17, carbon isotopes ($\delta^{13}C$), V/(V+Ni), Th/U, and TEs enrichment factors (TEs–EF) in the QZS and DY–3 Fm. were compared. The results showed that high thermal maturity resulted in similar ratios of certain organic geochemical biomarkers (such as the Pr/Ph), which could not be well distinguish redox conditions exactly. However, the correlation shown among the ratios between $\delta^{13}C$ values and some TEs ratios can still help distinguish between the QZS Fm. (anoxic) and DY–3 Fm. (dysoxic–suboxic).

Influence of paleo-sedimentary environment on shale oil enrichment in lacustrine basins: A case study of Shahejie Formation in Raoyang Sag, Bohai Bay Basin

Xiaocheng Wang[1*]
1. School of Earth Science and Technology, China University of PetroleumEast China, Tsingdao, Shandong, CHINA
E-mail: 605552984@qq.com

Keywords: Paleo-sedimentary environment, Shale oil enrichment, Elemental geochemistry, Shahejie Formation, Raoyang sag
Paleo-sedimentary environment, Shale oil enrichment; Elemental geochemistry; Shahejie Form

A set of high-quality hydrogen-rich shale was found in the upper third sub-member of Shahejie Formation (Es_3^U) in Raoyang sag, which has the geological conditions for shale oil enrichment. However, the formation paleosedimentary environment of the shale oil sweet spot reservoir is not systematically studied. Based on petrology, organic geochemistry, and elemental geochemistry analysis, the control effect of the characteristics of paleosedimentary environment on lacustrine shale oil enrichment is revealed and the shale oil enrichment model is established in this paper through the comprehensive study of the occurrence and migration of elements in different sedimentary facies areas. The results show that: 1) Carbonate-rich, calcareous and clay-rich shales are well developed in the study area, and the total organic matter content is high enough to meet the shale oil enrichment standards; 2) The parameters of V/(V+Ni), δU, Sr/Cu, Rb/Sr, Zr/Rb, Zn/Al, and Sr/Ba indicate that deep and semi-deep lacustrine deposits are developed in the target strata, which were characterized by strong reduction, semi-drought, high paleoproductivity, and brackish water. 3) Lake water evaporates in a hot and dry climate. And brief transgression events led to the increase of water salinity, the outburst of salt-eating organisms such as algae and nutrients from the provenance provided the material basis for the enrichment of organic matter. The quiet and strong reduction paleowater far away from the provenance provides good preservation conditions for the enrichment of organic matter. 4) The Mg^{2+} provided by transgression moved towards the center of the lake basin under the action of gravity, and the low magnesium and calcium-rich saline environment were conducive to the occurrence of penecontemporaneous dolomitization. Calcite and aragonite laminae were generated in the center of the sedimentation of the lake basin and interbedded vertically with the organic matter carried by fine-grained materials. 5) The areas where carbonate-rich, calcareous, and clay shales with rich organic matter developed are relatively developed are sweet spot reservoir areas of shale oil, which are mainly located in the center of the lake basin. Through the above studies, the shale oil enrichment model based on lithofacies and paleosedimentary environment is established, which can guide the shale oil exploration and development in the Raoyang depression successfully.

Source rock deposition of the Upper Permian Longtan Formation in response to co-evolution of environments and organisms controlled by tectonic subsidence and transgression, Sichuan Basin, SW ChinaEvidences from organic and inorganic geochemistry

Yamin Yu[1], Huayao Zou[1*], Pingping Li[1], Ruixin Guo[1], Yuqing Peng[1]
1. college of geoscience, China University of Petroleum-Beijing, Beijing, CHINA
E-mail: huayaozou@cup.edu.cn

Keywords: source rock, organic matter input, redox conditions, sedimentary environment, organic facies

The upper Permian Longtan Formation from the Sichuan Basin, one of the most petroliferous basins in China, were analyzed with sedimentological and geochemical techniques to characterize the lateral source rock heterogeneities, to reveal the environmental and ecological changes and to construct depositional models for marine source rocks under the influence of geological events including the tectonic movement induced by the Emeishan mantle plume activities and the marine transgression during the late Permian. The Longtan Formation displays widely variable lithology, stable carbon isotope composition of kerogen biomarker composition across the basin, suggesting changes in organic facies from marine to marine-continental transitional sediments. The Longtan Formation has distinctly different organic and inorganic geochemical indices, which indicate alkaline-saline marine environment with anoxic bottom water conditions and type I-II kerogens dominated in the northeast (higher ETR, lower 4-/1-MDBT, lighter $\delta^{13}C_{kerogen}$, lower 1,7-/1,9-DMP, lower 2,6-/2,10-DMP), acidic freshwater environments with dysoxic bottom water conditions and type II-III kerogens dominated in the southeast (lower ETR, higher 4-/1-MDBT, heavier $\delta^{13}C_{kerogen}$, higher 1,7-/1,9-DMP, higher 2,6-/2,10-DMP). Such environmental changes corresponded to changes in tectonic subsidence and transgression process, from the rapid subsidence and early marine transgression in the northeast to slow subsidence and late transgression in the southeast and resulted in synchronous changes in terrigenous materials input, phytoplankton contribution and primary productivity. The co-evolution of environment and organisms controlled by tectonic movement and transgression process accounted for the deposition and distribution of source rocks with distinctly different geological characteristics. Most basins experienced the change from marine to continental deposit. The geochemistry indices used and the model constructed in this paper may have important implications for organic facies classification and source rock prediction in other basin with similar geological setting, especially for the source rocks with high-over maturity.

Characteristics of Paleogene Source Rocks and Fine Oil-source Correlation in Liaohe Western Depression

Shasha Hui[1], Xiongqi Pang[1*], Guangdi Liu[1], Hong Pang[1], Tao Hu[1]
1. College of Geosciences, China University of Petroleum (Beijing), Beijing, CHINA
E-mail: pangxq@cup.edu.cn

Keywords: geochemical characteristics, sedimentary environment, oil-source correlation, biomarker

In order to clarify the differences in source rock characteristics and investigate the source of crude oil in different areas in the Liaohe Western Depression, the TOC, rock pyrolysis, Ro, and saturated hydrocarbon gas chromatography-mass spectrometry (GC-MS) are adopted to analyze the characteristics of source rock and crude oil, and the fine oil-source correlation is carried out. Results indicate that the Es4 source rock of Liaohe Western Depression is developed in the north (about 700 m), with high organic matter abundance but low maturity (<0.5%). The organic matter of Es4 source rock was dominated by terrestrial higher plants, mixed with a small amount of lower aquatic organisms, and the sedimentary environment was a partially reduced saline-brackish water environment; The Es3 and Es1 source rocks of Liaohe Western Depression are developed in the south with high abundance and maturity. The organic matter was mainly derived from aquatic organisms and deposited in the oxidized freshwater environment. Results show that the crude oil in the northern part comes from the Es4 source rock. The crude oil in the central part mainly comes from the Es3 source rock (the crude oil in the Lengjia area comes from the Es4 and Es3 source rock). The crude oil in the southern part comes from the Es3 and Es1 source rock.

Organic matter accumulation of the Lower Cretaceous shale in the southern Songliao Basin (NE China): Implications from geochemical analyses

Fan Qingqing[1], Liu Dongdong[1*], Liu Li[1], Yin Wei[1], Zhang ziya[1]
1. Unconventional Petroleum Research Institute, China University of Petroleum, Beijing, CHINA
E-mail: liuddcup@163.com

Keywords: Shale, redox, paleoclimate, organic matter enrichment

The Cretaceous period was a time of long-term variable climates with relatively warm temperatures resulting from high atmospheric greenhouse gas contents (Skelton et al., 2003). During this time, terrestrial sediments were continuously deposited within the Songliao Basin which record the paleoenvironmental and paleoclimatic information. The Songliao Basin is well-known as one of most prolific petroleum basins in China, and contains several organic-rich shale successions in the lower Cretaceous strata (Xu et al., 2019). Reconstruction of the paleoclimate and paleoenvironment is of great significance to understand lacustrine organic matter accumulation under the Cretaceous greenhouse climate conditions. Paleoenvironments and mechanisms of organic matter enrichment were investigated by lithology, mineralogy, major element and trace element geochemistry in the Lower Cretaceous Shahezi Formation which is divided into the first member (Ks1) and second member (Ks2). Redox proxies such as U/Th, V/(V+Ni) and V/Cr demonstrate that the Lower Cretaceous Shahezi shale was mainly deposited under dysoxic to anoxic condition. And paleoclimatic indicators (CIA values, Rb/Sr and Sr/Cu ratios) show that the Shahezi Formation was generally deposited under semiarid to arid condition. An obviously increasing of CIA and Rb/Sr ratios can be identified from bottom to top, suggesting a warmer paleoclimate. Ks1 is characterized by low terrigenous input, high salinity level, arid climate and anoxic water column condition which are stratified. During deposition of Ks2, the climate became somewhat warmer and more humid, which was marked by higher intensity of chemical weathering, higher terrigenous input, lower salinity and dysoxic bottom water condition. Relationship between geochemical proxies and TOC suggests that salinity and redox condition are critical factors controlling the enrichment of organic matter. While high terrigenous input may result in a dilution of organic matter. Anoxic water column, high salinity level and low terrigenous input are conductive to preservation of organic matter.

Coupled weathering-hydrothermal process and its geological significance during the Early Cambrian

Taohua He[1*]

1. Key Laboratory of Oil and Gas Resources and Exploration Technology, Yangtze University, Wuhan, Hubei, CHINA
E-mail: hetaohua_upc@163.com

Keywords: Paleo-weathering, Hydrothermal Activity, Early Cambrian, Paleo-productivity, Photic Zone Euxinia, Tarim Basin

To discuss paleo-weathering, hydrothermal activity, and their influence on organic matter (OM) enrichment, samples from the Lower Cambrian Yuertusi Formation black rock series in the Northwest Tarim Basin were analyzed for total organic carbon (TOC), rock-eval, biomarkers, carbon isotope of kerogen ($\delta^{13}C_{ker}$), sulfur isotopes of pyrite, major & trace elements, and rare elements. The combined weathering and hydrothermal processes enhanced the deposition of ^{13}C-depleted organic-rich shale with $\delta^{13}C_{ker}$ lower to -36‰ in the Lower Cambrian, according to the findings. Plankton blooms were driven by abundant teleorganic nutrients (e.g., Fe) and terrigenous clastics brought into the sea by paleo-weathering, which enhanced the adsorption and sink of OM in water, laying a material basis for the formation of organic-rich source rocks (TOC, up to 29.8%). Hydrothermal activity brought abundant reducing gases (H_2S) and hydrothermal silicon into the sea. The former induced a sulfur-anoxic sedimentary environment and photic zone euxinia, which improved sedimentary OM preservation. However, the latter may dilute the amount of sedimentary OM to some extent, resulting in the relatively organic-poor siliceous shale rocks. Paleo-productivity was high during the time of significant paleo-weathering and weak hydrothermal activity, whereas hydrothermal silicon dilution was minimal, promoting the production of black organic-rich shales. Paleo-productivity was low during a period of intensive hydrothermal activity and mild paleo-weathering, but hydrothermal silicon dilution was significant, resulting in the formation of organic-poor siliceous shales. The combined weathering-hydrothermal process thus regulated the formation of the Lower Cambrian source rocks in the Northwest Tarim Basin. Furthermore, the aryl isoprenoids-based oil-source correlation revealed that the source rocks formed during this linked process made significant contributions to the Tarim Basin's vast hydrocarbon resources. It will serve as a useful guide for future deep petroleum exploitation in the Tarim Basin and other similar basins throughout the world.

Geochemical Characteristics of the Middle Devonian Dacaozi-Tanshanping Shale Strata in the Yanyuan Basin, Southwest China

Zhang zi ya[1*], Song yan[1], Yang wei[1]
1. Unconventional Petroleum Science and Technology Institute, China University of Petroleum, Beijing, CHINA
E-mail: zyzhang3327@163.com

Keywords: Organic matter accumulation, Preservation, Devonian, Yanyuan basin, China

How the geochemical characteristics of organic matter shale for the carbonate platform facies remain uncertain, which restricts an integrated reconstruction of the model of organic matter accumulation and preservation. Here, we present new results from element geochemical fingerprinting and integrated analyses of paleoclimate, paleoproductivity, paleoredox environment, and terrigenous input of the targeted Middle Devonian Tanshanping and Dacaozi Formations in the Ninglang-Yanyuan Basin, Southwest China. It is worth noting that although the carbonate platform connects with the open sea partially, the redox environment will not be completely controlled by relative sea level variations. Specially, the paleoclimate, paleoproductivity, and paleoredox conditions are the main controlling factors of the accumulation and preservation of organic matter. In view of the paleoclimate indexes, we suggest that both a relatively warm- humid climate characterized by intensifified chemical weathering conditions and a higher terrigenous input are identifified as two major drivers forcing the reductive environment in the sedimentary waterbody. Finally, a comprehensive model is established for providing new insights into the mechanism of organic matter accumulation and preservation for the carbonate platform facies. The paleoredox environment, paleoproductivity, paleoclimate, and terrigenous input are believed to have exerted a very considerable force on reconstructing the model of organic matter accumulation and preservation for the carbonate platform facies. Specially, the coupling interactions between the paleoproductivity and redox condition are thus also stressed. We found that the preservation condition is much more important than the paleoproductivity, resulting in the degree of organic matter enrichment. Even if the paleoproductivity of a sedimentary waterbody of a depositional period of the Dacaozi Formation was higher, the TOC concentrations were relatively low due to the poor preservation condition by fall of the sea level and increase of the terrigenous input. In another aspect, the better preservation condition of the Tanshanping Formation makes the TOC concentrations higher in the case of lower paleoproductivity in the sedimentary waterbody.

Xihu Depression is situated in eastern Zhedong tectonic belt of the East China Sea Shelf Basin, and has great exploration potential for oil and gas resources. The Pinghu and Huagang Formations of the Paleogene are the coal-bearing series containing major source rocks in this Depression. The lithological types of the Pinghu and Huagang Formations include sandstone, siltstone, mudstone and coal. The Pinghu Formations was deposited in the tidal-influenced delta and tidal flat environment, while the overlying Huagang Formation was deposited in the fluvial, meandering river delta and lacustrine environment. The maceral contents of the coals were statistically counted by coal petrology, and based on the maceral compositions, the coal facies in different environments were analyzed. The results showed that although vitrinite is the dominant contributor to macerals with an average content of
90.1%, the exinite accounts for an obviously high level compared to the other common coal samples, attaining to 8.4% on average. In contrast the average content of inertinite is only 1.4%. The exinite macerals make a great contribution to both total hydrocarbon and liquid hydrocarbon though the content is low. The contribution of vitrinite, exinite and inertinite for total hydrocarbon are 63.21%, 36.46% and 0.33%, respectively. The contribution of vitrinite and exinite for liquid hydrocarbon are 40.95% and 59.05%, respectively. Four coal facies were recognized, including intermittent dry swamp facies, shallow water swamp facies, flowing water swamp facies and open water swamp facies. The hydrocarbon generation potential of the coal deposited in different depositional environments was determined by means of parameters including the organic matter abundance, organic matter type, and
organic matter maturity. The results showed that the TOC varied from 30% to 74.99% with an average of 44.16%, indicating a medium to high organic matter abundance. The “S1+S2” ranged from 42.76mg/g to 165.76mg/g with an average of 97.86 mg/g, demonstrating a high hydrocarbon generation potential. The organic matter types of the coals were dominated by type III and type III2 evidenced by relatively low HI and H/C value. The Ro values ranging from 0.31% to 1.41%, revealing that most of the coals were in the mature stage. The tidal flat and tide-influenced delta environments were developed in association with the favorable coal facies including intermittent dry swamp facies, shallow water swamp facies and thus have the best hydrocarbon generation potential.

Paleoenvironment controls on the enrichment of organic matter in the Middle Devonian Givetian shale, Youjiang Basin, South China

Yuzuo Liu[1], Wanzhong Shi[1*]
1. Resource, China University of Geosciences (Wuhan), Wuhan, Hubei, CHINA

Keywords: Shale, Sedimentary environment, Organic matter enrichment, Middle Devonian Givetian stage, Youjiang basin, South China

To reveal the shale processes of the organic matter enrichment in the Dian-Qian-Gui area during the middle Devonian Givetian Stage, the core samples from the slope regions and the basin regions were selected for the study. The sedimentary environment of shale was analyzed by means of petrology, multi-scale mineralogy, organic geochemistry and elemental geochemistry, using total organic carbon (TOC), X-ray diffraction (XRD), major elements, trace elements, optical microscope and field emission scanning electron microscope. The indicators of V/Cr, V/(V+Ni), V/Sc, V_{EF}, and the degree of pyritization (DOP) showed that the slope water columns were in the rich oxygen conditions and the basin water columns were in the poor oxygen environments. The values of Sr/Ba, Si_{bio} and Ba_{bio} indicated that the low salinity of the northern water columns and the productivity levels were increased by the blooming algae. The low TiO_2 and Al_2O_3 contents in the basin shale, indicating a low terrestrial detrital influx. The deposition environment was divided into four stages based on the analysis results. During Stage 1, oxic water columns were wide-spread, and dysoxic water columns were locally distributed; dysoxic water columns were reduced, and oxic water columns were expanded during Stage 2; the transgression had led to a large distribution of dysoxic-anoxic water columns during Stage 3; the depositional environment was changed to an oxygen-rich condition with the marine retreat during Stage 4. Laterally, the TOC contents are higher in northern basin water columns than in southern basins. The correlations between the indicators and the TOC contents indicate that anoxic environments, high palaeoproductivity, and low terrestrial debris flux are conducive to organic matter enrichment. The anoxic environment is the main controlling factor of shale organic matter enrichment. Accordingly, a model is proposed for the organic matter enrichment on the paleogeographic pattern of the platform-basin interval during the Givetian Stage.

Sedimentary environment characteristics of transitional shales in the lower member of Longtan Formation, Western Guizhou: Insights into the influence of Emeishan large igneous province and organic matter accumulation

Lu heng Bai[1], Wanzhong Shi[1*]
1. School of Earth Resources, China University of Geosciences, Wuhan, Hubei Province, CHINA
E-mail: 760231842@qq.com

Keywords: Longtan Formation, transitional shale, sedimentary environment, lagoonal shale, Emeishan large igneous province

The marine-continental transitional shale in the upper Permian Longtan Formation is not only an important target of shale gas exploration and development, but also an important research object of extreme paleoenvironmental events in Middle-Late Permian. Based on X-ray diffraction (XRD), polished sections, scanning electron microscopy (SEM), total organic carbon content (TOC) and elemental geochemistry, the paleoenvironment characteristics of the transitional shale in the lower member of Longtan Formation in Western Guizhou were studied, including primary productivity, paleo-redox conditions, paleoclimate, provenance. The influence of Emeishan large igneous province on sedimentary environment and the organic matter enrichment mechanism of transitional shale are analyzed. The results show that in the Middle-Late Permian transition, with the Dongwu movement and the eruption of Emeishan basalt, the paleogeographic pattern of high in the west and low in the east was formed in the Upper Yangtze region. The Western Guizhou was in a marine and continental transitional environment, and the lower member of Longtan Formation was deposited in a marginal tidal flat-lagoon environment. Influenced by seawater and rivers, sand and mud were interbedded frequently, and the organic matter content in shale were generally more than 5%. Longtan shales were deposited in a complex environment with warm and humid paleoclimate, anoxic-reducing, brackish to saline bottom water, high terrigenous detrital input and high deposition rate. The weathering products of Emeishan basalt were the main source of longtan Formation. The mineral and element composition characteristics of shale are closely related to Emeishan basalt. In addition, transitional shale was accompanied by a small amount of volcanic ash and hydrothermal input, and the elements carried by the hydrothermal increased the salinity of water, and was conducive to the anoxic-reducing environment. In general, the organic matter enrichment in transitional shale of the lower member of Longtan Formation is closely related to sedimentary facies. The shale deposited in mire has the highest organic matter content (>20%), followed by the shale deposited in tidal flat (10%). The organic matter content in lagoonal shale is the lowest (5%). Lagoonal shales are dominant in the lower member of Longtan Formation, and their organic matter enrichment mechanism is mainly “preservation model”. The lagoonal shales were deposited in a warm and humid, brackish-saline water, anoxic-reducing environment, with good preservation conditions for organic matter. The primary productivity was low and organic matter mainly came from higher plants. However, hot and humid climate strengthened terrestrial weathering and increased terrigenous detritus, diluting the organic matter content in shale. Higher deposition rate reduced the decomposition time of organic matter and was beneficial to the preservation of organic matter.

Lacustrine organic carbon burial in response to the rift sequence evolution and palaeoclimate changes across the Early Cretaceous Oceanic Anoxic Events

Yaohua Li[1], Qianyou Wang[2*], Xingyou Xu[1], Richard Henry Worden[2]
1. Oil and Gas Survey, China Geological Survey, Beijing, CHINA
2. Department of Earth, Ocean and Ecological Sciences, University of Liverpool, Liverpool, Merseyside, UNITED KINGDOM
E-mail: qianyou.wang@liverpool.ac.uk

Keywords: black shale, organic matter, rift sequence, palaeoclimate, Cretaceous, oceanic anoxic events

The Cretaceous rift lacustrine basins comprise extensive deposits of organic-rich black shales and archived high-resolution information from terrestrial climate changes. An integrated sequence stratigraphical and geochemical study was conducted on the Lower Cretaceous (Middle Aptian–Lower Albian) Shahezi Formation (K_1sh_{2-1}) rocks in Songliao Basin, northeastern Asia, to reveal the variation of lacustrine organic carbon sequestration in relation to rift stratigraphic evolution and palaeoclimate changes. The targeted layer was divided into two sedimentary cycles and four systems tracts (TST-1, HST-1, TST-2, and HST-2) through a combination of petrological, geophysical, and continuous 1-D wavelet transform methods. The intensive chemical weathering and warm-humid climates reflected by high CIAcorr and $Ln(Al_2O_3/Na_2O)$ values prevailed in the K_1sh_{2-1} period with intermittent cold-dry climate fluctuations. The terrestrial-sourced organic matter (OM, type III gas-prone kerogen) preserved during the long HST period largely contributed to the organic-rich shale deposition. And the proportion of aquatic-sourced OM (type I oil-prone kerogen) increased upward from TST-1 to HST-2, which was ascribed to decreased base level and cooling drought events. The high TOC concentrations of Shahezi Formation shales dominated by terrestrial OM resulted from a combination of volcanism, warm-humid climate, abundant vegetation, intensified chemical weathering, and anoxic bottom-water. Two time-equivalent sedimentary records from high- (Shahezi Formation, Songliao Basin, 118-111 Ma) and low- palaeolatitudes (Sialivakou-Argilles Vertes Formation, Congo Basin, 125-113 Ma) suggest that the shift from active-rift phase to post-rift phase is accompanied by an increase in TOC concentration and a change toward type I kerogen. And the correlation between lacustrine sediment with its marine counterpart (Albian-Santonian shale sequences in the south American Margin) may also reflect the variation of organic matter sources and abundance in relation to global terrestrial ecosystems across the Early Cretaceous oceanic anoxic events.

Organic matter accumulation of the Wufeng-Longmaxi shales in southern Sichuan Basin: Evidence and insight from volcanism

LING TANG[1], Yan Song[2*], Zhigang Zhao[1], Zhenxue Jiang[2], Xiaozhi Chen[1]
1. Unconventional National Gas Institute, CNOOC Research Institute, Beijing, CHINA
2. Unconventional National Gas Institute, China University of Petroleum, Beijing, Beijing, CHINA

Keywords: Volcanic activities, Bentonite,Redox condition, Paleoproductivity, Sedimentary environment,Trace elements

The Wufeng-Longmaxi Formations (WF-LM Fms) in the Sichuan Basin are sets of graptolite-bearing shale strata containing high-frequency bentonite layers. In order to investigate the influence of volcanism on the organic matter (OM) accumulation in shales, detailed observations of several typical profiles and wells were performed. Also, analyses including total organic carbon (TOC) contents and mineral compositions were conducted on 126 shale and 5 bentonite core samples. Major and trace element analyses were conducted on the selected 25 shale and 5 bentonite samples in the WF-LM Fms of well Lu-A. Results show that WF and LM1-4 members are the bentonites concentrated sections, while LM5-6 are the bentonites relatively concentrated sections and no bentonite is found in LM7-9 members. The high potassium (K) content of bentonites have the typical characteristics of intermediate-acid calcium-alkaline volcanic rocks such as andesite and dacite, which probably originated from intraplate collision or volcanic arc structural backgrounds related to the collision belt of the Cathaysia Block to the Yangtze Block. Productivity indicators (P content, excess Si, P/Al, Cu/Al, and Ni/Al) in the WF and LM1-3 members are all significantly higher than those in the Lingxiang (LX) and LM4-5+ members. The higher biological productivity during the Ordovician-Silurian (O-S) transition was attributed to the massive and intensive volcanism. The fertilization by volcanic ash brought abundant biologically relevant nutrient elements (N, P, Si, Fe, and Al) into the ocean, thus triggering the phytoplankton bloom and enhancing primary biological productivity. All the redox condition indexes (MoEF, UEF, NiEF, VEF, Mo/TOC, Corg/P, and U/Th) positively correlate with TOC content. During the O-S transition, the intensive and massive volcanic eruptions triggered global cooling, sea-level changes, late Ordovician mass extinction, and primary productivity increases, thus promoting anoxic, and possibly intermittently euxinic bottom conditions. In addition, the deposited bentonite layers had a strong capacity for oxygen isolation. Volcanism should be considered when modeling the OM accumulation of the WF-LM shales.

Development environment and main controlling factors of Permian main source rocks in Junggar Basin

jia fan jian[1], wu zhi ping[1*]
1. China University of PetroleumEast China, School of Geosciences, Qingdao, Shandong Province, CHINA
E-mail: jiafanjian@126.com

Keywords: Junggar, source rock, sedimentary environment, main controlling factors, development model

Years of exploration practice has confirmed that P_1f and P_2w are important source rock strata in Junggar basin. Predecessors have carried out a lot of in-depth research on the rock and mineral characteristics (Kuang Lichun et al., 2012; Zhu Shifa, 2013), geochemical characteristics (Zhang Shanwen, 2013; Qiu Zhen et al., 2016) and thermal simulation (Qiu Nansheng et al., 2002; Wang Chengyun et al., 2014) of the two sets of source rock series and obtained rich research results. However, there are few studies on the development environment of the two sets of source rocks and the main controlling factors causing the quality difference, This directly affects the evaluation of Permian oil and gas exploration prospect. Based on previous studies, combined with exploration and field geological survey data in recent years, the author studied the sedimentary environment of the two sets of source rocks, such as paleoproductivity, paleosalinity and redox conditions, through core observation, thin section identification, paleontological community combination and geochemical data analysis. The results show that the two sets of high-quality source rocks were formed in the sedimentary environment of anaerobic, low deposition rate, high productivity and under compensation. Among them, high productivity, low deposition rate, hypoxia and upwelling are important factors affecting the enrichment of organic matter. High productivity can provide a large amount of organic matter, and low deposition rate can enrich the slowly settling organic matter in a long time scale. The development of upwelling and limited sedimentary basin lead to hypoxia in the bottom water body, which is conducive to the supply of nutrients and the preservation of organic matter.

Petrographic and geochemical characteristics of organic-rich fine-grained rocks of the Upper Triassic Chang 7 member in the southern Ordos Basin, northern China: Implications for shale oil exploration

NingLiang Sun[1*], Tianyu Chen[1], Guanglei Cui[1], Jianhua Zhong[2], Jianbo Gao[2]
1. Key Laboratory of Ministry of Education on Safe Mining of Deep Metal Mines, Northeastern University, Shenyang, Liaoning, CHINA
2. School of Resources and Materials, Northeastern University at Qinhuangdao, Qing Huangdao, HeBei , CHINA
E-mail: 296182073@qq.com

Keywords: Organic-rich fine-grained rocks, Lithology, Geochemical characteristics, Biomarkers, Sedimentary model, Shale oil

Organic-rich lacustrine fine-grained rocks in Chang 7 member of the Upper Triassic Yanchang Formation are potential shale oil reservoirs. Petrographic and geochemical data were used to study their lithologic and geochemical characteristics, mineral composition and sedimentary environments. Three different types of deep lacustrine deposits are identified, including unstratified massive mudstone (muddy debrite), normally graded mudstone (muddy turbidite) and laminated shale. Mudstones and shales contain relatively abundant brittle minerals (quartz, feldspar, pyrite and carbonates), which are favorable for the hydraulic fracturing. Terrigenous input and diagenesis conversion process are the main sources of felsic minerals. Laminated shales yield the highest TOC values (average of 7.47%) as well as S1 and S2 values. Most of the mudstones and shales contain Type II organic matter, while contain little Type I organic matter.

The Ro and Tmax values combined with OEP versus CPI and C29ββ/(ββ+αα)sterane versus αααC29sterane20S/(20S+20R) discrimination diagrams and Ts/(Ts+Tm) ratios, indicate that the fine-grained rokcs are mature. Ph/C18 versus Pr/C17 and Pr/Ph versus gammacerane/C30-hopane discrimination diagrams together with U/Th, V/(V+Ni) and Ce/La ratios show that fine-grained rocks reflect a reducing depositional environment. N-alkanes of ΣnC21-/ΣnC22+ values and C27-C29 regular sterane distributions suggest that plankton and terrestrial plants are the parent materials of organic matter. In addition, small amounts of extended homohopanes (>C31) and gammacerane combined with Sr/Ba values support a fresh water depositional environment. These conditions have resulted in high quality and widespread distribution of organic fine-grained rocks, which are favorable for shale oil exploration.

E-mail: ahmed199110@hotmail.com

Keywords: Paleoenvironments, Organic matter enrichment, Paleoproterozoic source rocks, Cuizhuang Formation, Yuncheng Basin

The Paleoproterozoic Cuizhuang Formation dark shale is the main potential petroleum source rock in the Yuncheng Basin of northern China. Multiple mineralogy, organic and inorganic geochemical analysis were applied in this study to evaluate the sedimentary paleoenvironments and the factors that control the enrichment of organic matter and to reconstruct the organic matter accumulation model of the Cuizhuang Formation dark shale. Quartz and clay minerals are the most abundant minerals in the Cuizhuang Formation dark shale. The TOC content of the dark shale is relatively fair, ranging from 0.13% to 1.09% and averaging of 0.51%, with the organic matter having a high thermal maturity (mean of 2.24 Ro%) and type I kerogen. The Cuizhuang Formation shale was deposited in a passive continental margin setting, and the climate was under moderate warm and humid conditions with low salinity of seawater as evidenced by the proxies of chemical alteration index (CIA) and Sr/Ba. The paleoproductivity proxies of Ba_{bio}, Ba%, Ba/Al, P_2O_5 and P/Ti indicate low productivity with negative and no correlations with TOC content and thus did not control the organic matter enrichment. The low productivity may have significantly played a role in limiting the organic matter formation resulting in relatively low TOC content. The anoxic redox environment of the dark shale is indicated by the proxies of V/(V + Ni) and V/Sc, with strong positive correlations of V and V/Al with TOC. The anoxic redox environment in deeper waters and along with a higher sedimentation rate of the dark shale than the grey and red shale, played the main role in enriching the organic matter of the dark shale. Therefore, the Cuizhuang Formation dark shale in the Yuncheng Basin is regarded as a potential source rock, holding promise for petroleum exploration.

Palaeoenvironment and organic matter enrichment of Middle Permian source rocks in Taibei Sag of Turpan-Hami Basin, China

Boran Wang[1], Zhilong Huang[1*]
1. College of Geosciences, China University of Petroleum (Beijing), State Key Laboratory of Petroleum Resources and Prospecting, China, Beijing, CHINA
E-mail: huangzhilong1962@163.com

Keywords: Organic matter enrichment, Palaeoenvironment, Primary productivity, Salinity

The organic-rich source rocks in Taibei Sag of Turpan-Hami Basin are mainly developed in the Middle Permian Taerlang Formation (P2t) with great heterogeneity in-plane distribution. The controlling factors of organic matter (OM) enrichment in saline water lacustrine source rocks need to be further investigated to promote the oil exploration process. The organic and inorganic geochemical methods include total organic carbon (TOC), Rock-Eval pyrolysis, gas chromatography-mass spectrometry (GC-MS), X-ray diffraction (XRD), and trace elements are used to evaluate the quality, hydrocarbon generation potential, palaeoenvironmental conditions and OM enrichment of source rocks. The results show that the mudstone of P2t is high in organic content, ranging from 4% – 15% TOC, and has good hydrocarbon generation potential (Type II kerogen) in the mature stage (Tmax values ranging from 435 to 445℃). The analysis of biomarkers and trace elements shows that the P2t source rocks are mainly formed in a brackish lacustrine basin with a dysoxic water body and warm-humid environment. The salinity of water played an important role in the OM enrichment progress. The gammacerane index (indicator for salinity) is positively correlated with the total organic carbon (TOC) and the content of C28 regular sterane, indicating that the salinity of the water column controls the abundance of OM and the growth of salt-loving organisms. The contents of trace elements Cu and Zn are high and positively correlated with TOC, indicating that the primary productivity was sufficient in the P2t period and contributed to the enrichment of OM. The salinity of water columns dominates the enrichment of OM in source rocks of P2t from two aspects. The dysoxic and brackish-saline water columns contribute to the enrichment of OM through enhancing the primary productivity by promoting the growth of salt-loving microorganisms. The dysoxic environment created by saltwater column stratification is conducive to the preservation of OM, and the source rocks developed in these environments have high OM abundance. OM enrichment was greatly affected by the palaeoenvironment during the P2t period. The horizontal difference of paleoclimate and paleo-productivity controlled the distribution of organic-rich source rocks. The statistical results of paleo-salinity of P2t source rocks show an increasing trend from south to north in the study area, which provides evidence for the development of high-quality source rocks in the depression area in the north of the Taibei Sag.

Paleo-environment of the formation of pediastrum and its petroleum geological significance

Miao YU[1*]
1. School of Earth Sciences, China University of Petroleum,Beijing, Beijing, CHINA
E-mail: 461973844@qq.com

Keywords: Pediastrum,Paleoenvironment,Hydrocarbon generation simulation,Source rocks

The E_{2-3a} lacustrine sedimentary source rocks are widely developed in Junggar Basin. The research degree of this set of source rocks is relatively low at present, and their hydrocarbon generation parent materials, sedimentary environment and hydrocarbon generation potential have not been systematically studied. Due to the relatively low abundance of source Rock samples drilled by E_{2-3a} drilling, outcrop samples were systematically collected in the Anjihaihe section of Junggar Basin, and Rock-ever and TOC analyses were performed on the samples. The results show that the samples have a high abundance of organic matter. Through rock thin section, SEM observation by a large number of form a complete pediastrum, rich pediastrum samples for the analysis of trace and rare earth elements reveals its sedimentary paleoenvironment, contrary to previous studies is pediastrum in the salt water and brackish water environment can still be good enrichment, which has important indicating significance for sedimentary paleoenvironment. The high temperature and high pressure thermal simulation experiment was carried out on the samples with the highest abundance in a closed container. The results show that the algophytes have good hydrocarbon generation capacity, indicating that E_{2-3a} has the material basis for a good set of hydrocarbon source rocks.

Organic geochemistry and depositional environments of the Middle Jurassic shales in the Suotuo Subsag, Yabrai Basin, Northwest China

Jingjing Cao[1,2], Wenzhe Gang[1,2*]
1. State Key Laboratory of Petroleum Resources and Prospecting, China University of Petroleum (Beijing), Beijing, CHINA
2. College of Geosciences, China University of Peroleum (Beijing), Beijing, CHINA
E-mail: gwz@cup.edu.cn

Keywords: Geochemistry, Depositional environment, Shale, Biomarker, Yabrai Basin

The Suotuo subsag is located in the eastern part of the Yabrai Basin, northwestern China, where the shales of the Lower Member in the Xinhe Formation (LXH Fm.) and the Qingtujing Formation (QTJ Fm.) of the Middle Jurassic are mainly developed. Based on the analysis of total organic carbon (TOC), Rock-Eval pyrolysis, kerogen carbon isotope and biomarker of source rocks, the origin and depositional environment of organic matter were analyzed. The TOC and S_1+S_2 of shales in the LXH Fm. ranges from 0.27% to 15.46% (ave. 2.76%) and 0.26 mg HC/g rock to 676.14 mg HC/g rock (ave. 15.84 mg HC/g rock). Moreover, TOC and S_1+S_2 of shales in the QTJ Fm. ranges from 0.55% to 60.8% (ave. 5.36%) and 0.37 mg HC/g rock to 110.34 mg HC/g rock (ave. 20.83 mg HC/g rock). Organic matter type of the LXH Fm. is dominated by Type I with oil-prone characteristics. And there are also some Type II and Type III kerogens with oil and gas potential. The shale samples of the QTJ Fm. fall into the Type II kerogen with oil-prone and gas-prone, and some of the samples fall into the range of Type II-III kerogen. Most of the shales in the LXH Fm. and the QTJ Fm. are in the early mature-mature stage.

Applying the Pr/nC_{17} and Ph/nC_{18} cross plots can determine the organic matter sources and depositional environments of source rocks. Most of the source rocks from the LXH Fm. and the QTJ Fm. were formed in a strongly reducing depositional environment, and the type of organic matter is mainly Type I and Type II, mainly from lower aquatic organisms, such as algae. The depositional environment of the LXH Fm. was more reductive than that of the QTJ Fm. The relative compositions of C_{27}, C_{28}, and C_{29} regular steranes were commonly used to classify the origin of the organic matter. The source rocks of the LXH Fm. and the QTJ Fm. mostly fall into the area of plankton and terrigenous higher plants, indicating that the source rocks have mixed inputs of lower aquatic organisms and terrigenous higher plants. Applying the Pr/Ph and gammacerane index cross plots can determine the salinity conditions and water-column stratification of the depositional environment of the source rocks. The relationship between Pr/Ph and gammacerane index of source rocks in the LXH Fm. and the QTJ Fm. in Suotuo Subsag shows that most source rocks were formed in anoxic to strongly reducing environment and heavy reduction salt water with stratification in the water column.

Marine potential shale characteristics and hydrocarbon generation potential in the middle and lower Yangtze region

wang neng[1*]
1. , , , , CHINA
E-mail: wang19952023@163.com

Keywords: Middle and lower Yangtze, organic matter, shale, organic carbon, maturity, gas generation conditions.

Three sets of organic rich shale strata are developed in the middle and lower Yangtze region, mainly including Sinian Doushantuo Formation, Cambrian Niutitang Formation, Ordovician Silurian Wufeng Formation and Longmaxi formation.The second and fourth members of Doushantuo Formation deposit relatively stable dark mudstone in the region, and other strata develop dolomite and limestone, mainly developing clastic shore, carbonate platform, shelf and limited marine basin sedimentary environment. Black mud shale and carbonaceous mud shale are developed in the middle and lower part of Niutitang Formation, and the upper horizon is dominated by siltstone deposition. The main sedimentary environments include shore facies, shallow sea shelf facies (groove facies in shelf, shallow water shelf facies and deep-water shelf facies) and shelf margin facies. Carbonaceous and siliceous shales are developed in the lower part of Wufeng Formation, and bioclastic limestone is developed in the upper part, which is mainly deposited in deep-water shelf; The sedimentary water of Longmaxi formation becomes shallow, dominated by mud shale and siltstone, which is a relatively shallow shelf deposit. The middle and lower Yangtze region is rich in organic shale, and the thickness of organic shale in the lower Yangtze region is greater than that in the middle Yangtze region.

The heterogeneity of lithofacies types and sedimentary model of continental shale restricted by high-frequency an example from Paleogene Formation, Subei Basin, East China

Biao Sun[1,2], Xiaoping Liu[1,2*], Ming Guan[1,2], Gaocheng Wang[3], Honglin Shu[3], Yufeng Luo[3], Mengcai Liu[3], Tian Liu[1,2], Zuxian Hua[1,2]

E-mail: Liuxiaoping@cup.edu.cn

Keywords: continental shale, high frequency sequence, lithofacies, paleoenvironment, sedimentary model

Compared with marine shale, the lithofacies of continental shale change rapidly and the heterogeneity is obvious. The lithofacies characteristics and controlling factors pose some of the greatest challenges in sedimentology. The solutions to these problems will offer accurate predictions of continental shale. This study is established through wavelet transformation of the natural gamma curve the high-frequency sequence framework of the lacustrine shale. Here we also used thin-section observation, total organic carbon analysis, X-ray diffraction experiments, their elements and carbon and oxygen isotopic compositions to analyze the lithofacies characteristics. The results show that 12 types of lithofacies were developed in the continental shale. it is found that the formation is composed of three-level sequence of low-level system tract (LST), transgressive system tract (TST), and early high-level system tract (EHST), corresponding to 6 fourth-level sequences and 10 fifth-level sequences. The lithofacies type is affected by the paleoenvironment. The deeper the water body and the hypoxic conditions are the basis for the production and preservation of organic matter; the deeper the paleowater body reflects the stronger the weathering of the land surface, which is conducive to the accumulation of clay minerals and felsic minerals. Carbonate deposition is mainly controlled by ancient salinity; anoxic conditions and increase in ancient salinity are conducive to the development of laminar structures. The lithofacies of the Paleogene Formation show obvious vertical sequence and cyclicity under the sequence framework of different scales. The third-order sequence system tract controls the organic matter enrichment, and the fourth-order sequence controls the lithofacies subclasses and coupling rhythms. Three lithofacies assemblage models A, B and C developed in different system tracts were established, and sedimentary models of different lithofacies assemblage patterns were established based on the results of paleoenvironmental analysis. This study provides new insights that the lithofacies type is affected by the paleoenvironment. The lithofacies are regularly superimposed in the high-frequency sequence framework, and a lithofacies sedimentary model is established of continental shale.

Geochemical characteristics of Linxing area and influencing factors of shale organic matter enrichment

Feisheng Mou[1], Xiangdong Yin[1*]
1. School of Earth Sciences and Technology, southwest petroleum university, Chengdu, CHINA
E-mail: 272868175@qq.com

Keywords: Ordos Basin, Linxing area, REE, Environment, TOC

In recent years, major breakthroughs have been made in the exploration of Sea-land transition phase shale gas, but the evaluation system is still in its infancy. And basic research on the development characteristics, sedimentary characteristics, and organic matter enrichment characteristics of transitional shale needs. further research. Based on the trace elements of 17 shale samples in the Linxing, Ordos Basin, results have been achieved in terms of material sources and sedimentary environment. The results show that from the Benxi Formation to Shihezi 8 section is a marine to the terrestrial environment, furthermore, the oxidation gradually increases. It is concluded that the sediments of the Upper Paleozoic strata in the study area are from the northeast margin of Ordos Basin in the Yinshan area. The organic matter enrichment is mainly controlled by redox conditions, moreover, Taiyuan formation is a reduction environment and with the highest total organic carbon content. The analysis of the sedimentary environment and sedimentary sources in the study area provides a strong basis for shale gas exploration, and the evolution characteristics of the Ordos Basin during the Permian period are inferred from the seawater variation in the Linxing area.

New insight on crude oil types genesis and evolution of Fengcheng Formation in Mahu sag, Junggar Basin, China

Wenlong Dang[1], Gang Gao[1*]
1. School of GeoSciences, China University of Petroleum Beijing, Beijing, CHINA
E-mail: gaogang2819@sina.com

Keywords: Crude oil type, Thermal maturity evolution,Fengcheng formation, Mahu Sag, Junggar Basin

The Mahu Sag in the Junggar basin is one of the hot spots of oil-gas exploration, with rich oil-gas resources and great exploration potential. The Fengcheng Formation of Mahu Sag is not only an important source rock but also an important oil-gas accumulation play. Previous studies have focused on the hydrocarbon source rocks, reservoirs and crude oil characteristics of the Fengcheng Formation. Some scholars believe that different types of crude oil of Fengcheng Formation come from different horizons, while others believe that those come from Fengcheng Formation. Based on the geochemical parameters of source rocks and combined with the hydrocarbon generation thermal simulation experiment of source rocks, this study comprehensively analyze the genesis and evolution characteristics of different crude oil types. The research shows that the crude oil of Fengcheng Formation can be divided into three types according to the relative content of C_{20}, C_{21} and C_{23} tricyclic terpane: ascending, mountain-shaped and descending types. The three types of crude oil are orderly distributed in space. The hydrocarbon generation thermal simulation experiment of source rocks shows that the experiment products gradually transition from ascending type to descending type with increased maturity, indicating that different types of crude oils come from the different maturity stages of Fengcheng Formation source rocks. The natural evolution profile of crude oil shows that the biomarkers parameters of crude change regularly with the increased maturity, including the relative content of tricyclic terpane gradually increases, the relative content of C_{20} and C_{21} tricyclic terpane decreases first and then increases, the content of C_{28} sterane gradually decreases, and the crude oil types gradually transit from ascending to descending type. This research reveals that different types of crude oils of Fengcheng Formation come from different thermal evolution stages of Fengcheng Formation source rocks, and the biomarkers thermal evolution of crude oil has a complete sequence. According to the biomarkers characteristics of crude oil, the thermal maturity stage of crude oil can be judged, and then judge its accumulation period, which has important enlightenment significance in the further exploration and development of Fengcheng Formation.

Relationship Between Extended Tricyclic Terpene Index ETR and Several Geochemical Indices in Lacustrine Source Rocks:By Taking Lishu Fault Depression in Songliao Basin for Example

Luo Yu ting[1], Zhang Min[1*]
1. Hubei Key Laboratory of Petroleum Geochemistry and Environment, Yangtze University(College of Resources and Environment), Wuhan, Hubei, CHINA
E-mail: zmjpu@163.com

Keywords: Extended tricyclic terpene, Lishu Fault Depression, ETR, Maturity, Source rocks

Extended tricyclic terpene index ETR[ETR=(C_{28}TT+C_{29}TT)/(C_{28}TT+C_{29}TT+Ts)] was first developed by Holba et al.[1] proposed for dividing the parameters of the Triassic and Jurassic, due to the thermal stability of Ts is better than hopane, compared with tricyclic terpene(TT)/C_{30}H, ETR can weaken the effect of thermal maturation of parent material source, its relevant parameters are usually used to water chemical conditions in lacustrine environments[2], indicates the effect of transgression[3] and judgment of biodegradation[4], and thus more and more cause the attention of geologists to extended tricyclic terpene. Songliao Basin is one of the largest continental petroliferous basins in China, Lishu fault depression is a secondary tectonic unit of songliao Basin. In this paper, gas chromatography and gas chromatography-mass spectrometry (GC-MS) data for saturated hydrocarbons of 48 lacustrine source rocks samples in Lishu fault were analyzed, and the relationship between ETR and several geochemical indexes in source rocks was discussed in detail. Results show that: (1) ETR is negatively correlated with Pr/Ph, but not with G/C_{30}H (degree of salinization), indicating that the relative abundance of extended tricyclic terpanes is related to the degree of oxidation-reduction of water during organic matter deposition, but not with water salinity. (2) ETR is correlated with the diahopanes (C_{30}*, C_{29}*, C_{29}Ts) and C_{24}TeT/C_{26}TT, indicating that the extended tricyclic terpanes and diahopanes have similar parent material sources, and the more continental the organic matter sources in higher ETR. (3) Difference in maturity of source rocks in Lishu depression is the main factor influencing the relative abundance of extended tricyclic terpanes. ETR is negatively correlated with maturity parameters Ts/(Ts+Tm), C_{29}-(ββ/ββ+αα) and disterane sterane/regular sterane, and high degree of thermal evolution of source rocks is not conducive to the enrichment of extended tricyclic terpanes. (4) In addition, the ETR values of lishu fault depression are also correlated with the internal parameters of tricyclic terpanes, specifically, ETR is negatively correlated with (C_{19}TT+C_{20}TT)/C_{23}TT, C_{19}TT/C_{20}TT, and positively correlated with C_{23}TT/C_{21}TT. The correlation between these different tricyclic terpanes may reflect the changes of parent materials of hydrocarbon generation during deposition and record the evolution of lacustrine geochemistry.

Sedimentary environment and biological source evolution of shales in Lucaogou Formation in Jimusaer Sag, Junggar Basin, ChinaImplication for source rock hydrocarbon generation and expulsion

Gang Gao[1*], Shiju Liu[1]
1. College of Geosciences, China University of Petroleum (Beijing), Beijing, CHINA
E-mail: gaogang2819@sina.com

Keywords: Sweet spot, Shale oil, Biological source, Lucaogou Formation, Junggar Basin

The Lucaogou Formation in the Jimusaer Sag is a hot spot for the exploration and development of lacustrine shale oil in China. In this paper, the shale oil potential is evaluated from the perspective of source rock hydrocarbon generation and expulsion. Based on a detailed organic petrological and geochemical characterization of the target interval within the key well JHBE, kinetic experiments were conducted on representative shale samples from well JHBE, and the lower limit index of hydrocarbon expulsion of the source rock is established. According to the findings of this study, the Lucaogou Formation shale is generally good to excellent source rock and mainly contains type I-type II1 of organic matter (OM) in the mature thermal evolution stage. Biomarker shows that the Lucaogou Formation shales were deposited in the dysoxic to anoxic and clay-poor lacustrine environment with normal to higher water salinity, and their OM was contributed from both lamalginite and telalginite with minor vitrinite and intertinite. The development of different primary organic matter is related to the salinity of the water column. The lamalginite was prone to flourish in water with lower salinity, while the telalginite was developed in water with relatively high salinity. Both lamalginite and telalginite have good-excellent hydrocarbon generation potential, although the former has a higher OM content than the latter, the current generated hydrocarbon amount is lower than the latter, for the telalginite has a higher hydrocarbon conversion rate than lamalginite in the current thermal maturity, which is indicated by higher HCI, EOM/TOC, C29ββ/ (αα+ββ) and C29ααα20S/(20S+20R) ratio values from telalginite than lamalginite, as also evident by the difference of activation energy distribution between lamalginite and telalginite source rock. Determined by relationships of sterane maturity parameters C29ββ/ (αα+ββ) and C29ααα20S/(20S+20R) vs. EOM/TOC ratio and HCI values, the lower C29ββ/ (αα+ββ) and C29ααα20S/(20S+20R) limit for active rocks is around 0.28 and 0.44 respectively. So, the reservoirs adjacent to the effective source rocks determined by the above-mentioned have good shale oil exploration potential in the Lucaogou Formation.

Sedimentary environment and model for lacustrine organic matter enrichment: lacustrine shale of the Early Jurassic Da'anzhai Formation, Central Sichuan Basin, China

Qingbo He[1*]
1. , , Chengdu, Sichuan, CHINA
E-mail: 373749630@qq.com

Keywords: Lacustrine shal, Sedimentary environment, organic matter enrichment

Based on the analysis of element geochemistry and total organic carbon (TOC), this study investigates the main factors controlling organic matter (OM) enrichment, reconstructs the evolution process of the sedimentary environment, and proposes a dynamic OM enrichment model of the Jurassic Da'anzhai (D) Formation, Sichuan Basin. The results indicate that the Sichuan Basin was generally dominated by a warm and oxidizing sedimentary environment, but with some peculiarities, such as a hotter climate in the D1 member and more anoxic lake water in the D2a member. The sedimentary evolution of the Da'anzhai Formation can be divided into a fluctuating sedimentary stage, a stable sedimentary stage and a reef-building stage. The D2a member showed the strongest hypoxia, the weakest weathering, the largest amount of terrestrial inputs, and the highest TOC content. The TOC is positively correlated with reducing conditions and terrestrial inputs, negatively correlated with weathering. Based on these findings, it is suggested that the global climate in the Early Jurassic period had a complex regional effect and the global oceanic anoxic events of the Toarcian did not spread to the Sichuan Basin. Thus, the anoxic deep water, high terrestrial inputs, and weak weathering were conducive to rapid deposition and preservation of lacustrine OM.

Distribution pattern change of tricyclic terpane in humic coal under the transgression

xiang wei [1], Zhang Min[1*]
1. Hubei Key Laboratory of Petroleum Geochemistry and Environment (Yangtze University), Yangtze University(College of Resources and Environment), Wuhan, Hubei, CHINA
E-mail: zmjpu@163.com

Keywords: Tricyclic terpane, transgression,kuqa depression,sichuan basin

Tricyclic terpenes (TT) are an important component of saturated hydrocarbons, which are widely present in source rocks and crude oil. The variation of tricyclic terpenes' distribution can well reflect the changes of sedimentary paleoenvironment, paleoclimate and tectonic movements. This paper uses geochemical analysis to research on the humic coal in the Kuqa Depression of the Tarim Basin and the Sichuan Basin, and found that there are three different distribution patterns of tricyclic terpenes in the Kuqa Depression and the Sichuan Basin: "C_{19}TT>C_{20}TT>C_{21}TT >C_{23}TT" descending type, "C_{19}TT<C_{20}TT<C_{21}TT>C_{23}TT" and "C_{19}TT<C_{20}TT<C_{21}TT<C_{23}TT" single peak type. In addition, the Kapushaliang River profile and the Sichuan Basin humic coal posses a high maturity (1.1%<Ro<1.485%), but the distribution pattern of tricyclic terpenes does not change within a certain maturity range (Ro<1.5%)[1]. Therefore, maturity exert a rare impact on the distribution pattern of tricyclic terpenes. The tricyclic terpane of humic coal in the Kuqa River profile basically controlled by C_{19}TT descending distribution, while the Sichuan Basin and Kapushaliang River profiles are still being a single peak distribution of C_{21}TT and C_{23}TT. over and above that,compare with the Kuqa River profile,some geochemical parameter are especially different ,such as the higher gammacerane index around 0.21, the lower Pr/Ph value around 0.62, and the higher SF/OF value around 5.42, which is different from the geochemical parameters of conventional humic coal,too. Previous studies have shown that the Kapushaliang River profile, the Sichuan Basin and the Kuqa River profile were all affected by transgression[2-4], but the distribution of tricyclic terpenes between the Kuqa River profile, the Kapushaliang River profile and the Sichuan Basin was significantly different. The study shows that the tricyclic terpenes of humic coal in the original swamp facies environment that affected by the transgression perform the same distribution characteristics as fluvial/delta facies, while the tricyclic terpenes distribution of the original lacustrine facies obtain more C_{23}TT after the effect of the transgression. But without massive alien resources imput and long term transgression,in general the distribution of the "C_{19}-C_{20}TTC_{21}TTC_{23}TT" still bias to lacustrine sedimentary environment.

Element geochemical characteristics and organic matter enrichment mechanism of mud shale: A case study of the first member of Qingshankou Formation in the northern Songliao Basin

Ying Li[1*], Min Wang[1], Yu Yan[1]
1. Key Laboratory of Deep Oil and Gas, China University of Petroleum (East China), Qingdao, Shandong Province, CHINA
E-mail: 1782603331@qq.com

Keywords: elemental geochemistry, depositional environment, organic matter, enrichment mechanism

Elemental geochemical tests were conducted on shale samples in the first member of Qingshankou Formation in the northern Songliao Basin, and a series of element indicators were used to identify paleo-climate, paleo-salinity, paleo-productivity and paleo-redox conditions. By restoring the depositional environment of black shale, the enrichment mechanism of organic matter in mud shale is further explored. According to the characteristics of organic matter content and geochemical element indicators, the first member of Qingshankou Formation can be divided into three units: bottom unit, middle unit and upper unit. Due to the differences in organic matter content and sedimentary environment of the three units, the organic matter enrichment mechanism is also different.

The bottom unit develops oil shale, with the highest organic matter content. At this stage, affected by the massive death of organisms caused by transgressive events, high paleo-productivity develops. Meanwhile, the salinity stratification and reduction environment of lake water caused by transgression provide good conditions for the preservation of organic matter, which leads to the enrichment of organic matter; Mud shale with large depth range is developed in **the middle unit**, and the content of organic matter is high. The abundant nutrients brought by transgressive events resulted in biological bloom and high paleo-productivity, but at the same time, it also brought a certain degree of bioturbation to affect the organic matter enrichment. The strong reduction environment sedimentary environment at this stage is conducive to the preservation of organic matter. Therefore, even if there is a certain degree of bioturbation, the organic matter enrichment is well completed; **The upper unit** is mainly black shale, and the thin-layered siltstone is distributed at intervals, and the organic matter content is lower than the previous two units. The warm and humid climate brings a lot of rain, and the thin-layered siltstones are mostly related to the input of terrigenous materials along with rainwater, which also destroys the preservation conditions of organic matter, resulting in low organic matter content at the top.

Weathered Residual Petroleum in the Deep Water Sediment of the South China Sea; how much is there and where did it come from?

Stephen A Bowden[1,2*], Zhibin Wen[1]

E-mail: s.a.bowden@abdn.ac.uk

Keywords: Sediment Cycles, Organic Geochemistry, Thermal history, Biomarker, Sediment Sources

Organic carbon that has been geologically processed in sediment cycles becomes recalcitrant, and one of the most resistant types of organic matter is asphaltic weathered petroleum. Detecting this type of organic carbon is difficult because it is chemically unreactive and poorly solvent-soluble and consequently analysing small quantities is difficult. While some information on carbon cycling can be obtained from stable isotope measurements, this data lacks molecular specificity. Thus when different types of organic carbon are mixed together trace quantities of small amounts of weathered petroleum will be missed. This means that for asphaltic weathered petroleum, there is not currently a clear picture of how it is recycled over deep geological time or a direct quantification in major sediments reservoirs.

The quantities of resistant biomarker, and for the first time asphaltene, have been measured at trace concentrations in deep water sediments from the South China Sea by using Surface Enhanced Raman Scattering. By making comparisons to sediments found on continental shelves and in petroleum-bearing formations exposed on land, it can be shown that weathered asphaltic petroleum found in the distal parts of the South China Sea has survived transportation to its current location despite likely moving through sediment reservoirs on shelves to the north and north east. Furthermore, based on the relative proportions of resistant biomarker, asphaltic petroleum may have been degraded only very lightly during this process and therefore the main process that lowers concentrations is dilution by mixing with other sediments.

Previously trace quantities of petroleum biomarker within sediment have mostly been considered only in the context of carbonate rocks, however the reworked petroleum-bearing formations within the deepwater sediments of the South China Sea show that siliclastic sediment can still possess organic geochemical finger-prints and this has consequences and applications for determining thermal history and for carbon cycling, as well as applications for determining sediment provenance and mass balancing petroleum systems on geological timescales.

Organic-Rich Strata of the East Beni Suef Basin, Egypt: Implications on Source Rock Potentiality

Ahmed Yousef Tawfik[1,2*], Robert Ondrak[3], Gerd Winterleitner[1], Maria Mutti[1]
1. Institute of Geosciences, University of Potsdam, Potsdam, Brandenburg, GERMANY
2. Geology Department, Suez University, Suez, EGYPT
3. Section Organic Geochemistry, Helmholtz Centre Potsdam GFZ German Research Centre for Geosciences, Potsdam, Brandenburg, GERMANY
E-mail: Yousef1@uni-potsdam.de

Keywords: East Beni Suef Basin, Source Rock Evaluation, Kerogen Types, Organic Matter Richness, Thermal Maturity

The Mesozoic deposits of the Tethyan realm represent the most prolific source rocks, which contribute approximately 70% of the total world hydrocarbon reserves (Huc, 1995). The East Beni Suef Basin is an extensional rift basin in north-central Egypt that has initiated under tensional tectonics in the wake of the post-Hercynian break-up of Gondwana. The basin stratigraphy consists of a mixed siliciclastic carbonate succession ranging from the Albian to the Eocene (Zahran et al., 2011), where the Upper Cretaceous Abu Roash Formation comprises the essential petroleum system elements of the basin. The main goal of this study is to evaluate the source rock potentiality of the sedimentary succession in terms of organic matter richness, thermal maturity, and kerogen types. To achieve this goal, we used an extensive data set of geochemical and kerogen analyses including total organic carbon (TOC), Rock-Eval pyrolysis, and visual kerogen composition that were performed on 190 cutting samples from three wells in the East Beni Suef Basin and made accessible through the Egyptian General Petroleum Corporation. Based on the organic richness, the sediments show a wide range of fair to excellent source potential, where The Abu Roash “F” Member shows the highest hydrocarbon-generating potential (1.04–4.02 wt% TOC and S2 from 3.55 to 27.91 mg HC/g rock), while the Bahariya Formation exhibits the lowest source potential (0.5–2.25 wt% TOC and S2 from 0.54 to 4.43 mg HC/g rock). Three kerogen types can be distinguished: oil-prone type II kerogen in the Apollonia Formation and Abu Roash “F” Member, mixed type II/III kerogen in the Abu Roash “A” and “G” members, and gas-prone type III kerogen in the Abu Roash “E” Member and Bahariya Formation. In general, the sediments are distributed along most of the kerogen evolutionary pathways due to variations in organic matter and lithologic composition, which in turn reflect the different depositional environments of the sedimentary succession from lagoonal to open marine setting. Visual kerogen composition reveals variation in the maceral composition of the sedimentary succession from liptinite to vitrinite with minor traces of inertinite, which reflects variations in the depositional conditions as confirmed by the Rock-Eval pyrolysis results. The vitrinite reflectance profiles show that most of the analyzed sediments are immature to marginally mature (0.39–0.71% Ro), which is confirmed by the Tmax and the thermal alteration index measurements. Based on the source rock evaluation, it could be concluded that the Abu Roash “F” Member is the main source rock with good to excellent source potential, oil-prone mainly type II kerogen, and immature to marginal maturity levels.

Paleoenvironments and enrichment of organic matter of the Yuertusi Formation shaleTarim basinA study of the Luntan 1

Pengwei Liu[1], Jingqiang Tian[1*], Wang Qi[1]
1. school of geoscience, China university of Petroleum(East), Qingdao, Shandong, CHINA
E-mail: tianjq@upc.edu.cn

Keywords: Early Cambrian, Tarim block, Hydrothermal activity, organic matter enrichment

The organic-rich sediments were widely deposited over the Tarim Block during the Early Cambrian. But the depositional mechanism and organic matter enrichment processes are poorly understood. In this study, we investigated the systematic changes in total organic carbon, X-ray diffraction, major elements and trace elements for samples from the Luntan 1 borehole, located in the Lunnan depression, to reconstruct the climatic conditions, redox changes, primary productivity. Yuersiti Formation mainly includes mudstone in the lower part and limestone in the upper part. Paleoclimatic proxies (Sr/Cu ratios and C-values) suggest that the Yuertusi formations experienced significant changes from warm-humid to cold-dry. Paleoredox indices (U/Th, Ni/Co, V/(V+Ni), Mo_{EF} and U_{EF}) also demonstrate fluctuating redox variations from anoxic to oxygenated. Paleoproductivity parameters (TOC, Ba_{bio} contents and Cu/Al ratio) suggest that the low sections of the Yuertusi formation were deposited with high biological productivity while the upper sections were deposited with low biological productivity. Moreover, the evidence for the existence of hydrothermal activities consisted of high contents of quartz and pyrite, large positive Eu anomalies related to hydrothermal fluids. These data demonstrate large climatic and oceanic fluctuations during the Early Cambrian, providing essential controlling factors on the oceanic anoxia, productivity, and organic-rich black shale depositions in the Tarim block during the Early Cambrian.

Geochemical tools points to organic richness and possible unconventional hydrocarbon potential in previously underestimated organic rich Triassic and Jurassic strata, Precaspian Basin, Kazakhstan

Gyuzel Yeltay[1*], Milovan Fustic[1], Riza Nurbekova[1], Madina Taubassova[1], Mels Edilbayev[2]

2. Geology Department, Falcon Oil and Gas Ltd. , Almaty, Almaty region, KAZAKHSTAN
E-mail: gyuzel.yeltay@nu.edu.kz

Keywords: source rock, biomarker analysis, pyrolysis, shale oil, petroleum geochemistry

Precaspian basin (Kazakhstan) is a globally important petroleum province. The basin is divided into two main sequences separated by thick Kungurian (Permian) salt deposits. The source rock for super-giant sub-salt oil fields (i.e. Tengiz, Kashagan, and Karachaganak) are believed to be deep marine carbonate facies (Type IIS) formed syndepositionally with Devonian and Carboniferous reef build-ups (Ulmishek, 2001). This interpretation is supported by a very high (4-20%) sulfur content in all sub-salt oil fields.

The origin of oil in post-salt Triassic and Jurassic reservoirs is debatable. Their physical properties and composition are affected by a variable degree of biodegradation that followed oil emplacement. In contrast to pre-salt oils, the reported bulk oil composition from post-salt reservoirs shows dramatically lower concentrations of sulfur (0,1-1,5%).

Detailed study of biomarkers including sterane homologues ratios, hopanes, and tricyclic terpanes from more than 100 reservoirs of Emba region (Seitkhaziyev et al., 2019; 2020) suggests that post-salt reservoirs are charged from two distinct sources: carbonate and shale facies. Our quantitative analysis of published Dibenziothiophenes (DBT) to Phenanthrene ratios and Pristane – Phytane ratios (both depositional paleoenvironment indicators) confirms that conclusion and suggests mixed-sourced oils in some reservoirs. The question is where the clastic shale source rocks are?

Integration of data from oil-shale potential (surficial mining) studies of shallow shale subcrops (Sapargaliev, 2017) with paleo-geographic maps, pyrolysis results, and subsurface logs, allowed us to suggest that Late Permian, Triassic and Jurassic clastic shales have matured in deeper parts of the basin. This interpretation supports Pairazian et al., (1999) assumption based on interpreted tectono-stratigraphic framework. The presence of post-salt source rocks explain the origin of compositionally different oils in post-salt oil accumulations. Furthermore, it points to a likely presence of overseen unconventional reservoirs. Characterization of post-salt organic rich strata, their burial history, and hydrocarbon generation potential is a subject of ongoing research. Results are expected to provide new information for revising the petroleum system and assessing the unconventional potential in post-salt sedimentary successions of Precaspian Basin.

This project is supported by Nazarbayev University Grant No 080420FD1905.

Enrichment mechanisms of Organic matter in late Triassic Xujiahe Formation mud shale, southeastern Sichuan Basin

Huang Hao[1*], Zhang TingShan[1,2], Zhang Xi[1], Zhu HaiHua[1,2], Zeng JianLi[1], Li ShiXin[1], Lu TengHui[1]

E-mail: 271463156@qq.com

Keywords: Late Triassic, Sedimentary environment, Climate, Organic-rich sediments, Sichuan Basin

The upper Triassic Xujiahe Formation in Sichuan Basin is characterized by self-generation and self-preserving reservoir. As a source rock, the mud shale of Xujiahe Formation has high abundance and wide distribution of organic matter(OM), which is of great research value. There are few studies on the mechanism of OM enrichment in the Xujiahe Formation in southeastern Sichuan Basin. Based on the investigation of the Xujiahe section in southeastern Sichuan Basin and the analysis of element geochemistry, the evolution process of the sedimentary environment is reconstructed. Combined with previous studies, the factors that control OM enrichment during the Rhaetian are discussed. The sedimentary system in the study area of the Late Triassic Xujiahe Formation was lacustrine-delta. The ratios of U/Th and Ni/Co indicate that the organic-rich sediments were mainly deposited in a weakly oxidized environment, which is not conducive to the preservation of OM. The chemical index of alteration (CIA) indicates the palaeoclimate. A warm and humid paleoclimate favored the growth of organisms, which could enhance the surfcial biotic productivity. The sedimentation rate in southeast area is much lower than that in western Sichuan depression. Slower deposition rates are also detrimental to the preservation of OM. According to the data analysis, OM enrichment in southeastern Sichuan Basin is mainly affected by redox environment and climate, and is almost not affected by sedimentation rate. The upper part of the third member of Xujiahe Formation has the lowest oxygen content, the warmest and wettest climate, and the highest TOC content. These studies reveal that sedimentary environment and paleoclimate might be responsible for the enrichment of OM in the Xujiahe Formation in southeastern Sichuan Basin.

Biological sources and sedimentary environment of organic enriched Member 2 of Kongdian Formation (Paleogene) in Cangdong Sag, Bohai Bay Basin, China

cheng wu[1], Lin Chen[1*], Zongsheng Lu[1], Jiaxin Yan[1]
1. , , , , CHINA
E-mail: chenlin@cug.edu.cn

Keywords: Source rock,Biomarker,Organic input,Depositional environment,Ecological evolution,Cangdong Sag

The Member 2 of Kongdian Formation(Ek2, Paleogene) in the Cangdong sag is an oil-rich interval in the Bohai Bay Basin, China. In this research, we are committed to studying the organic matter composition, ecological community structure, and sedimentary environment of Ek2 through rock pyrolysis and molecular geochemistry. The studied samples have vitrinite reflectance (Ro%) values of 0.66–0.82 % and maximum pyrolysis temperature (Tmax) values of 443–457 °C, suggesting that organic matter is mainly located in the low mature to mature stage. Biomarkers are mainly distributed as low-to-high-molecular-weight n-alkanes (n-C14 to n-C35), The decrease in the value of L/H throughout the period represents a gradual increase in the input of higher plants. the trend in the ratio of C24 TeT to C26 TT is consistent with the trend in the relative content of C29 steroids, implying that at 3170 m the relative amount of higher plant input begins to increase. The relative bloom of zooplankton species represented by C27 steroids occurs at 3170 m. The change in vegetation appearance can be reflected by the ratio of (C27 +C29) to (C31+C33). The ratio changes more frequently throughout the deposition period, but generally decreases, implying a gradual evolution of vegetation appearance from woody to herbaceous plants. The relative changes in the Paq and Pwax ratios can be used to reflect the relative inputs of higher plant input species submerged versus phytoplankton and emerging plant plants, showing an opposite trend, with phytoplankton and submerged plants gradually decreasing relative to emerging plant plants at 3065 m. while Pr/Ph and Gammacerane/C30 hopane values are both low reflecting a reduced and freshwater depositional environment, and at 3070 m, Gammacerane/C30 hopane values gradually increase and Pr/Ph was decreased, shown the salinity of the water column increases. Pr/n-C17 vs Ph/n-C18 also confirms that the water body is a reduced environment. Based on different indicators of biomarker compounds and other types of data, we have derived the pattern of lake evolution, evolution of biotopes and biological composition of hydrocarbon source rocks in three stages (Ek 4 2-Ek 3 2, Ek 2 2, Ek 1 2)) in different periods during the deposition of the Member 2 of Kongdian Formation. which is very favorable for the preservation of organic matter and favorable to the formation of high-quality hydrocarbon source rocks

Microscopic pore throat structure of the Permian Wutonggou formation reservoir in the eastern Junggar Basin

Weiyan Sheng[1*]
1. Department of Geology, Northwest University, Xi'an, Shanxi, CHINA
E-mail: sheng.wei.yan@163.com

Keywords: Reservoir,Microscopic pore throat structure,Junggar Basin

Due to the influence of sedimentation and diagenesis, the reservoirs of the Permian Wutonggou formation in the Dongdaohaizi sag in the eastern Junggar basin and the Di'nan-8 wellblock in the Baijiahai uplift generally show rapid lithologic changes, compact lithology, poor physical properties, and significant differences in reservoir microscopic characteristics. At present, the distribution of the reservoir facies belt is unknown, and the detailed research on reservoir characteristics is consequently insufficient, resulting in a bottleneck restricting the prediction of high-quality reservoir distribution and oilfield development in the study area. Based on observation and description of the rock core, as well as microscopic observation and identification of conventional sheets and casting sheets, the characteristics of the Permian Wutonggou formation reservoir in the Di'nan-8 wellblock are studied by analyzing heavy minerals, porosity, and permeability, high-pressure mercury injection, clay mineral X-ray diffraction, graphic granularity, graphic pore-throat, microbeam fluorescence, homogenization temperatures of fluid inclusions, laser Raman component, and scanning electron microscopy. Under the development mechanism of the fan-delta reservoir, the reservoir characteristics such as micro petrological characteristics, physical properties, pore-throat structure distribution, and clay mineral composition are clarified. Furthermore, the types and characteristics of diagenesis, the classification of diagenesis stages, the diagenesis-pore evolution and pore development, and the prediction of secondary pore zones are determined. The following results can be obtained: The physical properties of the reservoir are jointly affected by the water power in deposition and diagenesis, and the rock particle size affected by the water power determines the quality of the original reservoir. Cementation is the main diagenesis (average pore reduction of 25.1%) for the loss of primary pores in the reservoir; and secondly, compaction (average pore reduction of 10.2%) and dissolution (average pore increase of 6.5%) enhance the reservoir performance to a certain extent. The reservoir in the uplift zone experiences weak compaction but strong cementation and dissolution; in contrast, the reservoir in the sag experiences strong compaction, whereas cementation and dissolution are relatively weak. The Wutonggou reservoir is a matrix and fractured dual porous media reservoir with very low porosity and permeability. The pores are mainly secondary dissolved pores, but the pore-throat structures are complex and variable. The seepage capacity and oil saturation of a reservoir are controlled by both matrix pores and fractures. The research findings will be useful in the future for oil reservoir evaluation, wellblock location deployment, reservoir evaluation, and effective production, accelerating exploration and development, and increasing reserves and production of Permian oil and gas reservoirs in the Di'nan 8 wellblock.

Multiple controls on the organic matter accumulation in early Cambrian marine black shales, middle Yangtze Block, South China

Zixuan Liu[1], Detian Yan[1*]
1. School of Earth Sciences, China University of Geosciences (Wuhan), Wuhan, Hubei, CHINA
E-mail: yandetian@cug.edu.cn

Keywords: primary productivity, redox condition, hydrothermal activity, upwelling

The Lower Cambrian black shales are considered important source rocks possessing huge potential in shale gas exploration. To unravel the differential organic matter accumulation, we present a detailed analysis of mineralogy and major and trace elements for the lower Cambrian Shuijingtuo Formation in the outer-shelf Three Gorges area. Based on the investigation of primary productivity (EF(Cu), EF(Ni)), redox condition (Mo-U covariations, Corg/P), and terrigenous input (Ti/Al), the Shuijingtuo Formation is divided into three units. The organic-poor lower unit (TOC=0.69% on average) records suboxic-oxic conditions, low primary productivity, and high terrigenous input. The organic-rich middle unit (TOC=5.40% on average) was featured by anoxic-euxinic conditions, high primary productivity, and low terrigenous input. The organic-moderate upper unit (TOC=1.12% on average) is characterized by shifting anoxic-suboxic conditions, decreasing primary productivity, and low terrigenous input. At first, the transgression from southeast to northwest brought about the anoxic bottom water condition in the basinal area. The organic matter accumulation in the shelf (Unit 1) was controlled by both suboxic bottom water and low primary productivity. Later, this situation was intensified by the release of reduced gas by hydrothermal activity, and increased oxygen consumption due to the phytoplankton blooms promoted by upwelling and hydrothermal activity. The anoxic even euxinic bottom water manipulated the organic matter accumulation of Unit 2. Last, as the hydrothermal and upwelling weakened, the organic matter accumulation of Unit 3 was dominated by the low primary productivity. The vertical variations in primary productivity and bottom water conditions reflect the different intensities of upwelling and hydrothermal activities in a semi-restricted environment linked with sea-level changes. In summary, the organic matter accumulation of the lower Cambrian Shuijingtuo Formation is ultimately controlled by the bottom water redox condition, where the primary productivity exerts indispensable influence.

Paleoenvironment and origin of heavy oil of the lower Cretaceous-Oligocene: a case study

Zengyuan Zhou[1], Jungang Lu[2*]
1. State Key Laboratory of Marine Geology, Tongji university, Shanghai, CHINA
2. School of Geoscience and Technology, Southwest Petroleum University, Chengdu, Sichun, CHINA
E-mail: 19361612002@qq.com

Keywords: Hetao Basin, geochemical characteristics, Biomarkers, thermal simulation of gold tube

Many heavy oil wells have been found in the Jilantai shallow depression in the Hetao Basin. The origin of heavy oil in the study area was analyzed comprehensively according to the physical properties and geochemical characteristics of heavy oil. Two sets of source rocks were detected in the Guyang and Linhe groups, in the Hetao Basin. During the Guyang Formation, the differences of sedimentary environments resulted in brackish water sedimentary environment in the south of the study area and freshwater reducing environment in the north of the study area. The high content of boron in the source rocks of Linhe Formation indicates its saltwater environment. By the method of oil source comparison, it is found that the Pr/Ph of the crude oil in Jilantai area and Linhe Formation is lower than 0.50, and the Pr/nC_{17} is between 0.7 and 3.5, which should come from the source rock of the first segment of the southern moderate lacustrine Guyang Formation. The C_{29} sterane 20S/(20S+20R) and C_{29} sterane ββ/(αα+ββ) parameters indicate that the low maturity of crude oil is the main cause of heavy oil formation. The research on the genesis and geochemical characteristics of Jilantai crude oil indicates that the northern and central depression of the Hetao Basin is a rich area of favorable resources.

The Origin and Genesis of the Permain Hydrocarbon in the Northeast of Dongdaohaizi Depression, Junggar Basin, China

Xueting Wu[1], Zengyuan Zhou[1], Shijia Chen[1*]
1. School of Earth Science and technology, Southwest Petroleum University, Chengdu, Sichuan, CHINA
E-mail: 740622523@qq.com

Keywords: Thermal evolution of source rocks, Biomarkers, Pingdiquan formation, Petroleum geochemistry, hydrocarbon evolution, oil-source correlation

Studying the geochemical characteristics of the source rock extract and the surrounding structural crude oil in Dongdaohaizi Depression, the differences in stable carbon isotope, biomarker compound, and molecular relative composition of the three sets of main source rock products in the research fields are summarized. The results reflect that the drying coefficient of natural gas in the study area is generally low, and the fractional distillation value of methane and ethane is 0.32, which is most likely due to the loss of oil and gas migration and the mixing of different types of natural gas. The carbon isotope value is relatively low, Pr/Ph is generally less than 3.0. The content of sterane C_{29} is the highest in the relative composition of steranes, followed by the range of sterane C_{28}, accounting for more than 80% of the total sterane content and the lower content of C_{27} sterane, accounting for only 5%−20% of the total content, which generally conforms to the characteristics of Permian Pingdiquan Formation source rock products. The carbon isotope value of crude oil ranges from −30.94‰ to −28.31‰, which is different from the characteristics of typical Permian source rocks (value is −34.49‰ to −28.21‰) while is related to typical Carboniferous products (value is −29.98‰ to −24.1‰), which indicates that small amounts of Carboniferous source rock products were mixed in different degrees in the Dinan fault area. According to the distribution law of oil and gas, the geochemical characteristics and hydrocarbon sources were considered the oil source in the east of Dongdaohaizi Depression, mainly from the source rocks of the Permian Pingdiquan Formation. The products of the peak period of hydrocarbon generation in the source rocks of the Pingdiquan Formation have not been transported to the high structural positions on a large scale to form reservoirs. It may still exist in the deep part of the Depression and the slope area. The low-amplitude structural and lithologic traps in the slope area of Dongdahaizi Depression are promising targets for finding the products of the peak period of hydrocarbon generation. It is of great significance to reveal the Permain hydrocarbon evolution in Junggar Basin and guide further research on the oil-source correlation of natural gas from paleo-strata.

Low-latitude sedimentary records response toof late Carboniferous glacial cycles

Wang Ye[1], Lu Jing[1*], Yang min fang[2], Bian Xiao[1], Fan min[1], Zheng ke xin[1], He zhen[1], Shao long yi[1], Hilton Jason[3]

E-mail: lujing@cumtb.edu.cn

Keywords: Carboniferous, North China Plate, sea-level fluctuation, zircon dating

The late Paleozoic ice Ages (LPIA) of the Carboniferous and Permian (~360-260 Ma) is the only documented icehouse-to-greenhouse transitions on earth, providing a deep temporal perspective on climate-glacier-environment coevolution and future climate change. In order to reveal the sedimentary response of LPIA in low latitude area. We investigate the sections material of Palougou and Shimenzhai in the middle of the North China Plate (NCP), the Benxi-Taiyuan Formation of Pennsylvanian has been studied in terms of chronostratigraphy and sedimentology. Three new radiometric dates from tuffaceous claystones provide a precision stratigraphic framework and constrain the succession to ~315 to 299 Ma. Results date the Benxi Formation to the late Bashkirian-late Moscovian stages of the Carboniferous, and the lower part of Taiyuan Formation ranging from the late Moscovian stage of the Carboniferous to the early Asselian stage of the Permian. Based on the analysis of the depositional environment of the two sections, the eight facies can be divided into three depositional systems: Delta plain, Delta front and Prodelta, and Offshore Marine., Sea level change during the Pennsylvanian is recovered based on the vertical superposition model, the relatively high sea level during the late Bashkirian-early Moscovian interglacial, the large sea level decline during the middle Moscovian, and the sea level rise during the late Moscovian-Gzhelian interglacial, the Asselian sea level decreasing. The sea level change curve of the NCP is highly coupled with the glacial-interglacial cycle of the high latitude Gondwana. In addition, the extensive development of ferrite nodules, limestone and volcanic deposits in the late Bashkirian, Kasimovian and Gzhelian periods in the North China Plate reflects the warm and hot paleoclimate during the interglacial period in the study area. The enhancement of coal accumulation in the early -middle Moscovian and early Asselian reflects the extensive development of coal forming plants due to shallow or even exposed water caused by sea level decline, and the enhancement of coal accumulation due to peat accumulation caused by the change of sedimentary environment caused by regressive. Our results also confirms that the fluctuation of ice sheets at high latitudes affects the sedimentary records at low latitudes through changes in sea level.

Carbon mobility and degassing at the contact between organic-rich rocks and magmatic intrusions

Andrea Schito[1*], David Muirhead[1], John Parnell[1]
1. Department of Geology and Geophysics, University of Aberdeen , Aberdeen , Aberdeenshire, UNITED KINGDOM
E-mail: andrea.schito@abdn.ac.uk

Keywords: dispersed organic matter, magmatic intrusions, Raman spectroscopy, carbon degassing

There is increasing interest in recent years in the interaction between organic-rich rocks and magmatic intrusions due to a growing focus on unexplored hydrocarbon plays in continental rift or back-arc settings (Alves et al.,2020), and because of the role of carbon degassing in past climate shifts (Svensen and Jamtveit, 2010).
Classical studies based on organic geochemistry and numerical thermal modelling have shown that enhanced maturation and carbon degassing approaching the magma are the main effects of these thermal anomalies in the shallow crust.
New Raman spectroscopy and petrographic data from two sites in the isle of Skye and one from the Midland Valley, all in Scotland, help to shed light on the behaviour of different carbon phases that are formed and migrate as a consequence of magmatic heating.
Starting from the general assumption that carbon content decreases towards an intrusion (Iyer et al., 2017), our data show that this is true only in some cases, while in other cases it remains constant or can also increase. The generation of liquid hydrocarbons and carbonaceous alteration products (i.e., bitumen) has been found to play a pivotal role on carbon mobility. This implies that the original organic matter composition as well as the petrophysical properties of the rocks strongly influence the products derived from carbon degassing.
This conclusion will help to progress towards more refined carbon degassing models to be used in paleoenvironmental studies.

E-mail: paolo.martizzi@gmail.com

Keywords: Euxinic, Middle-upper Miocene, Onnagawa Formation, Organic petrography, Rock-Eval 7S, Sulfur-rich kerogen

Middle-upper Miocene siliceous formations from the North Pacific Sea are important source rocks for oil and gas. These formations include large amounts of phytoplankton-derived kerogen, which can be enriched in organic sulfur (type IIS kerogen with atomic Sorg/C > 0.04). Due to the different petroleum generation kinetics of Type IIS and Type IS kerogens, these source rocks can generate oil at lower thermal maturities than sulfur-lean Type I and Type II.

In this study, twenty samples from the middle-upper Miocene Onnagawa Formation`s siliceous shales, Akita Prefecture, were collected from a 42 m-long core. Organic petrography and organic geochemical characterization through the new Rock-Eval 7S analyzer were used to define the organo-facies and determine sulfur species (i.e., organic vs. inorganic sulfur), hydrocarbon potential, and kerogen type (i.e., type II vs. type IIS kerogen, based on the Sulfur Index of Carvajal-Ortiz et al. (2021)). The data were coupled with Iron (Fe) from XRF and petrographic observation of framboidal pyrite to interpret the paleo-oxygenation conditions of the water column in the Akita Basin.

Based on microscopic observations, the organic matter consists mainly of telalginite with golden-yellow fluorescence. Fluorescent pollens, rare phytoclasts (vitrinite-like and inertinite), and solid bitumen were also recognized. Rock-Eval 7S analysis indicated moderate amounts of total organic and pyritic sulfur, and low amounts of sulfate sulfur. The majority of Sorg is associated with the reactive and thermally labile portion of the TOC (S2-Sulfur or S2-S). Additionally, TOC, S2, and HI values suggest a fair to very good potential for the generation of hydrocarbons and the prevalence of kerogen type IIS, Type II, and mixed II/III. SI values greater than 100 mg/g TOC (equivalent to Sorg/C > 0.04) suggest that most of the analyzed samples are enriched in reactive organic sulfur (Type IIS and Type IS).

Additionally, the TOC-TS-Fe relationship indicated that Onnagawa Formation was characterized by a high degree of pyritization. More than 95% of the pyrite is framboidal and small-sized (average diameter = 4.73–5.55 μm). Thus, our results suggest that a euxinic water column was established in the Akita Basin during deposition of the Onnagawa Formation. The euxinic conditions in the bottom waters favored the preservation of hydrogen-rich, oil-prone organic matter and the occurrence of sulfur-rich kerogen.

Constraints on the Organic Matter Accumulation of Lower Cambrian Niutitang Shales in the Middle Yangtze Region, South China

Xing Niu[1*]
1. School of Geosciences, Yangtze University, Wuhan, Hubei, CHINA
E-mail: xingncug@163.com

Keywords: Niutitang Formation, Hydrothermal activity, Redox conditions, Primary productivity, Sea level

The lower Cambrian Niutitang shales, as one of target intervals with the greatest potential for shale gas exploration and development, have attracted much attention. Nevertheless, the organic matter enrichment mechanisms of the lower Cambrian Niutitang shales need further study, especially in the hydrothermal active zone. In this study, samples from ND1 well in western Hubei Province, middle Yangtze region, South China, were investigated for the controlling factors of organic matter accumulation of Lower Cambrian Niutitang shales by detailed petrographic, mineralogic, and geochemical proxies. The results show that hydrothermal activity and sea level fluctuation controlled the redox conditions and paleoproductivity of seawater and ultimately controlled the organic matter accumulation of Niutitang formation. In the Niu-1 member, the intense hydrothermal events lead to a suboxic to anoxic environment, which is conducive to the organic matter preservation. However, low sea level strengthens the restriction of water mass and reduced nutrient upwelling into the shelf, leading to decreased marine primary productivity, which was ultimately responsible for depleted organic matter accumulation in the Niu-1 member. In the Niu-2 member, the anoxic-euxinic environment and high paleoproductivity, driven by continuous hydrothermal activity and rising sea level, were the main factors controlling the enrichment of organic matter. In the Niu-3 member, the dysoxic to oxic condition plus low primary productivity, caused by the disappearance of hydrothermal activities and sea-level fall, resulted in the unfavorable organic matter accumulation. The results of this paper enrich the model of organic matter enrichment in the lower Cambrian black shale in the middle Yangtze region.

Palynomorph Darkness Index: a quantitative and well-constrained optical method for defining the thermal maturity of organic matter

Nicoletta Buratti[1*], Spina Amalia[2], Ramon De Luca[3,1], Lorenzo Garuti[3,1], Andrea Sorci[2], Geoff Clayton[4]

E-mail: nicoletta.buratti@totalenergies.com

Keywords: Palynomorph Darkness Index, Reflectance Vitrinite, Thermal Maturity of Organic Matter

The assessment of thermal maturity of organic matter is a fundamental task in many types of geological investigation, including the reconstruction of burial history of stratigraphical successions in sedimentary basins, paleotemperature profiling and the detrmination of hydrocarbon generating potential. Palynomorph Darkness Index (PDI) is a quantitative method for evaluating thermal maturity in sedimentary basins, based on the image-analysis of palynomorphs. The growing use of this method has demonstrated the need for calibration with other maturity indicators such as reflectance vitrinite, Tmax, Raman spectroscopy, SCI (Spore Color Index) and TAI (Thermal Alteration Index). In this study, calibration of miospore PDI against Vitrinite Reflectance (VR) was achieved on a set of 82 borehole samples of known VR, ranging from 0.20 Ro% (immature stage) to 2.06 Ro% (overmature stage). We present a strong correlation of VR with PDI. This demonstrates that PDI is not only an excellent, independent, quick and cheap method for defining the thermal maturity of organic matter but that it also has potential for the elucidation of phenomena such as reworking and recycling that may not be recognizable by the use of VR or Tmax.

Sedimentary Environment Identification and Hydrocarbon Source Significance of Black Shale in Ordovician Meitan Formation, Banqiao section, Zunyi,Guizhou, China

Hai Tian Huang[1*]
1. School of Earth Science and Technology, Southwest Petroleum University, Chengdu, Sichuan Province, Sichuan, CHINA
E-mail: hth19990126@163.com

Keywords: black shale, source rocks, shallow water sedimentary environment, trace elements, Meitan Formation

The Middle Ordovician Meitan Formation in the Upper Yangtze area of South China is a set of thick mud shale deposits, in which black shale is well developed. However, the current understanding of its sedimentary environment is controversial. Taking the Banqiao section of Zunyi as an example, this paper focuses on the analysis of the relative water depth, sedimentary hydrodynamics and physical and chemical properties of paleo-seawater during the deposition of black shale and its symbiotic rocks through the comprehensive study of the sedimentary characteristics and geochemical characteristics. The results show that: (1) The black shale of Meitan Formation is characterized by its dark color and well-developed horizontal texture, and does not produce micropaleontology fossils. It is mainly produced in the symbiotic form of frequent interbeds with different thicknesses of bioclastic limestone or calcareous siltstone, indicating that the black shale of Meitan Formation should not be the sedimentary product of deep-water environment, but deposited in the low-energy shallow cement lagoon environment in the mixed platform. (2) Interbedded with black shale, the bioclastic limestone section mostly develops the tapering inverse graining structure, and iron oxides can be seen at the top, while the calcareous siltstone, interbedded with black shale, mostly develops interlaced bedding and biological drilling, showing shallow water deposition characteristics; (2) The bioclastic limestone interbedded with the black shale mainly developed the reverse sequence structure of the lower fine and the upper coarse, with iron oxides at the top, while calcareous siltstone with the black shale is mainly composed of wavy cross bedding and biological boreholes, showing the characteristics of shallow water deposition; (3) The average values of V/ (V+Ni), Th/U, V/Cr and Ni/Co of black shale are 0.71, 5.52, 1.07 and 2.04, respectively, indicating the hypooxidation-oxidation environment; Sr/Ba values range from 0.11 to 2.20, with an average value of 0.55, indicating fresh-brackish water environment; (4) Macroscopically, obvious erosion surface can be seen in some sections of bioclastic limestone, and karst development can be seen through microscopic observation. At the same time, the REE distribution pattern tends to be horizontal, and the ∑ REE value is higher and Y / Ho is lower, showing the characteristics of exposed karst. (5) TOC values of black shale ranged from 0.09% to 1.05%, with an average of 0.39%. TOC values of recovered black shale ranged from 0.28% to 3.16%, with an average of 1.25. The average Ro is 2.095, and the organic matter is mainly sapropelic. Comprehensive analysis of this study shows that: The black shale of Meitan Formation in Banqiao section of Zunyi is a set of effective hydrocarbon source rocks formed in an shallow water and oxygen-lean environment and high paleoproductivity is the main reason for the organic matter enrichment. The research results provides strong evidence for identifying the sedimentary environment and hydrocarbon generation potential of black rock series in Meitan formation in southern Sichuan, and also provides a new example for the identification of sedimentary environment conditions of shallow-water black shale.

Response of Paleofire to Paleoclimate since Late Pleistocene in the Dajiuhu

Qingquan Sun[1], Xiao Lin[1,2*], Xianyu Huang[2,3], Dan Chen[1]
1. School of Geography and Information Engineering, China University of GeosciencesWuhan, Wuhan, hubei, CHINA
2. Hubei Key Laboratory of Critical Zones Evolution, China University of GeosciencesWuhan, Wuhan, Hubei, CHINA
3. State Key Laboratory of Biogeology and Environmental Geology, China University of GeosciencesWuhan, Wuhan, Hubei, CHINA
E-mail: linxiao@cug.edu.cn

Keywords: Dajiuhu,monsoon,Paleofire,charcoal

The paleoclimate changes of Dajiuhu from the last glacial period has been reconstructed in previous studies. However, the charcoal and history of wildfires in this area have not been revealed. In this study, charcoal and TOC in the 300cm drilling core of 20ZK-5-2 has been used to reconstruct the paleofire events and clarity the response mechanism of fire to climate. The results of charcoal abundance show that the area concentration was 0.91~195.77mm2/g, with an average value of 17.27±15.32mm2/g, and the average TOC content was 27 %. The maximum value of charcoal concentration appeared at the depth of 25~40 cm (0.5~1kaB.P.), reflecting the obvious drought event in this period. In addition, the peak of charcoal also appeared at 50~65 cm and 104~120 cm (around 4kaB.P.), and the average area concentrations were 24.69 mm2/g and 17.21 mm2/g, respectively.

(1) From Late Pleistocene to Holocene, the charcoal and TOC was low with weak fluctuation, indicating that the climate is humid and cold. It is in good agreement with the cold and wet characteristics of the last glacial period.

(2) In the early Holocene, with the charcoal and TOC increasing gradually, the climate began warming and drying, but the range is small. it generally inherited the characteristics of the late glacial climate, cold and humid; meanwhile, the charcoal reflected the cooling events about 8.2ka B.P., with a peak of 26.31 mm2/g, indicating drought events.

(3) In the Middle Holocene, fires increased and indicated that the current climate warming dry; thereinto, the charcoal appeared high value at 4ka B. P. to point more prominent drought events. Huang et al used BNA15 to reconstruct the paleotemperature of Dajiuhu in 2013 and the paleoclimate reconstructed by Hu et al to δ18O of Heshang Cave in 2008 show that this stage is a process of gradual weakening of monsoon and relatively less precipitation. In addition, the mid-late Holocene monsoon recession around 4ka B.P. is characterized by a rapid shift from warm and humid climate to cool and dry climate.

(4) In the Late Holocene, Fires increased significantly and began to appear larger fluctuations, indicating that the current climate warming dry; the sharp increase in charcoal may derive from the use of fire in this period of human activity. But the frequency of fire decreases since 0.5ka B. P, this record is consistent with the TOC and other indicators of other sedimentary columns in the Dajiuhu, indicating that the climate in the Dajiuhu region has gradually turned to cold and humid and the reduction in slash-and-burn behavior.

The climate and environmental evolution information recorded by the various indicators of the Dajiuhu Lake is consistent with the charcoal record, which is a good response to the climate change since the Holocene in the Dajiuhu. Compared with the similar sedimentary profiles in the East Asian monsoon region, with the monsoon change model of “dry after the weakening monsoon in the early-middle Holocene”, the dry-wet change model maybe can be constructed using charcoal.

Petrology and geochemistry features of the Middle Triassic Anisian shale in Sichuan Basin, South China: Implications for the climatic and environmental condition change.

Yunbo Ruan[1], Huaguo Wen[1*], Fei Huo[1], Tao Luo[1], Huiwen Huang[1]
1. Institute of sedimentary geology, Chengdu University Of Technology, Chengdu, Sichuan, CHINA
E-mail: wenhuaguo08@cdut.edu.cn

Keywords: Middle Triassic, Shale, Chemical weathering, Anoxia

The Middle Triassic was an important stage during which the global environment gradually stabilized following the severe environmental disturbance of the Late Permian to Early Triassic. After entering the Anisian stage, the recovery rate of ocean ecosystems suddenly accelerated and the cracking of the Pangea continent peaked and responded in the Leikoupo Formation, located in the Sichuan Basin in South China. Shallow-water carbonate rocks were deposited in the Leikoupo Formation but there was also the abrupt deposition of a thick shale interval in the Lei^3 member. A comprehensive analysis of the elemental, geochemical, and stable isotope ($\delta^{13}C_{org}$ and $\delta^{15}N_{org}$) characteristics of the black shales was performed.

The chemical weathering intensity was high during the Anisian, as indicated by the weathering proxies (e.g., CIA) of shale. The CO_2 concentration, $\delta^{13}C_{org}$ and $\delta^{15}N_{org}$ excursions indicated the promotion of paleoproductivity by the high degree of weathering. This was consistent with the rapid recovery of the ecosystem in the Anisian period after the P-T mass extinction.

The CO_2 concentration in seawater gradually decreased, the ocean acidification weakened, the $CaCO_3$ production rate increased, and the corresponding lithofacies changed. Furthermore, anoxic bottom water conditions were confirmed by the enrichment of U, V, Mo, and other elements. The sedimentation of the shale intervals and the enhanced weathering intensity were likely linked to the regional tectonic movements induced by the continental cracking of Pangea.

Organic material in the geological cycle: Deciphering the Earth's past using an intergrated approach

Tim A Moore[1*]
1. School of Earth and Atmospheric Sciences, Queensland University of Technology, Brisbane, Queensland, AUSTRALIA
E-mail: tmoore@ciphercoal.com

Keywords: organic material, palynology, fossil charcoal, palaeomire

Terrestrially derived organic material in the Earth's crust is common, but typically comprises only a small percentage in any sedimentary sequence. Nonetheless, the amount of information that can be gleaned from examination of these particles is huge and often underrated. Whereas most sedimentologists may concentrate on the inorganic sediment facies and their structure and composition, organics are mostly lumped into a general category of 'terrestrial'. This is a mistake, especially in sequences where other data can be hard to come by or interpret. Fundamentally, organics from plants use the sun's energy to drive photosynthesis, which in turn creates large molecular structures made up of C, H, O, and N. When these organics become buried they preserve clues to the past in many ways. For example, we can understand what types of vegetation grew in palaeomires and adjacent ecological niches by studying the palynology, biogeochemistry or identifying the preserved tissues. Palaeoclimate, fire frequency and even atmospheric oxygen level can be estimated through the study of fossil charcoal. Examination of trends in stable carbon isotopes can also help to unlock both regional and global events that were impacting on the organics during deep time. The organics we find in sediment, either in dispersed or concentrated (i.e. coal) forms are vital puzzle pieces that help to give high resolution reconstruction of the Earth's past. So, remember, the truth is out there, and it's probably in the organics!

E-mail: chshwang@cugb.edu.cn

Keywords: High resolution mass spectrometry, Polar molecular compounds, Molecular structure evolution, Organic matter maturity, Source rock evaluation

The maturity of sedimentary organic matter is one of the key parameters in oil and gas evaluation. The accuracy of its evaluation results is particularly important for high-quality exploration and development of oil and gas resources. However, the existing maturity evaluation indexes are mostly limited by the measurement principle and can not fully meet the needs of current oil and gas geochemical evaluation. Fourier transform ion cyclotron resonance mass spectrometry (FT-ICR MS), as an ultra-high resolution mass spectrometry analysis technology, has gradually been paid attention to and widely used in the field of energy geology. The composition and content of polar molecular compounds of sedimentary organic matter can be analyzed with high accuracy by FT-ICR MS. The components and contents of polar molecular compounds of organic matter deposited in different basins and strata show similar changes in the process of thermal evolution of organic matter. The carbon number and DBE of each target compound generally decrease with the increase of maturity, and the types of compounds also decrease in varying degrees with the increase of maturity. Count the signal abundances SA1 and SA2 (signal abundances) corresponding to the defined interval, and finally calculate MIFT (Maturity index of FT-ICR MS) according to the formula MIFT = (SA1) / (SA2), so as to realize continuous quantitative maturity evaluation. In order to fully verify the feasibility and universality of MIFT, representative typical source rock samples are selected from different strata in different basins around the world. The MIFT of the above typical samples is fitted and compared with the commonly used maturity indexes vitrinite reflectance (Ro) and pyrolysis peak temperature (Tmax). In general, the MIFT analysis method is based on the general law of the structural evolution characteristics of organic matter, follows the logic of "element-molecule-compound" analogy, quantifies the structural characteristics of polar molecular compounds in the thermal evolution process of organic matter, and the evaluation principle returns to the essence of the molecular structure evolution of organic matter compounds in the thermal evolution process, which is expected to become a new and practical maturity evaluation index.

Genetic mechanism of calcite cementation in continental sandstone and its petroleum geological significance

Meng Xiao[1*]

1. Geological Institute, PetroChina Research Institute of Petroleum Exploration and Development, Beijing, CHINA
E-mail: xiaom21@petrochina.com.cn

Keywords: Calcite cementation, genetic mechanism, calcareous interlayer, distribution prediction, Tahe Oilfield

Calcareous interlayer is widely developed in deep sandstone reservoir and is the key factor affecting the distribution of remaining oil. At present, the research on the genetic mechanism of calcite cementation is relatively weak, which restricts the prediction of the distribution of calcareous interlayer and increases the uncertainty of efficient oil and gas exploration and development. Taking the deep clastic rock reservoir of Lower Triassic oil formation in Tahe oilfield as the research object, combined with thin section analysis, XRD whole rock and clay test, cathodoluminescence, electron microprobe, element analysis and carbon and oxygen stable isotope analysis and testing, this project carries out macro and micro fine characterization of authigenic calcite cementation, and explores the distribution law of calcareous interlayer. The study shows that the calcareous interlayer rock type is mainly fine sandstone, and the cement is mainly calcite cement, with a content of 0 ~ 16.2%There is mainly two stages of calcite, and the pore water forming calcite is mainly fresh water, and a small part is a slight mixture of salt water and fresh water. The cementation content of early calcite is low (< 2%), mainly adherent particles are developed, bright yellow under cathodoluminescence, the values of iron and manganese are significantly higher than those of late calcite, the formation temperature distribution range is 60 ~ 75^{O}C, and the formation mechanism is microbial fermentation. The cementation content of late calcite is high, which is mainly filled with intergranular pores and cemented in the form of large particle continuous crystal. A few are located in the intergranular pores of feldspar or rock debris dissolution. The cathode luminescence is orange red, and the formation temperature distribution range is 90-122.2 ℃. The late calcite mainly comes from the decarboxylation of organic matter. The carbonate cementation zone occurs frequently and is easy to identify. The thickness of calcareous interlayer on the core can reach 4.6m. Calcareous septum is mainly distributed in the middle and lower part of positive rhythm and the top of anti rhythm. Calcareous interlayer is distributed in the delta plain and delta front. On the delta plain subfacies, the distribution range of calcareous interlayer is small and locally distributed in river sand bars. The calcareous interlayer of delta front subfacies is mainly distributed in distributary channels and river mouth bars for many periods.

E-mail: wujiaw5@mail.sysu.edu.cn

Keywords: Sr isotopes, Barite, Sapropel, Mediterranean Sea, Provenance, Marine sediments

In marine sediments, the Sr abundance and isotope composition (87Sr/86Sr) of the terrigenous detrital component are widely used to track changes in provenance and related transport and weathering processes. Accurately separating detrital- from other sedimentary Sr-phases is a prerequisite for such studies. Conventionally, it is assumed that Sr in the carbonate-free residue corresponds to detrital Sr alone. However, the decarbonated residue may contain barite with a significant amount of Sr, which could substantially affect the derived detrital Sr signal. The Mediterranean Sea is an ideal area to examine this hitherto unreported phenomenon, because 1) detailed provenance studies have been done using Sr and 87Sr/86Sr of the residual fraction, and 2) enhanced levels of barite repeatedly occurred in association with distinct, organic-rich sapropel sediments.

Here, we use the most-recent sapropel S1 interval to evaluate the effect of barite-bound Sr in the residual fraction after decarbonation. A total of 130 samples were taken from 10 cores in the eastern Mediterranean Sea (EMS) and from 1 representative core in the western Mediterranean Sea (WMS). This selection represents a geographic and bathymetric coverage of the EMS and permits a basin-wide comparison between the EMS and WMS. After decarbonation using 1 M HCl solution, the residual sediments were subject to NH4Cl extraction (2 M, pH 7), known to selectively dissolve barite.

Our results demonstrate the presence of Sr-bearing barite after traditional carbonate removal and its effect on the derived “detrital” Sr signature. This barite-Sr effect is significant for samples with barite-Ba >400 μg/g in bulk sediment. The impact of barite is prominent if accompanied by a detrital provenance background of high 87Sr/86Sr (>0.713) or low Sr/Al (<1.0 mg/g). In such cases, removal of remaining barite is required to obtain an adequate signal of detrital Sr. We recommend an improved procedure for detrital Sr separation in marine sediments, with an additional NH4Cl leaching step to eliminate any remaining barite after decarbonation. This approach is particularly important for areas/eras of high biological productivity, where sediments are often characterized by abundant barite content.

The origin, genesis and distribution of carbonate cements in Paleogene Shahejie Formation of Bohai Oilfield

Zongbin Liu[1*], Ya Wang[1]
1. Bohai Oilfield Research Institute, CNOOC China Limited, Tianjin Branch, Tianjin, CHINA
E-mail: liuzb@cnooc.com.cn

Keywords: carbonate cements, carbon and oxygen isotopes analysis, paleogeographic environment, Bohai Oilfield

Bohai Oilfield is the largest crude oil producer in China, and the Paleogene Shahejie Formation is one of the important exploration and development targets. The tight layers generated by carbonate cementation are widely developed in Shahejie Formation, which strongly influences reservoir performance by controlling fluid flow and recovery factors. The elucidation of the origin and distribution of carbonate cements is of great importance for the effective development of Bohai Oilfield.

Based on the comprehensive utilization of core scanning under white light and fluorescence, thin section analysis, cathodoluminescence, carbon and oxygen isotopes analysis, the carbonate cements are divided into three types, namely, pore-filling sparry calcite cements, basal calcite cements, bio-rich micrite calcite and dolomite cements.

Pore-filling sparry calcite cements account for the highest proportion in tight layers. The cathodoluminescence showed bright red, indicating low iron and magnesium content. The $\delta_{13}C_{PDB}$(‰) is between -6~0, which reflects that it is formed by precipitation from carbonate supersaturated alkaline fresh water, and its material source is related to the dissolution of feldspar and carbonate bioclasts. The pore-filling sparry calcite was cemented later than the oil and gas charging at Late Paleogene, so its distribution is significantly controlled by the fluid properties. The content of cements in the water layers where the pore fluid is alkaline is significantly higher than that in the oil layers where the pore fluid is acidic.

The basal calcite cements clearly show an eogenetic origin, formed before compaction. The cements in deltaic sandstones occurs as scattered and strata bound concretions at the flooding surfaces at the top of delta-front deposits. The cements are often associated with carbonate intraclasts, and their cathodoluminescence show dark red, indicating the characteristics of high iron and magnesium content. The $\delta_{13}C_{PDB}$(‰) is between 0 and 2, and the paleosalinity is basically greater than 122, reflecting that the eogenetic carbonate cementation is closely related to marine fluids. The carbon and calcium ions can be transferred directly from the sea water by diffusion subsequent to the establishment of chemical potential gradients with low ionic concentrations in pore waters due to calcite precipitation.

The bio-rich micrite calcite and dolomite cements constitutes fluid-flow barriers along layers rich in intraclasts or carbonate bioclasts. The original distribution of the carbonate bioclasts, which they consider to be the main cement source, and the number of nucleation sites are the primary controls on the spatial distribution and geometry of calcite and dolomite cement.

During the Middle-Late Paleogene, the lake basin in the Bohai Sea largely shrank, forming micro-geomorphic units such as limited shallow basins and underwater highlands. The shallow water, warm climate, and the strong evaporation had provided favorable paleogeographic conditions for the formation of carbonate cements.

Morphological characteristics of organic-rich shale pyrite and its significance to the restoration of sedimentary environment: an example from the first member of Qingshankou Formation, Gulong Sag, Songliao Basin

YAN WU[1], Min Wang[1*], Yu Yan[1]

1. School of Geosciences, china university of petroleumeast china, Qingdao, Shandong Province, CHINA

E-mail: wangm@upc.edu.cn

Keywords: Organic-rich shale, Pyrite, Morphological characteristics, Sedimentary environment, the first member of Qingshankou Formation

Pyrite, as an important constituent mineral in organic-rich shale, can be used to recover the depositional environment in the light of its morphology, the size distribution of pyrite framboids and sulfur isotope indicatively. In this study, we used the organic-rich shale in the first member of Qingshankou Formation, Gulong Sag, Songliao Basin(K_2qn^1) as the object, observed the morphology of pyrite by scanning electron microscopy and determined the sulfur isotope value of pyrite by the method of "chromium reduction", in order to restore the sedimentary environment of the target section. The study shows:

(1) Four types of euhedral pyrites, pyrite framboidals, fine-grained pyrite aggregates and polyframboids are developed in the K_2qn^1, and pyrites are often associated with organic matter (OM) and clay minerals, among which the OM is often filled in the intergranular pores of pyrite framboids, while the morphology of euhedral pyrites associated with clay minerals is often controlled by interlayer pores of clay minerals.

(2) In terms of pyrite morphology, pyrite framboids, some of which has the characteristics of cementation and overgrowth, are less developed while euhedral pyrite is more developed, and the size distribution of pyrite varies widely (ranging from 100nm to 10μm). Therefore, it is suggested that the pyrite in the K_2qn^1 has both bacterial sulfate reduction (BSR) and thermochemical sulfate reduction (TSR) genesis, and due to the increase of temperature at the later burial depth, the pyrite framboids of BSR is most likely to be transformed to euhedral pyrite by TSR.

(3) From the pyrite sulfur isotope, the pyrite sulfur isotope value ($\delta^{34}S_{py}$) in the area ranges from 13.3‰-23.3‰, with a mean value of 18.2‰, which is quite close to the sulfur isotope value of marine sulfate (18.55‰) during the deposition of K_2qn^1. The low isotopic fractionation value indicates that the marine incursion occurred during the deposition of K_2qn^1, the pyrite of BSR was formed in a closed system with limited sulfate supply, and the depositional environment was a reduction environment at that time.

Field based relationship between cellular sulfate reduction rate and ∂34S of chromium reducible sulfur in the shallow southern Baltic Sea

Mary Zeller[1*], Jens Kallmeyer[2], Judith Piontek[3], Patricia Roeser[1], Klaus Jürgens[3], Michael E. Böttcher[1,4,5]

5. Maritime Systems, University of Rostock, Rostock, Mecklenburg Vorpommern, GERMANY

E-mail: mary.zeller@io-warnemuende.de

Keywords: Sulfur isotopes, cellular sulfate reduction rates, shallow coastal sea, iron-sulfur authigenesis

The ∂^{34}S of chromium reducible sulfur (CRS; essentially pyrite) reflects the stable isotope composition of reacting dissolved sulfide. The ∂^{34}S of CRS is thereby shaped by factors like: cell-specific sulfate reduction rate, microbial community structure, organic matter content, temperature, availability of reactive iron, availability of sulfate, and sulfide oxidation. The latter may be impacted by sediment mixing due to the activity of organisms and anthropogenic disturbances. Experimental studies suggest an inverse relationship between cell-specific sulfate reduction rate and the ∂^{34}S signature of sulfide, but this specific relationship is only seldom investigated in field studies, and may vary with further site-specific conditions as organic matter quality and sulfate-reducing genera and fitness. Here, we report on results obtained as part of the project MGF-Ostsee, focusing on surface sediments of the shallow coastal brackish Baltic Sea in the Fehmarn Belt region. Sediment cores were collected at six adjacent sites (within a 5 km area), which have similar modern sedimentation histories. We assessed the porewater biogeochemistry, the sediment geochemical composition (TOC, TN, reactive Iron, ∂^{34}S-AVS, and ∂^{34}S-CRS), and depth resolved gross rates of sulfate reduction (SRR) via ^{35}S radiotracer incubations. Per-cell SRR were estimated using bulk sediment gross SRR, total cell counts (by microscopy) as well as estimates of the relative abundances of sulfate reducing microbes (amplicon sequences with taxonomic assignments). The gross rates of microbial sulfate reduction were highest in the top 5-7 cm below sea floor. We find that the ∂^{34}S of CRS was heaviest in the top 5-7 cm (between -34 and -37 ‰-VCDT), followed by a rapid decrease in ∂^{34}S signature with depth (over 1-2 cm) to minima of -39 to -42 ‰. We relate these changes in ∂^{34}S signature of CRS to changes in cellular SRR superimposed by sulfide oxidation in the top sediments. Sediments under impact of ground-net fishing activity were characterized by disturbances of the vertical isotope composition in an additional two sites.

Keywords: Carbon, Sulfur, Biogeochemistry

The research project MGF-Ostsee deals with the consequences of the exclusion of mobile bottom-contact fishing in the southern Baltic Sea, specifically to assess its effects on the biogeochemistry of surface sediments and across the benthic-pelagic food chain. In Summer 2021, an in-situ monitoring experiment was conducted to investigate the short-term impacts of bottom trawling. Herein, we present results on how this anthropogenic intervention affects the base of ecosystems, i.e., biogeochemical processes and associated elemental cycling, as well as the resulting changes in geochemical mineral tracers. We analyzed porewater and sediment, as well as the water column for major, minor and trace elements, and the stable isotope composition (C, S, O) of dissolved and solid carbon and sulfur species. The measurements of porewater gradients are combined with lander-based oxygen-consumption and radiotracer-based microbial sulfate reduction rates to elucidate how the potential disturbances affect element (C, P, Mn, Fe, S) and mineral (re)distribution on a long-term scale.
The controlled trawling experiment generated a re-suspension plume of up to 4 NTU and that reached up to 2 m above the sea floor. In the area affected by trawling, short cores were taken with a MUC prior and one to two hours after the experiment, and on the following day. In addition, sediment cores were recovered by divers from furrows and mounds of recent trawl marks. First results suggest that in the trawled area, the coupled Fe-Mn-P cycle reacts most sensitively, as expressed by altered porewater gradients. In the trawl marks, pore waters are affected differently whether sediments are removed, as in trawl furrows (erosion), or added/topped, as in trawl mounds (burial). In general, the tentative results point towards a loss of dissolved Mn in the trawling area and in the furrows, whereas in the mounds, Mn/(Fe+P) ratios are enhanced in the top few cm, a result similarly portrayed for instance in particle bound chlorophyll pigments.

Sulfate-methane transition zone movements in ancient marine sediments recorded by diagenetic barite-calcite-pyrite nodules in the Silurian Longmaxi Formation of the Yangtze Block, South China

Bowen Zan[1,2], Chuanlong Mou[2*], Jiaxin Yan[1]
1. School of Earth Sciences, China University of Geosciences, Wuhan, Wuhan, Hubei, CHINA
2. Key Laboratory of Sedimentary Basin and Oil and Gas Resources, Chengdu Institute of Geology and Mineral Resources, Chengdu, Sichuan, CHINA
E-mail: cdchuanlongmou@163.com

Keywords: Anaerobic oxidation of methane, Diagenesis, Sulfur and carbon isotopes, Early Silurian

The sulfate-methane transition zone (SMTZ), an important biogeochemical boundary, is ubiquitous in marine sediments, ranging in depth from a few centimeters to hundreds of meters. Organoclastic sulfate reduction (OSR), sulfate-driven anaerobic oxidation of methane (SD-AOM), fermentation, and methanogenesis, the dominant diagenetic processes near the SMTZ, play key roles in marine sulfur and carbon cycling (Jørgensen et al., 2019). However, under non-steady-state conditions that common to most sedimentary successions, frequent and large fluctuations in the depth of the SMTZ complicate or erase corresponding sedimentary and geochemical records, thereby making it difficult to uniquely recognize paleo-SMTZs in ancient rocks (Borowski et al., 2013). Moreover, the history of SMTZ movement in the geologic record has been rarely studied because of equivocal evidence (Lash, 2015). Toward an improved understanding of the dynamism of paleo-SMTZs, we report on a newly found interval of an authigenic barite-calcite-pyrite assemblages hosted by the Silurian Longmaxi Formation of west Hubei, South China. The inferred paleo-SMTZ comprises nodules made up of barite ($BaSO_4$), calcium carbonate ($CaCO_3$) and pyrite (FeS_2), and pyritic laminae. Strong ^{34}S enrichment of barite (50 to 62.1‰ VCDT) and modestly ^{13}C-depleted calcite (− 11.4‰ to − 5.3 VPDB) of the nodules associated with positive $\delta^{34}S$ values of pyritic laminae (4 to 6.2‰ VCDT) suggest precipitation of these minerals sourced by mixed carbon and sulfur sources close to and/or within the paleo-SMTZ. Nodules from center to edge display mineral zonation that may reflect the effects of depth fluctuations of the paleo-SMTZ. Initial (stage 1) barite mineralization in nodule centers appears to have occurred within the base of the sulfate reduction zone (SRZ). By the time if stage 2 mineralization, the stratigraphic locus of precipitation had migrated closer to highly alkaline SMTZ resulting in barite dissolution and calcium carbonate precipitation. Higher proportions of calcium carbonate exhibiting some enrichment of ^{12}C associated with cubic pyrite crystals in nodule centers are consistent with the occurrence of SD-AOM within the SMTZ. Stage 3 acicular barite mineralization along nodule edges likely took place near at the base of SRZ immediately above the SMTZ, whereas the replacement of barite by calcite during stage 4 mineralization occurred again within the SMTZ. Combined with published data (Zan et al., 2020), vertical movement of paleo-SMTZs suggested by the occurrences of barite-calcite-pyrite assemblages in the Longmaxi Formation across Yangtze Block, are likely the consequence of the complex interplay of varying sedimentation rate, organic matter quality, methane flux, and perhaps seawater sulfate concentration.

In the Black Sea, sediment cores covering the last brackish-limnic transition were recovered and investigated for anaerobic biogeochemical processes controlling sulfur, carbon, and metal cycling. The development of a sulfate-methane transition zone (SMTZ) is nowadays found below the brackish zone in the limnic part of the sediments that limits the upward migration of biogenic methane into surface sediments and the water column. The position of the SMTZ may have changed in the past due to dynamic fluxes of dissolved species in the pore water. Besides dissolved sulfate, metal-bearing minerals have been shown to serve as potential reactants, also converting CH4 into dissolved inorganic carbon (DIC). The pore water and sediment stable isotope (C, S, O) and geochemical composition were investigated, as well as in-situ microbial rates of sulfate reduction and total anaerobic oxidation of CH4 (AOM) obtained from sediment incubations for the identification of a potential contribution of manganese-bearing minerals to AOM in the limnic part of the sediments (Mn-AOM). In the limnic Black Sea sediments Mn-AOM is causes an upward flux of dissolved Mn whereas intense SO4-AOM located in shallower sediments leads to an increase in pH and a maximum in DIC concentrations in the SMTZ. The resulting change in saturation states leads to the precipitation of mixed MnCa-carbonate solid-solutions (‘rhodochrozitization front’) and the development of a zone enriched in excess sedimentary Mn(II). We further argue that these authigenic fronts may survive changes in pore water composition and are stable in the anoxic sedimentary record, marking the position of paleo-SMTZs. The persisting formation of this geochemical marker is in contrast to the temporal development of a sulfidization front of metastable mackinawite, that is fromed by the reaction of downard migrating sulfide with upward diffusing Fe(II), originating from SO4-AOM and Fe-AOM, respectively.

Mineral reaction kinetics: Very likely a prerequisite to correctly read the geochemical fingerprint of sediments

Andreas Luttge[1*]
1. Fachbereich 5, Bremen University, Bremen, GERMANY
E-mail: aluttge@marum.de

Keywords: mineral growth, mineral dissolution, kinetics, upscaling

How important are the results generated at the molecular scale and how do we connect these results with meso- and large scale processes? This is certainly a complex problem that may require complex answers. In other words how do we manage the upscaling task and make frontier research results accessible for the multitude of applications that our daily work demands?

Within a relative short time period of just a couple of decades the joined effort of field and experimental research, sophisticated analytical methods and (quantum) computational models has generated vast and important progress in our fundamental understanding of mineral reactions and its kinetics. Importantly, this progress was generated largely by studying so-called low temperature minerals – or better the formation and dissolution/weathering of minerals at low to moderate temperatures. Here, we will briefly review some of the highlights of these sometimes even exciting results. Results that are highly appreciated in the light of the ever increasing number of applications that demand a better quantitative understanding of mineral reactions. Their often critical role in large scale processes such as the prediction of long-term behavior of geo-reservoir rocks, ocean acidification, hazardous (nuclear) waste deposits, and – maybe most importantly – their role in global climate change demand our full attention and creativity.

Beside our challenge of making the cutting-edge achievements of mineralogical and (geo)chemical research accessible to a broad audience in sedimentology, geochemistry, and geobiology the ability to upscale our findings at the microscopic level to macroscopic system sizes should be a central task (e.g., Luttge et al., 2019). Often, the results at different scales are already available but the interfaces to connect them are still missing. To highlight just one example, we recognize that crystal dissolution, weathering and growth rates are not correctly described by a single rate constant but by a multitude of rates, a rate spectrum. However, this insight seems difficult to implement in reactive-transport models and is often met with significant skepticism. Consequently, we may have to focus on new strategies that will provide a pathway of up-scaling our results, i.e., how do we utilize the fast increasing results at the molecular scale with the meso- and large(r) scale problems, both in length scale as well as in time.

Disentangling the biological role in authigenic pyrite formation

Daniel Ariztegui[1*]
1. Earth sciences, University of Geneva, Geneva, SWITZERLAND
E-mail: daniel.ariztegui@unige.ch

Keywords: authigenic, pyrite, framboidal, geochemistry

The association of minerals and life has appeared very early in Earth History. Hence, the presence of certain authigenic minerals, even very small ones, can be considered as microarchives of former life. But determining the biological role in the development of these minerals is not always an easy task. This is the case for pyrite that often display a framboidal texture commonly interpreted as indicative of a biogenic influence. But determining factors controlling the development of the framboidal texture may be either external influence, due to biologic activity, or an internal consequence of pyrite crystallization (Sweeney and Kaplan, 1973 and references herein). Recent technical developments are now providing critical information to disentangle the role of the different players in their formation.

Modern lakes and their sediments offer the opportunity to study the relationship between their living and non-living compartments and, thus, the formation of authigenic minerals and their potential significance as environmental proxies. Greigite, a highly magnetic iron sulfide and often considered as a precursor of pyrite, has been clearly identified in Lake St. Moritz, Switzerland. The prevailing environmental conditions during the occurrence of this mineral have been recognized through existing historical data (Ariztegui and Dobson, 1996). Detailed SEM investigations along with XRD and magnetic data have shown a clear sequence from spherical and irregular crystal shapes often related to bacterial activity, further evolving to perfectly framboidal forms. At the time, however, the technical ability to precisely determine this bacterial role was missing.
Recent investigations by Marin-Carbonne et al. (2022) are providing critical data concerning the relationships between microbial metabolic activities and their signatures in pyrite forming in modern microbialites. The used geochemical approach is not only uncovering the biological role but also showing the importance of alternating redox conditions in the formation of these authigenic minerals. Thus, it is anticipated that micropyrite crystals in microbialites can be used as a mineral signature for reconstructing past Earth surface and microbial environments at different geographical and temporal scales

E-mail: michael.boettcher@io-warnemuende.de

Keywords: peatland, flooding, iron sulfides, sulfur isotopes, textures

Land-ocean interactions in the coastal zone are of particular interest regarding the exchange of substances, like carbon, sulfur, nitrogen, phosphorus, metals, and water. Rising sea levels enhance the pressure of salty solutions on previously fresh water ecosystems. We present new results on the isotope biogeochemistry of a modern rewetted wetland, at the southern Baltic Sea coast, the Huetelmoor, that is under impact by event-type flooding by brackish seawater. Sediment cores on transects within the wetland were investigated for the chemical composition of the pore water and the soil. The soil samples were analyzed for elemental composition, mineral micro-textures, and the stable isotope composition of different fractions to understand the water and biogeochemical carbon-sulfur-metal cycles and the geochemical signatures in authigenic mineral phases.

Flooding events with brackish water enhance the availability of sulfate as an electron acceptor for microbial carbon transformations. This additional sulfur in the peatland impacts the remineralization capacity of organic substrates, and creates space for mineral authigenesis with distinct textures. The characterization yields isotope signals that are indicative for ecosystem biogeochemistry and allow for a transfer of proxy information to other modern and past coastal peatlands.

The cored peat sequence was found to reflect the activity of sulfate-reducing bacteria and the associated formation of pyrite with different textures, as well as isotope evidence for a sulfurization of organic matter. Sedimentary sulfur fractions and their stable isotope signatures are controlled by the availability of dissolved organic matter and/or methane, reactive iron, and in particular by the availability of dissolved sulfate. Therefore, their formation varies with the relative position from the coast line further depending on surface topography and peat characteristics. Mechanistic investigations consider the role of dissolved organic sulfur upon changing sulfur substrate availability.

Sedimentary geochemical characteristics of deep and shallow lacustrine source rocks: a case study of Zhusan depression, Pearl River Mouth Basin, China

Xiaoyan Fu[1], Shijia Chen[1*]
1. School of Earth Science and Technology, Southwest Petroleum University, Chengdu, Sichuan, CHINA
E-mail: csj199131010015@163.com

Keywords: sedimentary geochemistry, source rock, deep lake, shallow lake, Zhusan depression

Zhusan depression is a key exploration area in Pearl River Mouth Basin. Source rocks are distributed in Wenchang-A and Wenchang-B sags. Affected by tectonic movement, shallow lacustrine source rocks are developed in Wenchang-A sag, and a set of middle-deep lacustrine source rocks are developed in Wenchang-B sag. To explore the development environment and sedimentary geochemical characteristics of source rocks in different sedimentary facies in different sags, 355 samples from 6 wells were collected to carry out the main trace element experiment, 120 samples were used to rock pyrolysis, 50 samples were subjected to kerogen maceral and vitrinite reflectance experiment, and 30 samples were subjected to saturated hydrocarbon chromatography-mass spectrometry analysis. The result shows: i) The organic matter types of middle-deep lacustrine source rocks are mainly type I and type II_1, and the maturity is between 0.6 % and 0.9 %. The organic matter abundance is good-excellent. The organic matter types of shallow lacustrine source rocks are mainly II_2 and III, and the maturity is between 0.8 % and 1.2 %. The abundance of organic matter is widely distributed, with poor, good, good-excellent. Therefore, it can be considered that the medium-deep lacustrine source rocks mainly generate crude oil, and the hydrocarbon generation potential is better than that of shallow lacustrine source rocks. The shallow lacustrine source rocks mainly generate natural gas. ii) Sr/Cu reflects the climate change during organic matter deposition: the climate of middle-deep lacustrine source rocks is warm and humid, and the hot and dry climate is found at the bottom. The climate of shallow lacustrine source rocks was more humid than that of middle-deep lacustrine source rocks. Through the redox indicators of Cu/Zn, gammacerane/$C_{30}H$, Pr/Ph, rearranged sterane, etc., it was found that the middle-deep lake phase was dominated by the reduction environment, with high Cu/Zn value at the bottom, which was the oxidation environment, and the shallow lake phase was the transitional environment. The middle-deep and shallow lake facies source rocks are developed fresh water environment, and the water depths in different regions have certain changes. iii) Through the correlation analysis between each index and TOC, it was found that paleoclimate and redox environment were the main factors affecting the enrichment of organic matter. The purpose of this study is to explore the sedimentary geochemical characteristics of different lacustrine source rocks in the same basin by combining organic and inorganic geochemistry, to clarify the difference of source rock characteristics in Zhusan depression, and to enrich the research methods of oil and gas system, to provide theoretical reference for exploration and development.

Keywords: TSR, H2S gas, RTM, Carbonate Reservoir

Hydrogen sulfide (H2S) is an undesirable constituent of petroleum, which is likely to be derived from thermochemical sulfate reduction (TSR) at concentrations higher than a few percent. TSR is the most important process to generate high level of H2S in carbonate reservoirs with anhydrite intercalations. The TSR modeling facilitates the investigation of organic-inorganic interactions and their impact on both petroleum and reservoir qualities.

In this study, we developed 1D reactive transport models to simulate the TSR process in Puguang gas reservoir in SW China. The models quantify the mass transfer processes of minerals and gases, including gas consumption/generation and mineral dissolution/precipitation. It integrates thermodynamic equilibrium reactions for gas-water-rock interactions and kinetic reactions for sulfate reduction. Based on burial depth, paleo temperature and pressure, and lithology of the reservoir, the model can simulate hydrocarbon consumption, H2S generation, anhydrite dissolution, and calcite precipitation in TSR process, and quantify the associated modification of reservoir quality.

The modeling results show that the abundance of effective anhydrite (as the oxidizing agent) and hydrocarbon (as the reducing agent) were responsible for the generation of H2S and calcite cements, as well as the porosity increase during TSR. It is noted that anhydrite abundance is an important factor to control the extent of TSR reaction and H2S distribution. However, the porosity generation during the TSR reactions are insignificant around 0.23%, probably because the impacts of anhydrite dissolution and calcite precipitation on porosity offset each other. After calibration, the predicted H2S and CO2 concentrations and gas souring index are comparable with the observed ones in the wells.

Reactive transport modeling (RTM) is a powerful tool to investigate the interaction of acid gas, water, rock and hydrocarbons and predicts subsequent modifications of hydrocarbon and reservoir qualities. It would be useful for evaluating H2S risk and mapping the detrimental gas in exploring and developing of carbonate reservoir.

Microbially mediated hydrothermal Mn redox cycling and Mn carbonate precipitation after the Marinoan glaciation

Bin Zhang[1], Jian Cao[1*], Kai Hu[1], Hua Chun Shi[2]
1. School of Earth Sciences and Engineering, Nanjing university, Nanjing, Jiangsu Province, CHINA

Keywords: Manganese, Mn-oxidizing bacteria, Mn-reducing bacteria, Nucleation site

Manganese is an important redox-active transition metal and bioelement in the Earth system, with transformation between dissolved Mn (II) and insoluble Mn (IV) in geological history being a response to environmental redox conditions (Wittkop et al., 2020). The predominant mechanism of Mn cycling involves redox conversion between Mn (II) and Mn (III/IV), controlled mainly by the type and availability of oxidants and reductants (Havig et al., 2015), and external environmental conditions (Barley and Groves, 1992). In addition, the recent research show that microorganisms may play a vital role in mediating Mn redox cycling in laboratory simulation (Myers and Nealson, 1988; Learman et al., 2011; Li et al., 2019; Yu and Leadbetter, 2020) and modern oceanic Mn nodules (Shiraishi et al., 2016; Jiang et al., 2020; Li et al., 2021). However, there is no solid evidence for microbially-mediated redox cycling of Mn under actual geological conditions. The carbonate-type Mn deposit in the Ediacaran Doushantuo Formation along the northern margin of the Yangtze Block, South China, provide an excellent natural laboratory for the research of Mn redox cycling in deep time.

In this study, we applied high-resolution in situ mineralogical and geochemical analyses based on the morphological characteristics of different types of microorganisms and geochemical markers generated by their biological activities processes. The geochemical results indicate that Mn in carbonates at the top of the Doushantuo Formation along the northern margin of Yangtze Block was derived from deep submarine hydrothermal fluids as Mn (II), increasing the concentration of Mn (II) in the seawater reservoir. According to the result of fossil morphology and geochemical markers, we presume the process which microorganisms fix CO_2 in organic matter by oxidizing Mn (II), providing energy for their metabolic activities under obligatory oxidation conditions can occur in natural geological environments. In oxidation condition, Mn-oxidizing bacteria oxidize Mn (II) to generate unstable todorokite symbiotic with organic matter, with accompanying Co and Ce oxidation and enrichment. Under suboxic conditions, heterotrophic Mn-reducing bacteria use organic matter as an electron donor and Mn bio-oxide as a terminal electron acceptor to generate Mn (II) and ^{12}C-rich dissolved inorganic carbon (DIC), which are the necessary materials for the formation of Mn carbonate minerals. Meanwhile, the bio-reduction of Mn (IV) provides the ideal alkaline geochemical environment for Mn carbonate minerals precipitation. On this basis, microorganisms and alga also provide nucleation sites for the precipitation of Mn carbonate minerals with biological morphology.

Our findings provide new evidence of the central role of microorganisms in Mn redox cycling and Mn carbonate mineral precipitation. Microbial activity facilitates Mn redox cycling and promotes precipitation of Mn carbonate minerals by providing nucleation sites. At the same time, microbially mediated Mn redox cycling also stimulates the cycling of Carbon between inorganic and organic environments, with C isotopic fractionation being a by-product of Mn biogeochemical cycling in deep time. Therefore, the process of microorganisms mediate Mn redox cycling and precipitation of Mn carbonate minerals may be universal phenomenon in geological evolution.

Influence of activities of deep thermal fluids on the reservoir diagenesis and quality: A case study of the Zhuhai formation reservoir in the Baiyun Sag, Pearl River Mouth Basin, South China Sea

Zhonghao Zhang[1,2*], Hancheng Ji[1,2], Yanqing Shi[1,2]
1. College of Geosciences, China University of Petroleum (Beijing), Beijing, CHINA
2. State Key Laboratory of Petroleum Resources and Prospecting, China University of Petroleum(Beijing), Beijing, CHINA
E-mail: zhonghao_zhang@foxmail.com

Keywords: Deep thermal fluids, Fluid-rock interaction, Diagenesis, Reservoir quality, Baiyun Sag

With the continuous research of the sedimentary basin fluid, the study of deep thermal fluid changes from the process of earlier mineralization to the influence of reservoir diagenesis. The diagenetic fluid components and sources are excellently significant to understand the diagenetic process, fluid-rock interaction and reservoir quality. Recently, the influence of the deep thermal fluid on reservoir diagenesis and pore evolution has come to the frontier in hydrocarbon exploration and development. Baiyun Sag which belongs to the Southern Depression Belt of Pearl River Mouth Basin (PRMB), is one of the largest deep-water sags, with its main body located beneath the present continental slope[1]. The thermal state of the Zhuhai formation was changed by the tectonic thermal event after Baiyun Movement which occurred across the Oligocene-Miocene boundary at 23.8Ma[2], and the thermodynamic conditions become one of the principal factors affecting the diagenetic evolution of the deep reservoir.

Previous studies show that the CO_2 of mantle-sourced magma origin charges the reservoir in the Baiyun Sag[3], but the thermal fluid activity range and its influence on the diagenetic process are still unclear. This study focuses on the fluid activity range and the reformation of the reservoir diagenetic sequences by thermal fluid to determine the beneficial reservoir distribution and the developmental mechanism and assess the influence of the reservoir quality. Based on the thin section, SEM and cathodoluminescence microscopy, the reservoir diagenetic sequences of the Zhuhai formation are divided, then combined with X-ray diffraction, fluid inclusion and geochemistry analysis to determine the fluid activity range and assess the influence of the thermal fluid on the reservoir diagenesis. The results show: (1) sharp decline of smectite content and occurrence of dawsonite indicate that the Zhuhai formation reservoir is affected by the external thermal fluid; (2) with temperature rises, the dissolution of albitite, calcite and iron calcite occurs in the CO_2 charged reservoir. The dissolution intensity is enhanced by rising temperature and forms secondary pores, which improves the pore space of the reservoir; (3) the authigenic kaolinite precipitates and carbonate cements form through the heat-mass transfer process with the continuous increase of CO_2 charge. When the CO_2 partial pressure keeps increasing and the temperature ranges from 25℃ to 100℃, kaolinite dissolution provides the dawsonite cement with additional sources of Al^{3+}. Cements forming is adverse to reservoir space and permeable space preservation, which causes poor physical properties; (4) The overall result shows that the influence of mantle-sourced CO_2 charged in the deep formation on the reservoir is double-edged, however the cementation intensity is lower than dissolution intensity in the study area. These results are of great significance for understanding the diagenetic process, fluid-rock interaction and assessing reservoir quality.

Keywords: mud volcano systems, emitted gases, mud breccia and brine water, host rocks, organic-inorganic interactions, bleaching effect

As one kind of geofluids emission systems on the Earth surface, petroleum-related mud volcanoes are significant to petroleum resources evaluation, environmental impacts, natural hazards, and also the tourism resources. A series of samples including emitted gases, formation water, erupted mud, and also their host rocks were collected from the Dushanzi mud volcano system along with one argillite sample distal from the mud volcanoes for comparison in southern margin of the Junggar Basin, NW China. Their mineral and chemical compositions and also iron species were determined using XRD, XRF, and Mössbauer spectroscopy, respectively. The results indicated a series of marked oil-gas-water-rock interactions in the mud volcano systems with the followwing main variations: 1) chemical and isotopic variations for emitted gases compared with well gas samples from the corresponding reservoir nearby; 2) some conversion of clay minerals from smectite into chlorite and illite, and also the precipitation of newly formed metals carbonate preicipitant inlcuding calcite and siderite; 3) silicon depletion and significant elemental enrichment of Fe, Mg, Mn, Ca and P etc; 4) transformation of Fe from ferric species in hematite and smectite into ferrous species in siderite, chlorite, illite and even pyrite. These geochemical alteration likely induced various colour change of the original reddish Neogene argillite to the mud breccia in grey or black, resulted in elemental reduction and/or mineral alteration along with hydrocarbons oxidation, which is so-called as bleaching effect. Such a complex process might be positively contributed to the reduction of greenhouse effort of erupted gases from mud volcanic systems compared to direct emission of natural gas from the corrrespoding petroleum reservoirs, and also eventually significant to a better understanding of physical properties such as porosity and permeability of reservoir rocks and also the migration pathways, and even implicable to the evolution of long-term stability of geologically sequenced carbon dioxide.

Study on the adsorption pattern of alkanes on inorganic mineral surfaces based on molecular simulation method - An example from the Ordos Basin

penglei yan[1*]
1. School of Geosciences, China University of Petroleum(East China), Qingdao, Shandong, CHINA
E-mail: 991196058@qq.com

Keywords: Ordos, Geochemistry, Molecular simulation, Organic-inorganic, Hydrocarbon accumulation

The Ordos Basin is a complex basin with gentle slopes and simple tectonics, formed through multiple phases of tectonic movements. The late strata were deposited on top of the Paleo-Late Proterozoic North China Craton Basin. It is also one of China's largest oil and gas producing areas. The main source rock series in the basin is the Triassic Yanchang Formation. The Yanchang Formation develops high-quality lacustrine black shale, and the content of organic matter abundance (TOC) is exceptionally high, generally above 5 %, and the highest is above 30 %. Maturity is moderate. The organic matter type of source rock is mainly II_1, which is in the stage of oil generation. Ordos Basin has high-quality source rocks, but the research on its accumulation mechanism and resource reserves evaluation is not yet mature. It has become a problem restricting exploration and development. Therefore, it is of great significance to study the migration state of oil and gas underground for the accumulation mechanism of oil and gas. The existing experimental methods cannot intuitively show the interaction between alkanes and pore walls, so the molecular dynamics simulation technology is used to intuitively show the adsorption state of oil on the mineral surface. This paper uses Gromacs software to study the interaction between alkanes and pore walls. Based on the geochemical data of Ordos Basin, a mixed proportion model of n-C_8, n-C_{12}, and n-C_{15} n-alkanes was established, and kaolinite slits were used to replace inorganic pores. The interaction between alkanes and inorganic mineral surfaces was simulated, and the adsorption characteristics of alkanes were obtained. The adsorption density curve can then calculate the adsorption capacity per unit area, and the adsorption free ratio of oil and gas in the pores can be calculated. The results show that heavy alkane is easier to adsorb on the wall of kaolinite and exists in an adsorption state. Light alkanes are more accessible to migrate in the form of a free state due to their strong interaction with the kaolinite wall. The adsorption free ratio model is established by unit area adsorption capacity, which can calculate the momentum in the migration process and judge the migration efficiency of oil and gas in the pores, which is beneficial to the evaluation and optimization of resource quantity.

Geochemical characteristics and significance of aromatic hydrocarbons in Suowa Formation carbonate rocks in Shuanghu area, Qiangtang Basin

Yizhuo Yang[1], Zhilong Huang[1*]

1. College of GeosciencesChina University of PetroleumBeijing, Beijing, China, College of GeosciencesChina University of PetroleumBeijing, Beijing,China; State Key Laboratory of Petroleum Resources and Prospecting, China University of PetroleumBeijing, Beijing, China, Beijing, CHINA

E-mail: huangzhilong1962@163.com

Keywords: Qiangtang basin, Suowa formation, Source rocks, Aromatic hydrocarbon geochemical characteristics, Origin of parent material, maturity

Qiangtang basin is a large Mesozoic marine sedimentary basin, and there are several sets of source rocks in the basin. In order to understand whether the carbonate rocks of Suowa formation in Shuanghu area of Qiangtang basin have hydrocarbon generation capacity, the abundance, type, source of organic matter, sedimentary environment and maturity of source rocks will be analyzed. In this study, the geochemical characteristics of aromatic compounds in source rocks were analyzed by total organic carbon, kerogen carbon isotope, extraction and separation and gas chromatography-mass spectrometry. The results show that the source rocks of Suowa formation in the study area have high abundance of 1,2,5-trimethylnaphthalene, 9-Methylphenanthrene, graphene and chrysene series compounds, indicating the source of higher plants. The distribution characteristics of trifluorene series compounds, alkyl dibenzothiophene, alkyl dibenzofuran and triarylesteroid series compounds indicate that the sedimentary environment of source rocks of Suowa formation is a strong reducing environment. The comprehensive study on the maturity parameters of alkyl naphthalene, alkyl phenanthrene, alkyl dibenzothiophene and triarylstane series compounds shows that the source rocks of Suowa formation in Shuanghu area of Qiangtang basin have reached the maturity stage, which is consistent with the results of equivalent vitrinite reflectance Rc1, Rc2, Rc4 and Rc5. Based on the discovery of many ancient oil reservoirs and hydrocarbon displays in Suowa formation in Shuanghu area, and comprehensive analysis of organic matter abundance and types of the Suowa formation carbonate rocks, it is concluded that the Suowa formation carbonate rocks in Qiangtang Basin have certain exploration value of oil and gas resources.

Keywords: Oxygen isotopes, Fe- and Mn-oxides, Fe- and Mn-carbonates, Anaerobic oxidation of methane, Rare earth elements

Fe- or Mn-rich carbonates with d13C < -10‰ spread widely over the Proterozoic to Archaean sediments, and may have precipitated from HCO3- from sulfate reduction or microaerobic methane oxidation in anoxic water columns or via reactions between Fe-/Mn-oxides and organic matter or methane during diagenesis (Wittkop et al., 2020; Cai et al., 2021). However, it is hard to distinguish these two processes. Here, we demonstrate that strongly 13C- and 18O-depleted Mn-rich carbonate cements from the Triassic conglomerate of Junggar Basin, China, may have both oxygen and carbon derived from Mn oxides via redox reactions with methane. The Mn-rich calcites have bulk (5.9 to 13.6 ‰, n=6) and SIMS (4.1 to 15.5 ‰, n=40) d18OVSMOW values that correlate negatively with MnO concentration and d13C with R2 of 0.81 and 0.74, respectively. They display decrease in SIMS d18OVSMOW values towards those of the coexisting Mn-rich hematite (from -5.8 to 3.3 ‰), and shifts from normal or negative Y, Ce and Eu anomalies to the positive with increasing Mn contents or reducing degrees. These features may have resulted from increasing transfer of 18O-depleted oxygen from Mn oxides and intense alteration of rare earth elements and yttrium due to progressive Mn reduction in a closed diagenetic system. Similarly Fe-/Mn-rich carbonates with 18O-depletion and Eu positive anomaly have been reported from the Proterozoic worldwide (Baur et al., 1985; Heimann et al., 2010), thus, we propose that such carbonates may have a similar origin, and thus may have played an important role in the global carbon cycles especially in low sulfate early Earth.

Evolution of nC16H34-water-mineral systems in thermal capsules and geological implications for deeply-buried hydrocarbon reservoirs

Guanghui Yuan[1*]
1. Department of Geology , China University of Petroleum, East China, Qingdao, Shandong, CHINA
E-mail: yuan.guanghui@upc.edu.cn

Keywords: nC16H34-water-mineral systems, organic-inorganic interactions, hydrocarbon degradation, mineral alteration, deeply buried hot reservoirs

Organic-inorganic interactions between hydrocarbons and most minerals in deeply buried reservoirs remain unclear. In this study, gold capsules and fused silica capillary capsules (FSCCs) with different combinations of nC16H34, water (distilled water, CaCl2 water) and minerals (quartz, feldspar, calcite, kaolinite, smectite, and illite) were heated at 340 °C for 3-10 days, to investigate the evolution and reaction pathways of the organic-inorganic interactions in different hot systems.

After heating, minerals exhibited little alteration in the anhydrous systems. Mineral alterations, however, occurred obviously in the hydrous systems. Different inorganic components affected nC16H34 degradation differently. Overall, water promoted the free-radical thermal-cracking reaction and step oxidation reaction but suppressed the free-radical cross-linking reaction. The impact of CaCl2 water on the nC16H34 degradation was weaker than the distilled water as high Ca2+concentration suppressed the formation of free radicals. The presence of different waters also affects the impact of different minerals on nC16H34 degradation, via its impact on mineral alterations. In the anhydrous nC16H34-mineral systems, calcite and clays catalyzed generation of low-molecular-weight (LMW) alkanes, particularly the clays. Quartz, feldspar, and calcite catalyzed generation of high-molecular-weight (HMW) alkanes and PAHs, whereas clays catalyzed the generation of LMW alkanes and mono-bicyclic aromatic hydrocarbons (M-BAHs). In the hydrous nC16H34-distilled water-mineral systems, all minerals but quartz promoted nC16H34 degradation to generate more LMW alkanes, less HMW alkanes and PAHs. In the nC16H34-CaCl2 water-mineral systems, the promotion impact of minerals was weaker than that in the systems with distilled water.

This study demonstrated the generation of different hydrocarbons with different fluorescence colors in the different nC16H34-water-mineral systems after heating for the same time, implying that fluorescence colors need to be interpreted carefully in investigation of hydrocarbon charging histories and oil origins in deeply buried reservoirs. Besides, the organic-inorganic interactions in different nC16H34-water-mineral systems proceeded in different pathways at different rates, which likely led to preservation of liquid hydrocarbons at different depth (temperatures). Thus, quantitative investigations of the reaction kinetics in different hydrocarbon-water-rock systems are required to improve the prediction of hydrocarbon evolution in deeply buried hydrocarbon reservoirs.

Origin of authigenic kaolinite with implications for Permian tight gas sandstone reservoirs in the northern Ordos Basin, Central China

Jiachen Gao[1], Benben Ma[1*], Yongchao Lu[1]
1. Key Laboratory of Tectonics and Petroleum Resources, China University of Geosciences (Wuhan), Wuhan, Hubei, CHINA
E-mail: mabenben@cug.edu.cn

Keywords: Authigenic, kaoliniteTransport mechanism, Permian tight gas sandstone, Ordos basin

Authigenic minerals are commonly developed during progressive diagenesis in the siliciclastic rocks and exert significant impacts on reservoir properties. Therefore, it is important to decipher the origins of these authigenic minerals and accurately determine their temporal and spatial distribution in buried sandstones. Authigenic kaolinite is pervasively developed in alumosilicate-rich sandstone reservoirs, owing to the interaction of acidic groundwater with alumosilicate minerals from early to late diagenetic regimes. However, whether or not authigenic kaolinite is precipitated in a geochemically open or closed system has been debated for decades and the essence of this debate is mainly associated with the scale of mass transfer for fluid-rock interactions during kaolinite precipitation. One group of geologists argues that authigenic kaolinite can be formed in an geochemically open system owing to high influx of meteoric waters extensively flushed into the siliciclastic sediments and the resultant dissolved ions can be transported out of the system for long distances; this process would create net porosities for total reservoir quality. The second group of geologists considers that authigenic kaolinite is precipitated under extremely low velocity of pore-fluids in a geochemically closed system and that the dissolved ions would be precipitated in-situ or be transported for very short distances within the system; this process leads to little or no net porosities within the system and would not enhance total reservoir porosities. Therefore, the origin and distribution pattern of authigenic kaolinite are strongly related to the mass transfer in a geochemically open or closed system, which significantly affects the total reservoir quality of a sandstone.

This study deciphers the origin of authigenic kaolinite in the lower unit of Permian Shihezi Formation (P2x) tight gas sandstones in the Hangjinqi gas field, northern Ordos Basin, China, to determine its implications for reservoir quality. Authigenic kaolinite is the most abundant diagenetic cement and two occurrences of authigenic kaolinite are identified in the P2x sandstones: 1) in-situ replacive kaolinite; and 2) pore-filling kaolinite. Petrographic and geochemical evidence reveals that authigenic kaolinite is mainly derived from dissolution of K-feldspar via flushing with organic fluids from underlying source rocks. This evidence includes: 1) spatial association of partially dissolved K-feldspar and authigenic kaolinite; 2) the amount of K-feldspar dissolution is mostly equal to that of kaolinite precipitation within sandstones; 3) a homogenization temperature of 110-120oC for aqueous inclusions in quartz overgrowths; 4) negative stable carbon isotopic compositions of calcite cements (δ13CPDB from -16.05‰ to -9.35‰). Dissolution of K-feldspar, coupled with precipitation of kaolinite and quartz, is interconnected fluid-rock interactions within sandstones that are inferred to simultaneously occur in a relatively closed system. Intra-formational diffusive transport is inferred to be the dominant transport mechanism during these fluid-rock interactions, which may result in precipitation of in-situ replacive kaolinite or pore-filling kaolinite. This transport pattern may have been localized (several centimeters to meters). The fluid-rock interactions lead to redistributional secondary porosity and would not significantly enhance total reservoir porosity. The occurrence of authigenic kaolinite greatly reduced reservoir permeability by occluding the pore-throats in the P2x sandstones.

The “Three-factors driving”on origin of microbial carbonate rocks reservoir and their distribution

Anping Hu[1], Anjiang Shen[1,2*], Jie Zhang[1,2], Xiaofang Wang[1,2], Hui Wang[1,2]

1. Department of Marine Petroluem Geology, Petrochina Hangzhou Research Institute of Geology, Hangzhou, Zhejiang, CHINA
2. /, CNPC Key Laboratory of Carbonate reservoirs, Hangzhou, Zhejiang, CHINA

E-mail: shenaj_hz@petrochina.com.cn

Keywords: microbial carbonate rock, microbial dolostone, carbonate rock-evaporite sedimentary sequence, microorganic matter degradation and pyrolysis process, early dolomitization

Microbial carbonate rocks are very important hydrocarbon reservoirs.In view of the problems of that stromatolite & thrombolite carbonate rocks have a better reservoir-developing potential than other microbial carbonate rocks and no-microbial carbonate rocks and, this paper made a series of study on modern microbial sediments & salted lake sedimentssimulated experiment on early degradation and buried pyrolysis of microbial organic matter and simulated experiment on early low-temperature microbial-reduced protodolomite precipitation and replacive dolomite, three geological understandings could be achieved.1compaired with other microbial carbonate rocks and no-microbial carbonate rocks, stromatolite & thrombolite carbonate rocks have a higher original porosity and content of microbial organic matter,which results that high-grade microbial carbonate rock reservoir mainly developed in stromatolite & thrombolite carbonate rocks2the production of organic acid by early degradation and buried pyrolysis of microbial organic matter helps the protection and enhancement of original porosity in burial stage, which is the key factor for development of microbial carbonate rocks reservoir3early dolomitization is helpful for the protection of pre-buried porosity, and carbonate rock-evaporite sedimentary sequence easily occurs dolomitization by microbial-reduced and replacive process, which results that stromatolite & thrombolite dolostone reservoirs mainly developed in carbonate rock-evaporite sedimentary sequence.These understandings are of great significance for distribution & prediction of microbial carbonate rocks reservoir. Stromatolite & thrombolite facies belt in carbonate rock-evaporite sedimentary sequence beneficial for the development of stromatolite & thrombolite dolostone reservoirs

In situ calcite U-Pb geochronology by high-sensitivity single-collector LA-SF-ICP-MS

Shitou Wu[1*]

1. State Key Laboratory of Lithospheric Evolution, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, CHINA

E-mail: shitou.wu@mail.iggcas.ac.cn

Keywords: Calcite U-Pb geochronology, SF-ICP-MS, LA-ICP-MS, Sensitivity enhancement, Jet sample cones

U-Pb geochronology of calcite using laser ablation-inductively coupled plasma-mass spectrometry (LA-ICP-MS) is an emerging method, with potential applications to a vast array of geological problems. Due to the low levels of U and Pb in calcite, measurement using higher-sensitivity instruments, such as sector field (SF) ICP-MS, have advantages over more commonly used quadrupole (Q) ICP-MS instruments. Using a Thermo Element XR ICP-MS, we demonstrate that the Jet + X cone combination with the N2 enhancement technique provides the best sensitivity for measuring U and Pb isotopes. This higher sensitivity improves the precision of calcite U-Pb isotope measurements, and permits dating at high spatial resolutions (< 110 μm) and for samples containing low contents of 238U (< 1 μg g-1) and/or 207Pb (i.e. young samples < 10 Ma). Using a spot size of 85 μm with a low fluence (~2.0 J cm-2),the laser-induced elemental fractionation of 206Pb/238U in the NIST SRM 614, ARM-3 and WC-1 reference materials are insignificant (< 2.2%). Adopting the optimized instrument parameters, we analysed four commonly-used calcite U-Pb reference materials (WC-1, Duff Brown Tank, JT, and ASH-15). The results match well with published isotope dilution data, demonstrating the reliability of our technique. ARM-3, an andesitic glass, is shown to be an appropriate reference material for both 207Pb/206Pb calibration and instrument optimization because of its moderate contents of U (~3.75 μg g-1) and Pb (~12.7 μg g-1). We further demonstrate that the image-guided approach using LA-ICP-MS elemental mapping is an efficient tool in obtaining robust ages.

The evolution process of H2S in gas reservoir based on multi-sources sulfur isotope constraints —A case study in Longwangmion Formation, the central Sichuan Basin, China

Dawei Liu[1], Chunfang Cai[2*]

1. Institute of Exploration, Petroleum Exploration and Production Research Institute, SINOPEC, China, Beijing, CHINA
2. Key Laboratory of Cenozoic and Environment, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, CHINA

E-mail: cai_cf@mail.iggcas.ac.cn

Keywords: Sulfur isotope, Microbial sulfate reduction, Thermochemical sulfate reduction, Longwangmiao Formation, Pyrite

As multiple-source reservoirs and polyvalent reaction states of elemental Sulphur, it usually used as tracer evidences to monitor organic-inorganic reaction mechanisms, cyclic processes, and redox degrees. Within the case study of Longwangmiao Formation in Anyue Gas-field, there are large deviations of sulphur isotopes (δ^{34}SV-CDT) between contemporaneous gypsum, pyrite and H_2S, confusing the source and accumulation interpretation of H_2S in gas trap. To solve this question, this study applied in-situ $\delta^{34}S$ analysis (Nano Secondary Ion Mass Spectrometry) of multi-phase pyrites and $\delta^{34}S$ analysis of pyro-bitumen, combining with known $\delta^{34}S$ values of gypsum, water-soluble sulphate (WSS) and H_2S. The organic-inorganic evolution process of $\delta^{34}S$ was established in Longwangmiao Formation, revealing that: i) Early framboidal pyrite aggregates (Py1) and intergranular solitary crystalline pyrite (Py2) are the products of microbial sulfate reduction (MSR), and the $\delta^{34}S$ values gradually increase from -7.1‰ to +44.8‰, which contain a wide initial $\delta^{34}S$ fractionation up to 39.1‰ with contemporaneous gypsum (ca. +32‰). By Rayleigh fractionation model, MSR process could make the $\delta^{34}S$ of residual sulfate increased up to +80‰. ii) The middle to coarse crystalline pyrite (Py3, Py4) associated with later hydrothermal dolomites and hydrocarbon charging, recorded $\delta^{34}S$ variations in the range of +8.6 to +15.5‰, with small fractionation deviations (less than 10‰) from the $\delta^{34}S$ values of WSS (ca. +16.4 ~ +16.9‰), H_2S (ca. +19.7 ~ +21.6‰) and bitumen (ca. +20.7 ~ +26.0‰), which inferring the presence of thermochemical sulfate reduction (TSR) at deep buried realm. Therefore, late TSR process utilized exogenous sulfate in this process, e.g., underlying Ediacaran contemporaneous sulphate ($\delta^{34}S$ range from +15 to +23‰), indicating that deep-supplied sulfate through the fault stimulated TSR process within upper Longwangmiao Formation. Thus, the low H_2S content (<2%) in studied stratum is the result of early MSR depletion sulphate and TSR utilized limited deep source sulphate. This study further clarifies the H_2S formation in Longwangmiao Formation gas reservoirs based on multi-sulphur isotope studies.

Coupled marine iron and carbon cycles 1.4 billion years ago

Huajian Wang[1*]
1. Key Laboratory of Petroleum Geochemistry, Research Institute of Petroleum Exploration & Development, Beijing, CHINA
E-mail: wanghuajian@petrochina.com.cn

Keywords: iron, carbon, Mesoproterozoic ocean, siderite, hydrothermal

Most marine massive Fe deposits formed from 3.0−1.8 Ga, with a billion-year hiatus until a brief return around 0.8 Ga. During this gap period, the iron formation (IF) shortage was thought to be a result of significantly decreased Fe^{2+} concentrations in the ocean, which was either substantially oxidized or sulfurized. Recent studies provide increasing evidence that ferruginous water was still widespread in the deep ocean until 0.58 Ga. Although atmospheric oxygen levels are still controversial in the time window of 1.8−0.8 Ga, it is believed that oxygen was deficient compared to the last 0.7 Ga.

Thus, although IF deposition is limited from 1.8−0.8 Ga, there are recent reports of significant ferrous carbonate deposition generating siderite-dominated IFs, such as the ~1.40 Ga Xiamaling IF in North China and the ~1.33 Ga Jingtieshan IF in Qilian. Siderite deposits are also found in the ~1.45 Ga Sherwin ironstone in Australia. To further explore the mechanisms of siderite-dominated IF deposition and the associated marine Fe and C cycles, we analyzed the contents and isotopic compositions of Fe and C of the Xiamaling IF.

A genetic model is introduced to interpret the dynamic and coupled Fe and C cycles in Mesoproterozoic oceans and sediments. Although the positive Eu anomalies of Xiamaling siderites are relatively low in the Xiamaling deposits, an enhanced input of hydrothermal Fe^{2+} is recognized from the isotopic compositions of Fe and C. Our results show evidence for hydrothermal Fe2+ input during the deposition of Xiamaling IF, where the Fe and C cycles were tightly coupled. Hydrothermal fluid is suggested as a key controlling factor during the Xiamaling siderite deposition.

Formation of giant Datangpo Mn-carbonates deposits participated by organic matter with multiple aspects

Wanglu Jia[1,2*]

1. State Key Laboratory of Organic Geochemistry, Guangzhou Institute of Geochemistry, Chinese Academy of Sciences, Guanghzou, Guangdong , CHINA
2. CAS Center for Excellence in Deep Earth Science, Guangzhou Institute of Geochemistry, Chinese Academy of Sciences, Guangzhou, Guangdong , CHINA
E-mail: wljia@gig.ac.cn

Keywords: Mn-carbonates, organic matter, diagenetic reduction, pulsed oxidation, the Cyrogenian Datangpo Formation

Introduction: The Mn-carbonates deposits hosted by black shales of the Cyrogenian Datangpo Formation contribute to a large proportion of Mn sources of China. These Mn-carbonates are also rich in organic matter (~2 wt %), but the accumulation of organic matter and its roles in the formation of Mn-carbonates deposits are not well discussed, yet. Many recent studies have reported the contents and isotopic compositions of organic matter and Mo and Fe speciation of the Datangpo Mn-carbonates, providing a large database to addressing these questions.

Results and implications: (1). The total organic carbon (TOC) contents of Mn-rich samples (Mn>1 wt %) first decrease with increased Mn content (1−10 wt %) and then increase when Mn content further increase from 10% to 40%. Negative relationships between Mn content and the isotopic compositions of both organic and inorganic carbon are evident. These results suggest that consummation of organic matter (possibly oxidized by MnO_2) may be important to the formation of Mn-carbonates, but enhanced Mn-carbonates precipitation were accompanied by additional input of organic matter enriched in light carbon isotopes. (2) Mn enrichment is well correlated with several elements' contents and ratios, including Fe, P, Zn, Ni and Eu/Eu*, indicating a hydrothermal source for Mn and nutrients. Thus accumulation of organic matter along with Mn may be associated with elevated primary productivity and bacteria activities. (3) Fe speciation data suggests that pore water changed from sulfidic condition during the deposition of black shale to ferruginous condition during the deposition of Mn-carbonates. Large input of reduced Fe associated with hydrothermal activity may be responsible for this critical change. In addition, the oxidation of dissolved H_2S species in pore water by MnO_2 would produce hydroxide ions, resulting in alkaline pore water and facilitating the precipitation of Mn-carbonates.

Therefore, a first formation of MnO_2 that was then reduced by both organic matter (producing Mn^{2+} and CO_3^{2-}) and H_2S may be required for the formation of Mn-carbonates, indicating pulsed bottom water oxidation but ferruginous pore water. This is also supported by much lower Mo content but comparable Mo isotopic compositions of Mn-carbonates relative to those of the black shale that was deposited in sulfidic condition. These solid evidences support diagenetic reduction of MnO_2, related to changes in both material sources and redox condition, to be the main cause of giant Datangpo Mn-carbonates deposits.

Controls of diagenesis on the quality of shallowly buried terrestrial coarse-grained clastic reservoirs: A case study of the Eocene Shahejie Formation in the Damintun Sag, Bohai Bay Basin, Eastern China

Shuya Huang[1], Xia Zhang[1*]
1. School of Earth Sciences and Engineering, Nanjing Univeristy, Nanjing, Jiangsu province, CHINA
E-mail: zhangxiananjing@163.com

Keywords: Diagenesis, Mechanical compaction, Carbonate cementation, Reservoir quality, Shallowly buried clastic reservoir

A typical shallowly buried (800~2000 m burial depth) coarse-clastic, nonmarine, fan-deltaic reservoir is well developed in the Eocene Shahejie Formation, Damintun Sag, Bohai Bay Basin, China. In this study, diagenesis and its control on the reservoir quality of fan-deltaic sandstones and conglomerates in the Shahejie Formation were investigated in detail by petrographic and geochemical analyses, including cathodoluminescence, X-ray diffraction, scanning electron microscopy, electron probe microanalyses and X-ray fluorescence. The reservoir sandstones and conglomerates mainly consist of moderately sorted feldspathic litharenite, which has undergone various diagenetic processes such as mechanical compaction, cementation, and dissolution, and are currently in the eodiagenesis stage with porosity and permeability averaging 21.56% and 435.2 mD, respectively. Mechanical compaction and cementation caused an ~ 45% reduction in the original reservoir porosity, especially the former, which exerted a more significant influence. In regard to cementation, the late calcite that formed at the mudstone-sandstone interface is more destructive and enhances reservoir heterogeneity, and its source material is believed to be primarily derived from the adjacent mudstones in conjunction with oil and gas charging. Feldspar dissolution plays a limited constructive role in reservoir properties by creating ~ 10% secondary porosity and changing reservoir wettability to oil wet through the formation of authigenic kaolinite. As a result, massive primary pores (~ 90% of the total pores) in the shallowly buried sandstones and conglomerates in the Eocene Shahejie Formation are still preserved. This systematic study is expected to be applicable in a general way to other shallowly buried terrestrial clastic reservoir systems.

Calcite-cemented concretions in non-marine sandstones: An integrated study of outcrop sedimentology, petrography and clumped isotopes from Lower Cretaceous Qingshuihe Formation, northwestern margin of Junggar Basin

Binfeng Cao[1*]

1. Department of Geology, Northwest University, Xi'an, Shaanxi, CHINA

E-mail: cao_binfeng@126.com

Keywords: Calcite-cemented concretions, Clumped isotopes, Non-marine sandstones

Calcite-cemented concretions can reduce reservoir quality and form important low-permeability baffles for fluid flow in sandstone carrier beds/reservoirs. Understanding origin and distribution patterns of concretions have important implications for characterizing reservoir heterogeneity and developing fields. The origin of calcite concretions in non-marine sandstones without detrital carbonate to source the cement is still cryptic. Practical difficulty of obtaining precipitation temperature of concretion prevents the precise determination of the source of cement components, solute flux and porewater microenvironment in which cement precipitated. Carbonate clumper isotope thermometry can give unique constraints to temperature of concretion precipitation. This study focused on outcrops of the Lower Cretaceous non-marine Qingshuihe Formation in the Urho area, northwestern margin of Junggar Basin (West China). Four depositional facies were recognized: channel deposit, mid-channel bar, abandoned channel and overbank floodplain. Calcite concretions occur only in sandstones, including spherical, ellipsoidal and tabular forms. They are isolated and aligned in layers; selective to either the top, middle and bottom of channel and mid-channel sand bodies. The clumped isotope temperatures for the concretionary calcite range from 35°C to 45°C with standard error (SE) of <3°C. The calcite has the highly variable, low δ13C values ranging from –16.91 ± 0.01 to –2.93 ± 0.02‰ (VPDB). The δ13C depleted bicarbonate source was most likely linked to biodegradation of the oils at shallow burial due to uplift. δ18O values of the calcite are very consistent and fall between –12.30 ± 0.04 to –9.79 ± 0.31‰ (VPDB). Introduction of meteoric water was a dominant mechanism for the significant depletion in the oxygen isotope of pore water along with alteration of volcaniclastic materials in sandstones. Flushing of meteoric water down the regional paleo-slope might under arid paleoclimate conditions biodegraded the migrating oil and enable a sufficient flux for precipitation of concretions.

Native sulfur deposits along faults and implications for carbonate reservoirs

Lianqi Jia[1*], Chunfang Cai[2], Chenlu Ma[1]
1. Geology, Northwest University, Xian, Shaanxi, CHINA
2. Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, CHINA
E-mail: jialianqi@nwu.edu.cn

Keywords: Native sulfur, sulfur isotope, carbonate corrosion, hydrogen sulfide migration

Large native sulfur deposits can be part of sulfate-bearing (e.g. gypsum and anhydrite) salt diapirs caprock or strata-bound evaporite rocks. Native sulfur is formed by sulfate reduction when hydrocarbons come in contact with sulfate minerals in presence of liquid water. Here we present a study of native sulfur deposits in the Liuhuanggou, Xinjiang, China. Native sulfur deposits associated with gypsum are found in many 3-15m caves of Ordovician carbonate reservoirs, and are distributed along faults like a series of beads. Native sulfur and gypsum show wide range of $\delta^{34}S$ values from -30‰ to -3‰, and majority is less than -10‰. They are obvious less than those of seawater in all geological history (10~35‰). This indicates that native sulfur and gypsum are probably biogenic. The prevailing model is that sulfide produced by sulfate-reducing bacteria is oxidized to zero-valent sulfur and six-valent gypsum. However, bacteria sulfate reduction (BSR) might not occur in the Ordovician native sulfur deposits because: (1) there are no associated authigenic carbonate minerals, such as BSR calcite; (2) coexisting sulfur and gypsum have similar $\delta^{34}S$ values, even that $\delta^{34}S$ values of gypsum is less. Thus, H_2S are probably derived from underlying strata. Sulfuric acid is generated when rising H_2S encounters oxygen-rich water at or near the water table. Gypsum has similar Sr concentration, $^{87}Sr/^{86}Sr$ ratios and REE pattern to surrounding limestones. It suggests that gypsum formed after limestone corrosion by sulfuric acid. This process leaded to karst caves. Gypsum is extremely finely crystalline and porous, indicating rapid oxidation. When lack of enough oxidizing agent, H_2S can be characterized by production of native sulfur, which is proved by filling of sulfur in the pores of gypsum. Actually, the oxidation of H_2S has led to the formation of some of the world's largest caves through a process known as sulfuric acid speleogenesis (SAS). Significance of sulfuric acid-related dissolution for epigenic karstification probably been underestimated for carbonate reservoir. The new model for oxidation of external BSR-derived H_2S has potential implications of native sulfur deposits and carbonate reservoirs.

Local marine sulfate is unlikely the sulfur source of the Huize Pb-Zn deposit, South China

Kai Luo[1], Jia-Xi Zhou[1*], Alexandre Cugerone[2]
1. School of Earth Sciences, Yunnan University, Kunming, Yunnan, CHINA
2. Department of Earth Sciences, University of Geneva, Geneva, SWITZERLAND
E-mail: zhoujiaxi@ynu.edu.cn

Keywords: Evaporate sulfate, Sulfur source, Huize Pb-Zn deposit

The Mississippi Valley-type (MVT) Pb-Zn deposits became abundant after the second Great Oxidation Event (GOE; i.e., 1.8 Ga) when oxidizing evaporate sulfate minerals began to extensively accumulate in the sea. These new large sulfur reservoirs may act as sulfur sources for MVT deposits, but their role in the formation of MVT deposits is still debatable due to the ability of evaporite to dissolve or be altered. The Huize Pb-Zn deposit in South China is one of the largest MVT deposits in China (7 Mt Pb+Zn @25-35%) and mineralization is mainly hosted in Carboniferous dolostones. However, a new Pb-Zn orebody within the Ediacaran dolostones has been recently discovered and provides a rare opportunity to compare sulfur source(s) in these different ore-bodies. In this study, we present LA-(MC)-ICPMS in situ S isotopic compositions from sphalerite and pyrite hosted in Carboniferous and Ediacaran strata. They have similar $\delta^{34}S$ values ranging from +14.6‰ to +15.8‰, and from +14.5‰ to +18.1‰, respectively. These narrow ranges are different from the large ranges of marine sulfate documented during the Carboniferous ($\delta^{34}S$ = +15‰-+20‰) and Ediacaran ages ($\delta^{34}S$ = +20‰-+39‰). Therefore, the sulfur source of the two types of epigenetic MVT mineralization was likely derived from an external source, probably similar in origin, rather than from a local source related to marine sulfate hosted in the ore-hosting strata. This study encourages performing sulfur isotopic studies in various mineralization types hosted in different host-rocks before interpreting the origin of sulfur in a Pb-Zn deposit.

Effects of storm activity on pyrite sulfur isotope records from Holocene sediments

Kaixi Jiang[1*], Chunming Lin[2], Ming Su[1], Jiarui Liu[3]
1. School of Marine Science, Sun Yat-sen University, Zhuhai, Guangdong, CHINA
2. School of Earth Sciences and Engineering, Nanjing University, Nanjing, Jiangsu, CHINA
3. Department of Earth, Planetary and Space Sciences, University of California, Los Angeles, California, UNITED STATES
E-mail: jiangkx5@mail.sysu.edu.cn

Keywords: Sulfur isotope, Storm deposit, “Heavy” sedimentary pyrite

Storm-driven variations in depositional conditions can play key roles in modifying sulfur isotope signatures in sedimentary pyrites. Here we present the sulfur isotopic compositions of pyrites in a complete Holocene muddy storm deposit, which has been identified by a comprehensive study on sediment components, n-alkanes, bulk organic carbon isotope values (δ^{13}Corg), carbon and oxygen isotope values (δ^{13}C and δ^{18}O), and trace element concentrations. We observe that the positive (+5.83‰ to +15.76‰) and negative (–8.95‰ to –19.72‰) $\delta^{34}S_{pyrite}$ values were preserved in two intervals of the muddy storm deposit, which are exactly corresponding to the high-energy storm peak phase (HESPP) and the waning-energy late storm phase (WELSP), respectively. We propose that the ^{34}S enrichments in pyrites in the HESPP are due to the surficial and buried sulfide oxidation and high sedimentation rates promoting by storm activity. In contrast, the ^{34}S depletion in pyrites in the WELSP is attributed to microbial sulfate reduction (MSR) still playing a major role. The rapid shift in $\delta^{34}S_{pyrite}$ values can reflect the dramatic physical and chemical conditions transition in the depositional environment between the HESPP and WELSP. These results suggest that storm activity can both generate isotopically “heavy” and “light” sedimentary pyrites in the HESPP and WELSP, respectively, and thus pyrite sulfur isotope can be applied as a proxy for identifying and deciphering muddy storm deposits.

Sulfur isotope variations between pyrite and organic matter reveal influence of the Mesoproterozoic oxygenation event on ocean sulfur cycle

zi wen Jiang[1], chun fang Cai[1*]
1. Key laboratory of cenozoic geology and environment, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, CHINA
E-mail: cai_cf@mail.iggcas.ac.cn

Keywords: Mesoproterozoic, sulfur isotopes, ocean redox structure, oxygenation event, sulfur cycle

Great debase occurs about the atmospheric O_2 levels <0.1% to 1 % PAL or > 4% PAL in the Mesoproterozoic (Planavsky et al., 2014; Zhang et al., 2016). It has been found that Xiamaling Formation (about 1.4 Ga) in the North China Block is an excellent geological record providing information about atmospheric oxygen level (> 4% PAL) during the deposition of Xiamaling formation Unit 3. Paired organic sulfur and pyrite sulfur isotopes along with trace and rare earth elements were measured from two North China sections in this study and show a significant increase in the oceanic dissolved O_2 level upwards from Unit 3 to Unit 1, as indicated by an increasing trend in the difference ($\Delta\delta^{34}S_{OM\text{-}py}$) between pyrite $\delta^{34}S_{py}$ and OM $\delta^{34}S_{OM}$ from -16.7 to +9.57 ‰ and Ce anomaly. In Unit 3 the lowest strata we investigated, we find that organic sulfur $\delta^{34}S_{OM}$ is depleted in ^{34}S compared to the associated pyrite $\delta^{34}S_{py}$, or $\Delta\delta^{34}S_{OM\text{-}py} < 0$, which is rarely reported in the Phanerozoic sediments, and is attributed to low reactive iron availability and thus ^{34}S-depleted H_2S was preferentially incorporated in organic matter leaving later formed pyrite enriched in ^{34}S in low sulfate environment. In Unit 2, $\delta^{34}S_{py}$ values are roughly parallel with $\delta^{34}S_{OM}$ values, the $\Delta\delta^{34}S_{OM\text{-}py}$ values are increasing to -4.9 ~ +7.4‰ with an average of +1.09‰, suggesting both may have formed from reactions with H_2S. Then in Unit 1, the $\Delta\delta^{34}S_{OM\text{-}py}$ values were increased to -0.47 ~ +9.57‰, and there are positive Ce anomalies accompanied by Mn elements enrichment, which are not observed in the Units 2 and 3. Thus, the gradually elevated $\Delta\delta^{34}S_{OM\text{-}py}$ values in the Unit 1 suggests incorporation of intermediate S species from oxidation of H_2S by the ocean dissolved O_2 and/or oxidants (Amrani et al., 2006). This proposal is supported by Ce positive anomaly which indicates Ce release to the bottom water during reduction of Mn oxides in sediment-water interface and Mn oxides may have deposited from dissolved oxygen levels > 5 μM (Tostevin et al., 2016; Wu et al., 2019), which can be translated to the elevated atmospheric O_2 level.

Effect of illite on heavy oil biodegradation by Pseudomonas stutzeri L1SHX-3X strain isolated from Liaohe Oilfield

Lei Li[1], Yunyang Wan[1*]
1. College of Geosciences, China University of Petroleum, Beijing, Beijing , CHINA
E-mail: wanyunyang@cup.edu.cn

Keywords: Biodegradation, Illite, Pseudomonas stutzeri, Heavy Oil, Inhibition, Promotion

Illite is a widely distributed clay mineral with huge reserves in the earth's crust and its effect on microbial degradation of heavy oil is not clear even though it is very important for understanding biodegradation in heavy oil reservoirs or contaminated sites. This study takes illite, heavy oil and in-situ microorganism *Pseudomonas stutzeri* L1SHX-3X strain from Liaohe Oilfield as an example to explore the effect of illite on biodegradation. The results showed that illite slightly reduces the total degradation rates of heavy oil by *P. stutzeri* (4.5~8.5%), which is all contributed from the part of inhibition of all 64 detectable saturated hydrocarbons. Illite does not affect the biodegradation of all 96 aromatic hydrocarbons in terms of total amount for it has two equally opposite effects: promoting the biodegradation of 48 aromatic hydrocarbons and inhibiting the other 46 aromatic hydrocarbons. Generally, illite does not affect the microbial degradation mechanism. The transformation of crystal characteristics from illite to kaolinite under the action of microorganisms was observed at laboratory temperature and pressure conditions for the first time. These results are of great potentially helpful to the understanding of illite-modulated microbial degradation, the geochemical evolution of heavy oil and selective degradation of hydrocarbons.

The chemical and isotopic compositions of natural gas in the Dongdaohaizi Depression of Central Junggar Basin, China: insights into gas mixing

Xueting Wu[1], Shijia Chen[1*], Zengyuan Zhou[1]
1. School of Earth Science and technology, Southwest Petroleum University, Chengdu, Sichuan, CHINA
E-mail: 740622523@qq.com

Keywords: Thermal evolution of source rocks, Biomarkers, Pingdiquan Formation, Petroleum geochemistry, hydrocarbon evolution, oil-source correlation

The study of mixed natural gas can clarify the specific sources of natural gas accumulation and provide the basis for the exploitation of natural gas resources. Through the analysis of gas compositions and carbon isotope ratios of different components of a mixed natural gas, it is found that the carbon isotope fractionation of methane and ethane from different sources have a small difference after mixing. Ro% of the source rocks (C-J) between 0.48% and 1.7% (average =0.88%). Well DN8 and DN9 produced light oil with density between 0.75-0.82g/cm^3, viscosity between 3.3-1.63MPa·s. Generally, in the high maturity stage of organic matter, the carbon isotope fractionation values of methane and ethane of natural gas from single source should be display a difference of at least 4‰-5‰. The carbon isotope values of methane and ethane in well DN8 only 1.6‰. It is considered that the mixing of natural gas from different sources causes this phenomenon.

Research on Bleaching Genesis of Red Sandstone in Liujiagou Formation of the Middle Triassic in the Luxi Block, North China Craton

li Li[1*], xiangwei liu[1]
1. School of Geosciences, China University of Petroleum, Qingdao, Shandong province, CHINA
E-mail: lilywmwys@upc.edu.cn

Keywords: sandstone bleaching, carbon and oxygen isotopes, organic-inorganic interactions, oil and gas

The bleaching of red sandstone is an important process related to the organic-inorganic interactions, playing an important role in indicating fluid migration and carbon cycling. Red sandstone bleaching in the Triassic and Jurassic is a universal phenomenon which is widely distributed in the Luxi Block, but its genesis is less studied. In this paper, red sandstone bleaching in Middle Triassic Liujiagou Formation is systematically studied by petrological methods, diffraction of x-rays and carbon and oxygen isotope test to reveal the bleaching genesis. The bleaching occurred along bedding and rock fractures, the former being diffuse and speckled along the layer, while the latter being linear in the plane. Under the microscope, the red sandstone shows the mineral edge covered by iron oxide grain coating, and the coating of the sandstone mineral edge dissolved after being bleached by the reducing fluid. Noticing the content of hematite in the bleached sandstone is 0.69%, indicating the bleaching of red sandstone did not a complete organic-inorganic interaction. By comparing the other mineral contents of unbleached and bleached sandstone, we found that the calcite content of bleached sandstone is higher than that of unbleached sandstone, indicating that there is dissolution of primary calcite and formation of secondary calcite during the reduction fluid migration, and this change in calcite content is a strong evidence of organic-inorganic interaction. Carbon and oxygen isotopes show that $\delta^{13}C$ vales of the Liujiagou Formation bleached sandstone are -3.65‰~-1.75‰ and $\delta^{18}O$ vales of the Liujiagou Formation bleached sandstone are -14.45‰~-12.83‰, which representing a hydrocarbon fluid bleaching. The fluorescence thin sections of black residues in the flint strip of the field outcrop at the bottom of the Liujiagou Formation show the characteristics of yellow and light blue fluorescence under ultraviolet light, indicating that oil and gas migration have occurred in the Liujiagou Formation. All these evidences stated above demonstrating that the red sandstone bleaching of the Liujiagou Formation of the Luxi Block is attributed to the organic-inorganic interaction between oil and gas and hematite in rock. Reducing aqueous fluids such as organic acids or hydrogen sulfide in oil and gas reduce Fe^{3+} in red sandstone to Fe^{2+} through fluid-rock interactions, resulting in bleached sandstone. But the bleaching is incomplete and non-intense due to the long-distance migration of oil and gas from the Dongying Depression or the Dawenkou Depression.

Keywords: volcanism, the freshwater and saline lake, organic-rich shale, Chang 7 Member, Lucaogou Formation, Fengcheng Formation;

High organic matter abundance is necessary for large-scale hydrocarbon accumulation and enrichment in shale oil. Comparing conventional marine basins with lacustrine ones, the formation of organic matter in the latter usually changes rapidly with strong heterogeneity, which brings great challenges to identify sweet spot prediction and resource evaluation. In addition, water columns with different redox conditions also affect the burial and preservation of organic matter during the deposition of lacustrine shales, especially under the impact of ephemeral critical geological events such as volcanic activities. Therefore, determining the properties and the influencing factors on the water columns is one of the key scientific issues in revealing the differential enrichment of organic matter in such basins. By comparing the petrological and geochemical characteristics of organic-rich shales between a typical freshwater and a saline lacustrine basin, this study analyzes the depositional environment and water column properties during the burial and preservation of organic matter in the Ordos and Junggar basins. The results demonstrate that volcanic activity intensifies the degree of hypoxia during the formation of organic-rich matter, which in turn affects organic matter preservation. The sulfate reduction index (SRI) indicates that the organic-rich shale of the Chang 7 Member (Ch7) of Yanchang Formation in the Ordos Basin and the Lucaogou Formation (P2l) in the Jimsar Sag of Junggar Basin in freshwater-saline environments have a certain intensity of sulfate reduction (BSR) (SRI < 1.375). The organic matter consumed by BSR is lower than the preserved organic matter, resulting a higher TOC content. However, excessive volcanic activity or the input of hydrothermal fluids caused strong BSR (SRI > 1.375) of the Fengcheng Formation (P2f) in saline lake of the Mahu Sag in Junggar Basin. This indicates that a large amount of organic matter was degraded and consumed, causing more iron oxides (and other iron-containing minerals) dissolve gradually to form pyrite, reducing the TOC content. This study enabled us to understand the shale oil enrichment, sweet spot prediction and evaluation, and propose a better theoretical and practical model for hydrocarbon accumulation in shale formations, to guide future exploration efforts.

E-mail: abdus.saboor@uop.edu.pk

Keywords: Ooids, Cortex, Geochemistry, Jurassic, Indus Basin

The ooids are important contributors to the carbonate production on the globe and occur in sediments of almost all ages. Despite its common occurrence, their genesis is still ambiguous with no emphatic explanation and different factions of their biotic vs abiotic origin exist. Following the conventional mode of origin of ooids, this study uses an integrated petrographic and geochemical approach to explain the genesis of the cortical increments of ooids preserved in the Lower-Middle Jurassic sediments of the Indus Basin of Pakistan. The radial-concentric ooids epitomize dune mode of sedimentation across the region, having skeletal allochems and pellets as nuclei. Other constituents include miliolids, echinoderms, gastropods, pelecypods, pellets, intraclasts, and siliciclasts. Among them occur some exotic ooids having distinct cortical increments, conspicuous in the petrography, and the geochemical signatures of which signify differences across the cortex. The elemental concentration of conspicuous cortical increments is incongruent with the rest of the cortex and the cementing material. The increments reveal relatively low Sr, Fe, Si, Al, K, S, and slightly higher Mg, P and Mn concentrations. These increments are believed to represent the inherited cements, suggesting growth in the eogenetic environment, and subsequently modified by cement exhumation or physio-chemical abrasion during the transportation mode. The ooid development, fluid chemistry, and turbulence infer that the cortices of these ooids represent precipitation in the active dominant phase of ooids genesis, and the conspicuous increments signify eogenetic precipitation in the very shallow subsurface. Incorporation of thick or multiple eogenetic increments into the ooid cortices would reduce the average time duration for ooids to reach mature sizes.

Underestimated thermogenic methane hydrate dissociation in the modern and ancient Earth

Zichen Wang[1], Lei Jiang[1*]

1. Key Laboratory of Cenozoic Geology and Environment, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, CHINA

E-mail: lei.jiang@mail.iggcas.ac.cn

Keywords: Gas hydrate, anaerobic oxidation of methane, methane sources, authigenic carbonate, global carbon cycle, climate change

Methane hydrate dissociation (MHD) and the subsequent anaerobic oxidation of methane (AOM) have direct feedback to climate, oceanic and atmospheric chemistry, and biosphere during the Earth's history. Yet crucially, quantifying methane sources (biogenic vs. thermogenic) for gas hydrate through time is almost impossible due to the absence of these geological records, although they are of great importance to evaluation the abovementioned impacts from MHD. AOM pervasively occurs during MHD and may have preserved gas source information in its authigenic carbonate (AC). By compiling the global $\delta^{13}C$ data of methane and AC in the modern and recent cold seep sediments, and utilizing a numerical simulation approach of AOM and AC precipitation, we show that the varying $\delta^{13}C$ data of methane and AC could be best explained by the different proportions of gas sources (biogenic vs. thermogenic) and AOM rates. Crucially, our result suggests that thermogenic methane consists 5% to 85%, average at 35.7%, of the total methane volume in typical cold seep areas. Hence, the releasing of methane from MHD, which preferentially occurred in warmer climates during the past 350000 years, may have been underestimated by overlooking their contribution from thermogenic methane. The acceptance of vast thermogenic methane in the modern and ancient seep areas forces us to rethink the operation of global carbon cycles, climate change, and mass extinctions throughout geological time.

High resolution carbon and oxygen isotopes of the Early Ordovician-late Silurian of the Baltica: Implications for palaeoenvironmental changes and palaeotemperature trends

Bilal Gul[1*], Tõnu Meidla[1], Leho Ainsaar[1]
1. Geology, University of Tartu, Tartu, ESTONIA
E-mail: bilal.gul@ut.ee

Keywords: Stable carbon and oxygen isotopes, sea-level, brachiopods, palaeotemperature, Ordovician, Silurian

Oxygen isotope paleotemperature studies of the Paleozoic are based mainly on brachiopod shell material which is resistant to diagenesis and generally precipitated in isotopic equilibrium with ambient sea water. Here we present high-resolution brachiopod and bulk rock C and O stable isotopic data from the Ordovician-Silurian, for evaluating the palaeotemperature and palaeoenvironmental variability in the Estonian Shelf of the Baltoscandian Palaeobasin. As the region has not been influenced significantly by tectonic events or deep burial diagenesis, the studied carbonate rocks and fossils are well preserved in most of the locations. $\delta^{18}O$ and $\delta^{13}C$ values for the Ordovician and Silurian range between ca -7‰ to 0‰ and -1.5‰ to +7.6‰ respectively. High $\delta^{18}O$ values, sometimes accompanied also with higher $\delta^{13}C$ values, correspond to cooling if the isotope signal reflects the original oxygen isotopic composition in seawater, and vice versa. Several $\delta_{13}C_{brac}$ excursions identified in the Ordovician-Silurian in the Estonian Shelf reflect global chemostratigraphy and palaeoenvironmental history, being synchronous with the previously documented excursions in the bulk carbonate stable isotopic curves. Combining the published and new $\delta^{13}C_{brac}$ and $\delta^{18}O_{brac}$ data allow us to address chemostratigraphy in the interval from Lower Ordovician (Floian) up to the topmost Silurian (Přidoli). The $\delta^{18}O_{brac}$ data suggest warmer temperatures during early Ordovician (Floian-Dapingian) and a cooling trend into the Mid-Ordovician. The Hirnantian glaciation episode (corresponding to HICE) reveals the minimum temperature in this interval and the post-HICE data suggest a rising temperature trend. Another temperature minimum is evident in the strata reflecting the Ireviken Event (Sheinwoodian). Our study shows that $\delta^{18}O$ values from the brachiopod Ordovician-Silurian carbonates could tentatively be interpreted as reflecting the major temperature trends.

Triple Oxygen Isotope Relationships during Microbial Sulfate Reduction

Shanggui Gong[1], Yongbo Peng[2*], Dong Feng[1], Duofu Chen[1]
1. College of Marine Sciences, Shanghai Ocean University, Shanghai, CHINA
2. International Center for Isotope Effects Research, Nanjing University, Nanjing , JiangSu, CHINA
E-mail: ybpeng@nju.edu.cn

Keywords: triple oxygen isotope, isotope fractionation, porewater sulfate

The atmosphere O_2 and CO_2 levels are evolved with the environment's change in geological history, leaving the atmosphere signal (pO_2/pCO_2) in the minor oxygen isotope composition ($\Delta'^{17}O$) of sulfate mineral. However, the ubiquitous microbial sulfate reduction (MSR) adapts the oxygen isotope composition of sulfate. To extract the atmosphere signal from the MSR-adapted sulfate, the determination of diagnostic triple isotope exponent $^{17}\theta$ ($\equiv \ln^{17}\alpha/\ln^{18}\alpha$) for microbial sulfate reduction is required. The oxygen isotope fractionation during MSR depends on the reversibility of intracellular enzymatic steps, dominated by equilibrium isotope fractionation between intracellular water and intermediate valence state sulfur species under low high reversibility and dominated by the kinetic isotope fractionation during each step under low high reversibility. Here we propose that the porewater sulfate profiles ($\delta^{18}O_{SO4}$ and $\Delta'^{17}O_{SO4}$) in organic-poor sediment and methane-seeps can be used to deduce the apparent $^{17}\theta$ value dominated by equilibrium and kinetic respectively. The constrained triple isotope exponent of MSR in nature new insight into using $\Delta'^{17}O_{SO4}$ as a proxy for pO_2/pCO_2 and marine sulfate budget.

Distribution characteristics and genetic mechanism of calcareous sandstone of Shahejie Formation reservoirs in J oilfield, Bohai Bay

Chao Liu[1*], Zongbin Liu[1], Jiatao Wen[1], Ya Wang[1]
1. Bohai Oilfield Research Institute, cnooc, Tianjin, CHINA
E-mail: lc02un@qq.com

Keywords: Calcareous sandstone,reservoir properties,carbonate cementation,diagenesis,Bohai Bay

The deeper burial of the Paleocene Shahejie Formation reservoir and the abnormal development of carbonate cement in J oilfield of Bohai Bay have led to strong reservoir in-homogeneity, which has seriously affected the development and production of the oilfield. Using sedimentary mineralogy and petrology, combined with thin section identification, logging, core testing, carbon and oxygen isotopes and other analytical methods, the lithological characteristics, logging identification characteristics and distribution characteristics of calcareous sandstone of Shahejie Formation in J oilfield were researched, and the genesis mechanism of calcareous sandstone from the perspective of material origin and diagenesis were analyzed. On the basis, the influence of carbonate cements on reservoir quality was analyzed to provide a geological basis for reservoir description and remaining oil distribution in J oilfield.

The study shows that the calcareous sandstone of Shahejie Formation in J oilfield is mainly distributed in highly porous and highly permeable areas, such as at the bottom of the underwater diversion channel depositions and the top of the estuary dam depositions, and the carbonate cement content shows a distribution pattern that increases with the depth of burial and increases from the high part of the structure to the low part. The rock formation mainly includes compaction, cementation, accounting and dissolution, the diagenetic stage enters the early diagenetic B stage. The type of cementation is mainly early mud-powder crystal calcite, mud crystal dolomite and late iron calcite and iron dolomite cementation, with local development of rhodochrosite and iron dolomite colloid, oolite and iconoclastic development. The formation of carbonate cement is related to the decarboxylation of organic acids, and its material source is mainly from the dissolution of feldspar and hydration of clay minerals, while carbon and oxygen isotope analysis shows that the dissolution of abundant calcareous biogenic fossils is also an important source of calcium. The research shows that carbonate cement has a significant influence on the reservoir physical properties and non-homogeneity of the Shahejie Formation.

Carbonate cement distribution and Carbon and oxygen isotope enrichment characteristics of sandstone reservoirs in M Oil Formation in Shiyougou Oilfield

gou yingchun[1*]
1. , , , , CHINA
E-mail: gouyc@petrochin.com.cn

Keywords: Carbonate cement,Carbon and oxygen isotopes;M-oil group,Shiyougou oil field ,Jiuxi Basin

Carbonate cement is the most important authigenic mineral in M reservoir sandstone reservoir of Jianquanzi Formation in Jiuxi Basin, and its content and distribution form are the main factors affecting reservoir quality.Through mineralogy, petrology and geochemical analysis, it is concluded that the carbonate cements in this area are mainly composed of iron-free dolomite and calcite, and are often developed in the form of ring-side and speckle.The content of carbonate cement ranged from 2.11% to 56.39%, with an average of 12.93%.Microzone observation shows that the iron-free microcrystalline dolomite cements are distributed outside the particles and cover the whole particles, and they are mainly formed from cogenesis to the early stage of premorphic rock. The iron-free dolomite cements formed in the early stage increase the mechanical strength and compact-resistance of the rocks, which is beneficial to the development of the reservoirs in the study area.Speckle like sparry calcite cement mainly grows along the pore space and finally occupies the entire pore space. It is the chemical precipitation product in the late diagenesis, which is unfavorable to the development of reservoir.The value of δ18O (PDB) is -11.14‰~-3.25‰, and the value of δ13C (PDB) is -7.32‰~-0.42‰, indicating that the carbonate cement in this area comes from the brachywater environment and is related to the dissolvation-deposition process and is of chemical origin.The δ13C isotope is generally negative in the speck distribution of carbonate cements, which may be due to the addition of light organic carbon in the M oil layer, and the calcium ion produced by the organic acid produced by decarboxylation of organic matter under high temperature and pressure and the reaction with clay minerals provides the Source of Ca2+ for diagenetic diagenosis of carbonate cements.The study also shows that carbonate cementation may be one of the important factors that make the sandstone reservoir physical property of M oil group worse, and the porosity loss rate of M oil group is up to 16% due to carbonate cementation.The research results on the characteristics and formation mechanism of carbonate cements provide key parameters for quantitative evaluation of reservoirs and experimental support for acidification and stimulation measures.

High-resolution in-situ SIMS conodont apatite δ18O records from South China: Implications for the Frasnian–Famennian biotic crisis

Liyu Zhang[1,2*], Daizhao Chen[2], Kang Liu[2]

1. Wuxi Research Institute of Petroleum Geology, Petroleum Exploration and Production Research Institute, SINOPEC, Wuxi, Jiangsu, CHINA

2. Key Laboratory of Cenozoic Geology and Environment, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, CHINA

E-mail: zhangliyu.syky@sinopec.com

Keywords: Frasnian–Famennian transition, conodont, oxygen isotope, paleotemperature, biotic-crisis

The Late Devonian Frasnian–Famennian (F–F) transition is a critical interval in geological history during which major marine ecological crisis occurred, featuring the severe losses of low-latitude shallow-water benthic faunas. Climate change has long been proposed as a potential cause for this biotic crisis. The oxygen isotopic compositions ($\delta^{18}O$) of biogenic apatite (e.g., conodont microfossils) are considered as reliable carriers to reconstruct the paleotemperature due to their temperature sensibility and relatively higher resistant to diagenetic alterations. In this study, the in-situ Secondary Ion Mass Spectrometry (SIMS) conodont apatite oxygen isotopes ($\delta^{18}O_{apatite}$) from Luofu section (inter-platform basin facies) were measured to recover the high-resolution sea surface water temperature (SST) variations across the Frasnian–Famennian interval in South China. The new in-situ oxygen isotope datasets reveal a $\delta^{18}O_{apatite}$ decline from 18.55 ± 0.37 ‰ to 17.6 ± 0.23 ‰ (VSMOW) in the late Frasnian and a subsequent increase from 17.6 ± 0.23 ‰ to 18.85 ± 0.24 ‰ in the latest Frasnian-earliest Famennian, which translate into sea surface temperature (SST) warming of ~ 4.3 °C and cooling of ~ 5.6 °C, respectively. These $\delta^{18}O_{apatite}$ shifts temporally agree well with reported results from other paleocontinents using the thermal conversion–elemental analyzer–isotope ratio mass spectrometry (TC-EA-IRMS) method, which, thus, is suggestive of a global signal. Furthermore, the positive $\delta^{18}O_{apatite}$ shift during the latest Frasnian-earliest Famennian is coincident with an apparent positive $\delta^{13}C_{carbonate}$ excursion, indicating that enhanced burial of organic carbon resulted in the drop in atmospheric PCO_2 and concomitant climate cooling. Overall, the SST data from the Luofu section exhibit a warm-to-cool fluctuation pattern, especially the climate cooling during the F–F transition, which may further cause escalating detrimental ecological pressures and lead to the Frasnian–Famennian biotic crisis.

Sulfur and oxygen isotopic compositions of sulfate from Lingulida shell: Constraining the late Devonian ooidal ironstone formation in South China

Kai Xiang[1], Bing Shen[1*], Yuanlin Sum[1]
1. School of Earth and Space Science, Peking University, Beijing, CHINA
E-mail: Bingshen@pku.edu.cn

Keywords: Sulfur cycle, sulfur isotopic, oxygen isotopic, Lingulida

Since the Phanerozoic, the cycle of iron, as an essential life and mineral element, in the earth system has been widely concerned. The study of the iron cycle is inseparable from global iron formation. As a representation of the global iron formation, the genesis of ooidal ironstones has not been entirely explained. It is difficult to explain the genesis of ooidal ironstones if we only study the iron cycle. The sulfur cycle is coupled with the carbon cycle on the global scale and the iron cycle on the local or regional scales, so we can use the sulfur cycle to restrict the iron cycle. In our study, we analyzed sulfur and oxygen isotopes of trace sulfate extracted from late Devonian Lingulida fossils, which were collected between two ooids ironstone layers. The sulfur and oxygen isotopic compositions of sulfate from Lingulida shells to reconstruct the ancient marine environment is a new method, so we also analyzed the same in the living Lingula shells. The results of δ34S and δ18O in the living Lingula shells, 14.42±1.77‰ and 9.81±0.34‰, suggested that the new Lingulida method is reliable. The δ34S and δ18O in the Devonian, 29.42±0.99‰ and 14.22±0.92‰, suggested the oceans here have heavier δ34S and nearly identical δ18O. It probably indicates that ooidal ironstones' formation requires a unique environment, where the seawater is oxic, and the sediments are anoxic.

Conservative transport of dissolved sulfate in the Yarlung Tsangpo River constrained by triple oxygen isotopes

DONG ZHANG[1*]

1. SCHOOL OF RESOURCES AND ENVIRONMENT, HENAN POLYTECHNIC UNIVERSITY, JIAOZUO, HENAN , CHINA

E-mail: zhangdong@hpu.edu.cn

Keywords: Oxidative pyrite weathering, CO2 counteraction, microbial sulfate reduction, conservative sulfate transport, Yarlung Tsangpo River

Global carbon-silica cycles are classically viewed as the primary processes controlling the stability of Earth's climate system. However, oxidative weathering of pyrite (OWP) gives rise to sulfuric acid weathering carbonate coupled with CO2 release globally and particularly in rapidly eroding environments. The OWP induced CO2 counteraction needs the vital prerequisite of conservative transport of dissolved sulfate because microbial sulfate reduction (MSR) transfers organic carbon to HCO3- latterly precipitated as CaCO3 in the ocean. Yet, conservative sulfate transport in the terrestrial environments remain elusive. We conduced field work in the Yarlung Tsangpo River during monsoon season and no-monsoon season, sulfur and triple oxygen stable isotope ratios of sulfate constrained sulfate sources and behaviors along the 1800km main stem. The simultaneously increased δ34SSO4 and δ18OSO4 ratios coupled with decreased SO42- concentrations but relatively stable Δ′17OSO4 ratios were observed along the river flow path through these both seasons. This spatial variation of sulfate concentrations and isotope ratios were resulted from mixing between OWP-derived sulfate and atmospheric deposition, and MSR does not affect the riverine sulfate isotope compositions. Our findings support the hypothesis that the uplift and erosion in the Qinghai-Tibet Plateau release OWP-derived sulfate and counteract CO2 consumption via silicate weathering.

Pore fluid and diagenetic evolution in turbidite sandstone reservoirs: A case from the Eocene Shahejie Formation, Niuzhuang Sag, Bohai Bay Basin, China

Zhenhuan Shen[1*]

1. School of Earth Sciences and Resources, China University of Geosciences (Beijing), Beijing, CHINA
E-mail: shenzh9311@163.com

Keywords: pore fluid, diagenetic evolution, carbonate cementation, siliceous cementation

Turbidite sandstones is the crucial petroliferous clastic rock reservoirs in the Niuzhuang Sag, Dongying Depression. The evolution of diagenetic fluid during burial environment has always been an urgent and difficult point in the research of diagenesis of clastic reservoir, which contributes to explore the formation of high-quality reservoirs. Thus, the nature and source of diagenetic fluids in turbidite sandstone reservoirs are studied by means of core, thin section, cathodoluminescence and SEM observation, as well as fluid inclusion microthermometry, EPMA, C-O isotope of bulk rock, LA-ICP-MS and SIMS.

Geochemistry analysis indicate that diagenetic fluid of authigenic minerals is controlled by the surrounding mudstones owing to turbidite sandstone reservoirs are adjacent to mudstone in sedimentation. The siliceous fluid in turbidite sandstone reservoirs mainly originates from the transformation of clay minerals and dissolution of feldspars and other mineral particles, which also provide abundant metal ions into pore water in the reservoir. While diagenetic fluid of precipitation of late-stage carbonate cementation is mainly controlled by the dissolution of micritic carbonate within mudstone and early-stage carbonate cementation. However, the origin of acid fluid for the dissolution of minerals is obvious in the different wells. $\delta^{18}O_{VSMOW}$ values of siliceous cements and REE characteristics of late-stage carbonate cements in the well W107 indicate that pore fluid is affected by meteoric water in the strong tectonic activity area; In contrast, the acid fluid within the other wells sources from the thermal evolution of organic matters. Moreover, based on the burial history of wells in different tectonic setting and homogenization temperature of aqueous fluid inclusions within authigenic minerals, the transformation time of diagenetic fluid properties from alkaline-acid-alkaline in the turbidite sandstone reservoirs is determined, and the evolution history of diagenetic fluid is revealed. Ultimately, the differential evolution model of diagenetic fluid in the middle part of third member of Paleogene Shahejie formation are established in the Niuzhuang Sag, Dongying Depression.

Calibrating the high-precision measurements of triple oxygen isotopic compositions in sulfate

Yangfan Liu[1*], Xiaobin Cao[1], Haoran Ma[1], Haiyang Wang[1]

1. International Center for Isotope Effects Research, School of Earth Sciences and Engineering, Nanjing University, Nanjing, Jiangsu, CHINA

E-mail: yangfanliu@smail.nju.edu.cn

Keywords: Triple oxygen isotopes, Sulfate, High-precision measurements, Fluorination methods

By contrast with large mass-independent oxygen isotope fractionation signatures exclusive to a restricted set of mechanisms, small triple oxygen isotope variations are widely distributed in natural samples. Among them, small triple oxygen isotope variation signals in sulfate may bear critical information of the atmospheric pCO_2 and pO_2, bioproductivity, hydrological cycles, and biogeochemical cycling in the ocean through deep Earth history. To enable research into this field, sufficient analytical capacity for triple oxygen isotopic compositions in sulfate is required. However, current measurement approaches are far from satisfactory in both accuracy and precision due to the non-quantitative conversion from sulfate to O_2 (i.e. the only gaseous analyte for accurate triple oxygen isotope analysis) and the difficulty in pinning down the exact oxygen isotope fractionation effects imposed by the conversion. In this study, we will calibrate the oxygen isotope fractionation between O_2 and sulfate during the conversion processes through theoretical calculations, sulfate-water oxygen isotope exchange experiments at relatively high temperatures, as well as CO_2-laser fluorination and Ni-tube fluorination experiments. The obtained fractionation in oxygen isotopes during fluorination will be presented. And the factors which may influence the fractionation will be discussed.

Oceanic oxygenation evidenced from barite nodules in the Ediacaran black shales

Haiyang Wang[1], Haoran Ma[1], Yongbo Peng[1*]
1. School of Earth Sciences and International Center for Isotope Effect Research, Nanjing University, Nanjing, Jiangsu, CHINA
E-mail: ybpeng@nju.edu.cn

Keywords: Ediacaran, barite, sulfur isotope, oxygen isotope

Extensive anoxia and redox stratification, as well as low sulfate concentrations, have been widely suggested to characterize the oceans for most of the Ediacaran period (~635-539 Ma), although multiple episodes of short-term oceanic oxygenation might have occurred. However, abundant centimeter-scale barite nodules were in surprise observed in the Member II black shales of the Ediacaran Doushantuo Formation, which would indicate the marine sulfate were not as scarce as previously thought, if they were formed during the syn-depositional process. To reveal their origin, we did a systematic analysis of their sulfur (δ34S) and oxygen (δ18O) isotope compositions. The δ34S values range from 40.6‰ to 59.4‰, much higher than that in pyrite from the contemporaneous sediments. Together with the high δ18O values (14.8-24.3 ‰), the mechanism involving pyrite oxidized by seawater or meteoric water [O2] during post-deposition or outcrop weathering could be fairly excluded. Instead, their values, as well as a good correlation between, are consistent with a pore water realm during the early diagenesis. Given barite nodules could be destroyed through reductive dissolution within an anoxic setting, we propose they should have been formed under oxic water conditions with high sulfate concentrations, implicating at least local oxidation in the predominantly anoxic ocean.

E-mail: ybpeng@nju.edu.cn

Keywords: oxygen isotope of phosphate, phosphate extraction, igneous weathering profiles, R-Ca-R method, reproducibility

The oxygen isotope of phosphate (δ18OPO4) has been widely employed for reconstructing paleo-environment and tracing biogeochemical phosphate cycling. Several existing protocols of phosphate extraction from soil, sea water, fossils, and sediments as silver phosphate were tested for their use in igneous rocks and igneous weathering profiles. Each has its merit, but none can be successfully applied directly due to low yield, and unknown fluctuation of the δ18OPO4 in extracted phosphate sample. A simple and reliable method is needed. Through trial and error, we have developed an effective phosphate extraction method, which comprises dissolution, purification and crystallization. The purification method is characterized by two cationic exchange resin treatments separated by a step of calcium hydroxide addition (R-Ca-R), and the crystallization method is characterized by evaporating to dried or appearance of white crystals.

To evaluate the phosphate extraction method, KH2PO4 solution, phosphorite rocks and igneous rocks with rare or slight weathering were tested. As to the new R-Ca-R method, phosphate solution and phosphorite rocks had over 96% phosphate covert to calcium phosphate in reaction with calcium hydroxide. From dissolution of fine-grind rocks to final silver phosphate crystallization, all igneous rocks and phosphorites yielded enough well-crystallized silver phosphate. The δ18OPO4 values of igneous rocks are 6.4‰ - 8.0‰, consistent with the characteristics of fresh and slightly weathered igneous rocks. The differences (less than 0.5‰) within 2σ (0.6‰) analytical errors of all repeated samples indicate satisfactory reproducibility of this new phosphate extraction method.

E-mail: daniel_ibarra@brown.edu

Keywords: triple oxygen isotopes, opal, chert, sediments

The oxygen-18 isotopic composition ($\delta^{18}O$) of silica preserved in oceanic sediments is an important archive of Earth's temperature and/or seawater $\delta^{18}O$ from the Archean to present. Recent advances in high-precision measurements of both $\delta^{18}O$ and $\delta^{17}O$ values have been used to provide additional constraints on what the oxygen isotopic composition of chert reflects about past conditions. Here, we examine the effects on the triple oxygen isotopic composition of chert that occurs during transformation and recrystallization of biogenic opal-A to opal-CT to microquartz in deep sea sediments. We studied late Miocene to present samples from the Sea of Japan at ODP Site 795 and measured biogenic diatom opal-A, opal-CT, microquartz chert, and 'altered' opal-A samples—previously measured for $^{\delta 18}O$ values only—for both $\delta^{18}O$ and $\delta^{17}O$ values. We find that $\delta^{18}O$ decreases and $\Delta'^{17}O$ increases with depth, coincident with the conversions from diatom opal-A to opal-CT to microquartz. Silica samples deviate from the trend expected for triple oxygen isotopic equilibrium with modern seawater. To explain these data, we developed a model that shows that local temperature gradients and pore fluid $\delta^{18}O$ profiles in combination lower the measured opal-CT and microquartz $\delta^{18}O$ values and raise the $\Delta'^{17}O$ values relative to the initial opal-A, but deviate from triple oxygen isotopic equilibrium with seawater. We find that a steeper local temperature gradient and a larger influence of hydrothermal alteration of basalt at the base of the sediment column (which lowers pore fluid $\delta^{18}O$ values) in the past explain both the measured $\delta^{18}O$ and $\Delta'^{17}O$ values of the opal-CT and microquartz. The diagenetic processes taking place in the Japan Sea do not explain a large portion of the existing Archean to present triple oxygen isotope chert data, which likely require either changes in the oxygen isotopic composition of the source water (i.e., ocean water) and/or alteration by meteoric fluids. Further, our data demonstrate that the triple oxygen isotopic composition of preserved chert need not represent surface conditions, but instead may reflect processes that occur in subsurface sediments at elevated temperatures and with modified pore fluid oxygen isotopic compositions.

E-mail: theresa.nohl@fau.de

Keywords: sequence stratigraphy, oxygen isotopes, Corbula gibba, Northern Adriatic Sea

The occurrence and abundance of fossils is known to be steered by changes in the eustatic sea-level. Variations in sediment supply, sediment transport, bioturbation, erosion and accommodation space alter the concentration of fossils and the extend of time averaging systematically. These effects are well studied for the fossil record, though, an evaluation of effects on the geochemical proxy record extracted from these fossils is currently missing. We analysed the $\delta^{13}C$ and $\delta^{18}O$ record from ^{14}C- and amino-acid dated Holocene *Corbula gibba* shells from drill cores from the Northern Adriatic Sea near Piran, the Po river delta and the Panzano river. The samples cover transgression and sea level highstand since the last deglaciation. The hypothesis was that an increase in absolute age span, which is typical for the more time-averaged fossil assemblage in the transgressive succession, results in a higher range of $\delta^{13}C$ and $\delta^{18}O$ values as well, while a narrower age span from the highstand strata were expected to show a smaller range of isotope values. The first results show the expected increase in age range with sediment depth, though, the carbon and oxygen isotopic ranges decrease with a few exceptions. Possible causes are a higher variation or higher pace of environmental change during the highstand, or by diagenetic homogenisation downcore due to the increased time of exposition to diagenetic fluids and cement generation. Either way, the results give cause for concern about the extent of this bias.

Triple Oxygen Isotopic Geochemical Behaviors of Basalt Weathering

Fengtai Tong[1], Haoran Ma[1*]

1. a. International center for isotope effects research, School of earth sciences and engineering, Nanjing University , Nanjing, Jiangsu, CHINA

E-mail: mahaoran@nju.edu.cn

Keywords: Triple oxygen, Basalt Weathering, Continental weathering, Regolith

The triple oxygen isotope of seawater (δ18Osw and Δ17Osw) is determined by continental weathering and hydrothermal alteration of the oceanic crust. Exchanging between seawater and mid-ocean ridge basalt is leading to an increase δ18Osw with quickly decreasing Δ17Osw. Recent research of riverine fine-grained sediments suggested that continental weathering makes δ18Osw decline and Δ17Osw slowly increase. Therefore, these two processes might not maintain δ18Osw and Δ17Osw at the same time, indicating positive Δ17Osw and negative δ18Osw in archean, which is contradict the triple oxygen isotope of chert. The contribution of hydrothermal alteration could be well estimated, while the detail of weathering is still ambiguous. Fine-grained sediments come from various weathering profiles and lost the original information of protolith, which is not a direct material to restrict the influence of continental weathering. Because there are too many variants during continental weathering, such as temperature, rainfall, porosity, mineral composition, triple oxygen isotope of protolith and meteoric water. In this regard, we have studied the triple oxygen isotopes of four basalt weathering profiles located in different climatic regions. Our study found that δ18O of regolith (δ18OR) keeps increasing in every section, while Δ17O of regolith (Δ17OR) shows a different pattern. In the tropical zone, Δ17OR decreases slightly with increasing δ18OR, but Δ17OR decreases dramatically in the temperate region. Our result manifests that temperate, rainfall, and the triple oxygen isotope of precipitation could influence the process of basalt weathering.

Genesis of Saline Springs and Potassium-prospecting in Zhenyuan area, Yunnan

Wei Xi Qin[1*]
1. Department of Geological Engineering, Qinghai University, Xining City, Qinghai Province, CHINA
E-mail: 495975224@qq.com

Keywords: Recharge source, solute source, circulation and evolution, potassium-prospecting, reservoir temperature

Simao Basin in Yunnan province is an important salt-bearing basin in China. The Mengyejing solid potash deposit is located in the south of Simao Basin, which has a industrial exploitation value. Zhenyuan area is located in the ZhengDong salt belt of Simao Basin, and cretaceous evaporites, clastic sediments and saline spring water are widely developed in this place. Based on the hydrochemistry and isotopes ($\delta^{2}H$, $\delta^{18}O$, $\delta^{37}Cl$), this paper systematically analyzed the recharge source, solute source, reservoir temperatures, circulation evolution model of saline spring water in Zhenyuan area, and it also discussed the potash exploration prospect in study area. The hydrogen and oxygen isotope characteristics indicate that the saline springs in this study are mainly derived from meteoric water and/or ice and snow melt from the surrounding mountains (Ailao Mountain and Wuliang mountain).The element characteristics show that the solute source of saline springs is mainly derived from the leaching of halide minerals (rock salt), and partly from the leaching of sulfate minerals (gypsum, anhydrite) and Ca-carbonate minerals (aragonite, calcite, dolomite). The stable chlorine isotope characteristics show that rock salt leaching is the main Cl source of saline springs, while atmospheric precipitation recharge and water-rock interaction (volcanic rock, mudstone and sandstone) are the secondary Cl sources of saline springs. The estimated reservoir temperatures for the saline springs range from 44.3-72.4℃ and its estimated circulation depths range from 914 m to 1884 m. The hydrochemical characteristic coefficient shows that saline springs in this study are of rock salt solution filtrates genetic water, and the salt bearing strata have good sealing and high metamorphism degree. Both direct and indirect potassium exploration indexes show that Guohe village and Dahebian Village in Zhenyuan area are abnormal concentration areas for potassium exploration, which can be considered to be the most promising areas in search for potash ore.

Triple oxygen isotope of chert in South China during the Ediacaran-Cambrian transition

Haoran Ma[1*], Chenqing Li[2], Yongbo Peng[1], Bing Shen[2]
1. School of Earth Sciences and Engineering, Nanjing University, Nanjing, Jiangsu, CHINA
2. School of Earth and Space Sciences, Peking University, Beijing, CHINA
E-mail: mahaoran@pku.edu.cn

Keywords: Triple oxygen isotope, Quartz, Ediacaran-Cambrian transition, Ge/Si

As the foundation to explain the oxygen isotope of chemical sediments, the oxygen isotopic composition of the ocean has been discussed for a long time. Without paleo-ocean samples of primary nature, it is necessary to calculate δ18Osw by using minerals in equilibrium with the seawater. Based on chemical sediments and ophiolite sets, two completely different δ18Osw trends have been recovered. δ18O in calcite and silica shows a 10 ‰ increasing trend from archean to present. If the paleo-temperature is not very high, δ18Osw should have a similar curve. But the archean δ18Osw value recovered by ophiolite sets shows no difference from that of today's ocean, and this model suggests ancient chemical deposit has been altered by diagenesis. To deal with this debate, we measured the triple oxygen isotope of chert from six sections in South China deposited during the Ediacaran and Cambrian transition. Excluding contamination from detrital silicate and hydrothermal, pristine quartz precipitated from ocean records converged δ18O (~24.2‰) and 17O (~-0.145‰) following the fractionation slope between water and quartz. After analyzing the influence of diagenetic alteration, we suggest this phenomenon indicates that the Proterozoic ocean has a lower δ18Osw (about -5‰) with a positive 17O (about 0.0325‰).

The sulfur cycling process influenced by hydrothermal activities in the Cryogenian Nanhua Basin

Ping Wang[1,2], Yuansheng Du[2*], Wenchao Yu[2], Yuan Xu[2]
1. Institute of Resources and Environment, Henan Polytechnic University, Jiaozuo, Henan, CHINA
2. State Key Laboratory of Biogeology and Environmental Geology, School of Earth Sciences, China University of Geosciences, Wuhan, Hubei, CHINA
E-mail: duyuansheng126@126.com

Keywords: Neoproterozoic, Nanhua Basin, Hydrothermal activities, Sulfur isotope composition

The Nanhua Basin of South China records a nearly complete Cryogenian stratigraphic succession, including the syn-Sturtian Tiesi'ao Formation, the interglacial Datangpo Formation and the syn-Marinoan Nantuo Formation in ascending order. In the Songtao area, Guizhou Province, the Tiesi'ao and lower Datangpo (Mn-carbonate unit and the overlying black shale unit) formations are characterized by elevated CAS (carbonate-associated sulfate) $\delta^{34}S$ (+38.8-69.8‰, mean +56.0‰) and framboidal pyrite $\delta^{34}S$ values (+29.1-72.4‰, mean +54.8‰). This phenomenon is consistent with the coeval strata globally, such as Australia, Namibia and Canada, which is attributed to the low sulfate concentrations and high sulfate $\delta^{34}S$ values (e.g., Gorjan et al., 2000, 2003; Hurtgen et al., 2005; Li et al., 2012). However, the paired pyrite and CAS $\delta^{34}S$ show frequent negative sulfur isotope fractionations, and the $D^{34}S$ ($\delta^{34}S_{CAS}$-$\delta^{34}S_{pyrite}$) range from -11.6‰ to +13.5‰ with the mean of +0.7‰. Besides, the Tiesi'ao Formation show low TOC (0-2.7%, mean 0.2%) but high TS contents (0-4.6%, mean 2.4%), while the lower Datangpo Formation show high TOC (0.6-3.5%, mean 2.0%) and TS contents (0.5-4.8%, mean 2.2%), indicating that the in situ microbial sulfate reduction (MSR) cannot have been the sole control on pyrite $\delta^{34}S$, and other processes are necessary during the formation of the framboidal pyrites. The Cryogenian Nanhua Basin experienced intense hydrothermal activities, which are proved by Fe/Ti-Al/(Al+Fe+Mn), initial εNd(t)-$^{87}Sr/^{86}Sr$ crossplots and positive Eu anomalies (Yu et al., 2016 and this study). Based on these considerations, we propose that the sulfur cycling process in the Cryogenian Nanhua Basin was influenced by hydrothermal fluids which can release large amounts of ^{34}S-enriched H_2S to the water column. During the Sturtian glacial interval, material exchange between continent and ocean was suppressed, the pyrites were mainly formed through the reaction of the hydrothermal H_2S with the dissolved Fe^{2+}, resulting in the formation of large amounts of ^{34}S-enriched pyrites. After the Sturtian Glaciation, the released H_2S was partly precipitated as syngenetic framboidal pyrite and partly oxidized to sulfate, and the sulfate reservoir in the Nanhua Basin mixed with influx of open ocean seawater with relatively lower sulfate $\delta^{34}S$ (~ +30‰; Gorjan et al., 2000; Hurtgen et al., 2002, 2005), thus accounting for the unusual combination of high TS concentrations, similar strongly ^{34}S-enriched sulfur isotopic compositions for CAS and pyrite, and frequent negative $D^{34}S$ values in the Datangpo Formation. Our model provides new insights into sulfur cycling processes within a semi-restricted marine basin that are likely to have wider applicability to Neoproterozoic marine systems.

Intra-crystal variations of pyrite sulfur and iron isotopes fingerprint anaerobic microbial processes

Ruimin Wang[1*], Bing Shen[1]
1. School of Earth and Space Sciences, Peking University, Beijing, CHINA
E-mail: scorpionwrm@pku.edu.cn

Keywords: Dissimilatory iron reduction (DIR), Dissimilatory sulfate reduction (DSR), Nantuo Formation, Doushantuo cap dolostone, Ediacaran

Sedimentary and diagenetic pyrites archive the geochemical signals of microbial dissimilatory iron reduction (DIR) and dissimilatory sulfate reduction (DSR), which represent two of the earliest evolved metabolic pathways and account for the majority of anaerobic organic matter degradation in the modern ocean. DIR and DSR associate with significant fractionation in iron and sulfur isotopes, and accordingly pyrite sulfur (δ34Spy) and iron isotopes (δ56Fepy) have been applied to track the redox evolution in Earth's past. However, recent studies indicate that interpretations of bulk sample δ56Fepy and δ34Spy data are complicated by local environmental factors, obscuring the reconstructions of DIR/DSR processes and the redox landscapes in Earth's history. In order to develop a new geochemical proxy that can better constrain DIR and DSR processes and pyrite formation, in this study we conducted in situ (i.e., intra-crystal) δ56Fepy and δ34Spy analyses of two sets of diagenetic pyrite samples from ~635 million-year old sedimentary rocks in South China. The origins of these pyrite samples have been well characterized in previous studies. Pyrites from the top of Nantuo Formation were precipitated in sediment porewater with H2S diffused from sulfidic (H2S-rich) seawater, while the formation of pyrites in the basal Doushantuo cap dolostone was driven by DSR in sediment porewater with sulfate diffusion from ferruginous (Fe2+-rich) seawater. Both δ56Fepy and δ34Spy show intra-crystal variations with consistent core-to-rim trends. The Nantuo pyrite shows a core-to-rim increase of δ34Spy and a decrease of δ56Fepy, while the Doushantuo pyrite shows the opposite trends. The diffusion-advection-reaction (DAR) and coupled Rayleigh distillation models were developed to simulate core-to-rim variations of δ34Spy and δ56Fepy, respectively. The modeling results indicate that the intra-crystal isotopic variations of diagenetic pyrites are dependent on, (1) the location of DSR, i.e., water column or sediment porewater, and (2) the variation of degree of pyritization (fFe-py), which may be dominated by the relative rate of the supply of H2S and Fe2+. Our study indicates that in situ δ34Spy and δ56Fepy analyses in a single pyrite crystal can be applied to refine marine redox profile in paleoceans. Moreover, this approach could fingerprint the evolutions of DSR and DIR in the early Earth and their occurrences in other planets, such as Mars.

Impacts of paleoenvironmental evolution during Early-Middle Cambrian on organic matter accumulationA case of the Keping-Bachu area in the Tarim Basin, China

Siqi Ouyang[1], Xiuxiang Lv[1*], Jianxun Zhou[1]
1. College of Geosciences, China University of Petroleum(Beijing), Beijing, CHINA
E-mail: luxx_cup@163.com

Keywords: Paleoenvironment, source rock development model, Keping-Bachu area, Middle-Lower Cambrian, Tarim Basin

In order to understand the organic matter accumulation model of the Middle-Lower Cambrian source rocks in Tarim Basin more comprehensively, we used the experiment of TOC, major elements, trace elements, and carbon isotopes to test the samples from the Keping-Bachu area. Based on the research of sedimentary evolution, the Early-Middle Cambrian paleoenvironmental characteristics were analyzed, and the organic matter accumulation models in each period were established. The results show that the shale of the Yuertus Formation and the argillaceous carbonate rock of the Xiaoerbulak Formation in the Keping area deposited in the middle-outer ramp of the transgressive system. In the Yuertus period, upwelling and hydrothermal activity occurred, and the intensity of hydrothermal activity gradually weakened in the early stage stopped in the middle stage. The TOC, V/(V+Ni), U/Th, excess Ba(Baxs), and other indicators indicate that the organic matter abundance, paleo-productivity, and anoxic degree of sedimentary water first increased and then decreased from the first member of the lower part of Yuertus Formation to the first member and the second member of the lower part of Xiaoerbulak. The highest part was the lower part of Yuertus Formation, with the TOC average of 5.21%, the V/(V+Ni) average of 0.98, the U/Th average of 10.08, and the Baxs average of 95221×10^{-6}. In the Bachu area, the argillaceous carbonate source rocks of Xiaoerbulak and Awatag developed in the intra-platform lagoon in dry and hot paleoclimate. During the sedimentary period of the upper Xiaoerbulak Formation and Wusonger Formation, the deep lagoon made hypoxia possible. Therefore, the initial stage of the evaporation cycle is an anoxic environment, and it provides good preservation conditions for organic matter accumulation. In summary, sedimentary facies, paleogeomorphology, hydrothermal activity, sea level, and upwelling affect the paleo-productivity and redox environment, thus controlling the abundance and accumulation model of organic matter. The organic matter accumulation models in the Keping area from bottom to top are transgression-strong hydrothermal-upwelling model (the first member of the lower part of Yuertus Formation), the transgression-weak hydrothermal-upwelling model (the second member of the lower part of Yuertus Formation), the transgression-upwelling model (the middle part of Yuertus Formation), and transgressive model (The lower part of Xiaoerbulak Formation). In the Keping area, the transgression and upwelling are the basis, and the influence of hydrothermal on organic matter accumulation has two sides: promotion and inhibition. The organic matter accumulation of Xiaoerbulak and Wusonger Formation in the Bachu area is an evaporation-stratification model in intra-platform lagoon. Paleomorphology and sea-level change play a significant controlling role in this model.

Feedback Between Carbon and Nitrogen Cycles During the Ediacaran Shuram Excursion

Dongtao Xu[1], Xinqiang Wang[1*], Xiaoying Shi[1], Yongbo Peng[2], Eva Elisabeth Stüeken[3]
1. School of earth science and resources, China university of geosciences (Beijing), Beijing, CHINA
2. School of earth sciences and engineering, Nanjing University, Nanjing, Jiangsu, CHINA

E-mail: wxqiang@cugb.edu.cn

Keywords: Ediacaran, South China, Doushantuo Formation, Shuram excursion, nitrogen isotopes

The middle Ediacaran Period records one of the deepest negative carbonate carbon isotope (δ13Ccarb) excursions in Earth history (termed as the Shuram excursion). This excursion is argued by many to represent the large perturbation of the global carbon cycle. If true, this event may also have induced significant changes in the nitrogen cycle, because the carbon and nitrogen are intimately coupled in the global ocean. However, the response of the nitrogen cycle to the Shuram excursion remains ambiguous. Here, we reported high resolution bulk nitrogen isotope (δ15N) and organic carbon isotope (δ13Corg) data from the upper Doushantuo Formation in two well-preserved sections (Jiulongwan and Xiangerwan) in South China. The Shuram-equivalent excursion is well developed in both localities, and our results show a synchronous decrease in δ15N across the event. This observation is further supported by bootstrapping simulations taking into account all published δ15N data from the Doushantuo Formation. Isotopic mass balance calculations suggest that the decrease in δ15N during the Shuram excursion is best explained by the reduction of isotopic fractionation associated with water column denitrification (εwd) in response to feedbacks between carbon and nitrogen cycling, which were modulated by changes in primary productivity and recycled nutrient elements through remineralization of organic matter. The study presented here thus
offers a new perspective for coupled variations in carbon and nitrogen cycles and sheds new light on this critical time in Earth history.

Intensified continental chemical weathering linked to volcanism during the Triassic–Jurassic transition

Jun Shen[1*]

1. State Key Laboratory of Geological Processes and Mineral Resources, China University of Geosciences , Wuhan, Hubei, CHINA

E-mail: shenjun@cug.edu.cn

Keywords: Mercury, extinction, volcanism, continental sediments

Direct evidence of intense chemical weathering induced by volcanism is rare in sedimentary successions. Here, we undertake a multiproxy analysis (including organic carbon isotopes, mercury (Hg) concentrations and isotopes, chemical index of alteration (CIA), and clay minerals) of two well-dated Triassic–Jurassic (T–J) boundary sections representing high- and low/middle-paleolatitude sites. Both sections show increasing CIA in association with Hg peaks near the T–J boundary. We interpret these results as reflecting volcanism-induced intensification of continental chemical weathering, which is also supported by negative mass-independent fractionation (MIF) of odd Hg isotopes. The interval of enhanced chemical weathering persisted for ~2 million years, which is consistent with carbon-cycle model results of the time needed to drawdown excess atmospheric CO2 following a carbon release event. Lastly, these data also demonstrate that high-latitude continental settings are more sensitive than low/middle-latitude sites to shifts in weathering intensity during climatic warming events.

Genetic mechanism of authigenic chlorite in ultra-deep clastic rocks reservoir and its geological significance: inspiration from diagenetic physics simulation experiment

Sirui Chen[1], Benzhong Xian[1*], Jiaqi Li[1], Qianran Wu[1], Rongheng Tian[1]
1. China University of Petroleum, Beijing, College of Geoscience, Beijing, CHINA
E-mail: xianbzh@cup.edu.cn

Keywords: Authigenic chlorite, Genesis mechanism, Ultra-deep, Diagenetic physics simulation experiment, Southern margin of Junggar Basin

Authigenic chlorite exists widely in petroliferous basins, its effect on the quality of clastic rock reservoir in ultra-deep has been one of the hot-spot issues in globole researches. The ultra-deep clastic reservoirs in the southern margin of Junggar Basin have undergone a special burial process of "long-term shallow burial and late rapid deep burial", its diagenetic evolution is strongly influenced by volcanic materialsand authigenic chlorite is commonly found in the reservoirs. At present, the genetic mechanism of authigenic chlorite is not clear in this area, which restricts its application in oil and gas exploration. In this study, the geological burial process of "long-term shallow burial and late rapid deep burial" was taken as the constraint condition to reconstruct the process of loose sediment turning into rock through diagenetic physical simulation experiments, and combined with the actual geological data, comprehensively discusses the genetic mechanism of authigenic chlorite under the constraint condition of geological burial process and its significance to development of reservoir. The experimental results show that the geological burial process has an obvious control on the development of authigenic chlorite. The iron ions and magnesium ions required by authigenic chlorite are very sensitive to temperature and pH value. In the stage of long-term shallow buried, the combination of low temperature and dissolution of atmospheric fresh water results in low concentrations of iron ions and magnesium ions, and the lower temperature inhibits the montmorillonite which produced by volcanic ash alteration transforms into authigenic chlorite too. The above two points lead to a small amount of "thin coat" authigenic chlorite at the edge of grain in the stage of long-term shallow buried, which does not effectively inhibit the formation of siliceous precipitation. Overpressure was developed in the stage of late rapid deep burial, which not only protected the primary pores but also inhibited the transformation of montmorillonite into illite, indirectly laying the foundation for the formation of authigenic chlorite. At the same time, the organic acid charging and the gradual increase of temperature lead to the increase of concentration of iron ions and magnesium ions, and promote the transformation of montmorillonite to authigenic chlorite. Due to the low content of "thin coat" chlorite at the shallow burial stage, the crystals of late authigenic chlorite continue to grow along the early "thin coat" authigenic chlorite, which further increases the thickness of authigenic chlorite at the edge of grain, but does not occupy the intergranular pores. Authigenic chlorite in this stage strengthens the reservoir's ability to resist compaction, and inhibits the occurrence of siliceous precipitation, and effectively improves the reservoir physical properties. The surface of chlorite coat has oil wettability. The oil will be adsorbed on the surface of "thick coat" autogenic chlorite at the edge of grain after oil filling, which makes the reservoir show obvious oil wettability, and is conducive to oil migration and storage in the reservoir. Therefore, this study on the genetic mechanism of ultra-deep authigenic chlorite also reveals the geological significance of organic-inorganic synergy.

Biological matter enhanced iron release from the benthic bioturbated sediment: a case study from the Late Cretaceous sandstone, northern Saudi Arabia

YUNLONG ZHANG[1], Ziying Li[1*], Mingkuan Qin[1], Zhixing Li[1], Longsheng Yi[1], Guochen Li[1]

E-mail: z12322212@126.com

Keywords: burrows, bioturbation, biological matter, coastal sediments, iron cycling

Benthic bioturbation is a prominent function in marine ecosystem (Lohrer et al., 2004), enhancing pore-water ventilation (Jégou et al., 2001; Shull et al., 2009), oxygen and nutrition cycling (Meysman, 2014), and ecosystem productivity (Cribb and Bottjer, 2020). Here we investigated the cementation and element concentration in the benthic bioturbated sediment. The result shows that the well-preserved biological matter cemented and shaped the benthic burrows, making it highlighted from the surrounding sand grains. Micro-environments in the burrows play an important role in mediating oxidation and reduction of the iron. Reducing micro-environments are predominant in bioturbated sediments in research area where presumably have relatively high level of oxygen according to the shallow water setting and intensive bioirrigation. Reducing environment, various iron species, and enhanced hydrodynamic by bioturbation are likely accelerated the transportation and release of iron from bioturbated sediments into overlying water, which could be a potential source of micro-nutrients for ocean productivity.

Experimentally precipitated cryocalcites – towards a better understanding of complex cave archives formed at glacial-interglacial transitions.

Ozioma Carol Uwakwe[1*], Sylvia Riechelmann[1], Adrian Immenhauser[1]
1. Institute of Geology, Minerology and Geophysics, Ruhr University Bochum, Bochum, Northrhine Westphalia, GERMANY
E-mail: ozioma.uwakwe@rub.de

Keywords: Cryocalcite, experimental, morphotypes

Cryocalcites represent a specific type of speleothem precipitated from freezing ponds in caves during glacial-interglacial transitions and in the context of Dansgaard-Oeschger events. Over the past decade, considerable progress has been made concerning cryocalcite petrography, crystallography and geochemistry. Uncertainty remains, however, as the cave waters from which the cryocalcites formed are not preserved. Moreover, the number of well-constrained cryocalcites ^{230}Th/U data is still limited. Here we report, for the first time, the outcome of experimental work inducing cryocalcite precipitation in the laboratory. We apply gradually cooled, calcium-rich bicarbonate water with a known isotopic composition. The experiments include cryocalcite precipitation at temperatures of 2, 1, 0,-1 and -2^{o}C with complete freezing occuring at -2 ^{o}C and partial freezing at -1 ^{o}C. The δ_{18} O and δ^{13} C values, pH, conductivity, and alkalinity of the parent fluid were recorded before and after the experiment. The results show the significance of relevant parameters but are not accessible with regard to fossil cryocalcites. Experimental work documents a clear dependency of $\delta^{18}O_{cryocalcite}$ on the initial $\delta^{18}O_{water}$, the temperature at which the crystals precipitated, the freezing rate, the calcite saturation index of the water and kinetic effects during the cryogenic precipitation. A large increase in $\Delta^{13}C_{DIC}$ values is found between experimental fluids at the experiments' beginning and end (31.9 ‰). These maximum values coincide with the experiments running over 90 days. Reasons may include significant CO_2 degassing leading to a markedly ^{13}C enriched solution. In contrast, experiments running over seven days only record a $\Delta^{13}C_{DIC}$ of 7.11 ‰. Based on experimental data, crystal morphotypes can be placed in context with a precipitation sequence. Sharp-edged rhombohedra are precipitated first. These are followed by spherulitic types that form later only from frozen water with the solution's increasing calcite saturation index. The relation of specific morphotypes resulting from experimental parameters emphasizes the system's complexity, which must not be underestimated when exploring fossil counterparts.

Geochemical Characteristics and Environmental Implications of Trace Elements of the Paleocene in the West of Lishui Sag, East China Sea Basin

Shuai Yang[1], Qiang Fu[1*]
1. , , , , CHINA
E-mail: fuqiang@tongji.edu.cn

Keywords: Lishui Sag, Paleocene, Paleoenvironment, XRF, elemental geochemistry

Analysis of sedimentary environment during clastic formation process is of great significance for reservoir evaluation and dessert prediction. This paper focuses on the Paleocene in the West of Lishui Sag, East China Sea Basin. XRF fluorescence diffraction and carbon and oxygen isotope tests were carried out on core samples from four wells. Based on the geochemical characteristics of the samples and the changes of the ratios of the elements, combined with the lithologic characteristics and sedimentary structure, the paleoclimate, paleosalinity, paleowater depth, redox environment, paleowater temperature and other paleoenvironmental characteristics of the sedimentary period in the research area were analyzed. The results show that the Paleocene in the west of Lishui Sag is mainly in the reducing environment of brackish-salt water with weak water stratification. As a whole, the water depth shows a trend of becoming deeper, then shallower and then deeper. The upper part of E1m2 has the deepest water, the strongest reducibility and the highest salinity. The Sr element and oxygen isotopes were used to quantify the paleowater temperature. The sedimentary period of the Paleocene in the west of Lishui Sag was warm on the whole. However, the cotent of Sr becomes smaller after later deposition, so the calculated paleowater temperature is higher. In addition, oxygen isotopes are affected by diagenesis, resulting in a negative oxygen isotope value. Therefore, the calculated temperature is close to the diagenetic temperature, which needs further study. The values of Baxs, Znxs and the ratio of trace elements show that the paleoproductivity of the study area is low, and the hydrocarbon generation potential is poor. The content of nutrient elements mainly comes from terrigenous input rather than biological origin. Meanwhile, the Si/Al ratio also shows that the overall study area is greatly affected by the terrigenous input, the terrigenous intrusion characteristics gradually increased from the Yueguifeng Formation to the lower part of the Mingyuefeng Formation.

Mercury isotopes show vascular plants had colonized land extensively by the early Silurian

Mu Liu[1*], Wei Yuan[2], Daizhao Chen[1], Xinbin Feng[2]
1. Key Laboratory of Cenozoic Geology and Environment, Institute of Geology and Geophysics Chinese Academy of Sciences, Beijing, CHINA
2. Institute of Geochemistry, Chinese Academy of Sciences, State Key Laboratory of Environmental Geochemistry, Guiyang, Guizhou, CHINA
E-mail: liumu@mail.iggcas.ac.cn

Keywords: Paleozoic, Hg isotope, vascular plants, Silurian, land colonization

The colonization and expansion of plants on land is considered one of the most profound ecological revolutions in Earth's history. However, the precise timing of the onset and colonization patterns and processes remain controversial due to discrepancies between sparse micro/macro-fossil records and molecular clock results. Because land vegetation can enhance weathering intensity and terrigenous input to the ocean, changes in terrestrial plant biomass with distinct negative odd-MIF (Δ199Hg) and even-MIF (Δ200Hg) signatures have the potential to disturb the positive MIF signatures in marine sediments. By investigating secular variations in the mercury (Hg) isotopic composition of Cambrian to Permian marine sedimentary rocks from South China and peripheral paleocontinents, we highlight distinct negative excursions in both odd- and even- MIF at Stage level starting in the early Silurian. We propose that these geochemical signatures were driven by increased terrestrial contribution to ocean sediments due to the rapid expansion and accelerated diversification of vascular plants. These excursions broadly coincide with rising atmospheric oxygen concentrations and global cooling during the Paleozoic. Based on these geochemical data, we propose that vascular plants were widely distributed on land during the transition from the Ordovician to Silurian (~ 444 Ma ago), long before the earliest reported vascular plant fossil, Cooksonia (~ 430 Ma).

Revising the Mg isotopic systematics of siliciclastic components of sediments and sedimentary rocks: A new geochemical proxy of continental weathering in Earth's history

Tianzheng Huang[1*], Bing Shen[1]
1. School of Earth and space science, Peking University, Beijing, CHINA
E-mail: tzhuang@pku.edu.cn

Keywords: Saprolites, Mg isotope fractionation, South China, Carbonate, Soil clays

Continental weathering is the key geochemical process linking the terrestrial and marine systems, and has been playing the key role in the evolution of Earth System. Mg isotope is applied as a potential weathering proxy in deep time, based on increasing trend of δ26Mgsili with progressive weathering. However, it is recent studies show that Mg isotope fractionation between secondary clay minerals and dissolved Mg variates span positive to negative in different secondary clay minerals, challenging Mg applied as a weathering proxy. In this study, we find a decrease trend of δ26Mgsili with increase of weathering intensity of deep time samples. Combining our samples and modern weathering profile observation, we suggest that the trend is caused by formation and following dissolution of Mg-rich secondary clay minerals such as chlorite and vermiculite with extremely heavy Mg isotope composition. A three stages weathering model described by mixing of different Mg-bearing mineral component is developed to explain Mg isotope fractionation mechanism. In preliminary weathering stage, primary minerals dissolve and Mg poor secondary clay mineral formed causing in quantity loss of Mg and slightly increase of δ26Mgsili. Mg-rich secondary clay mineral massively forms at bottom of soil in transition weathering stage leading to abrupt increase of Mg concentration and δ26Mgsili. Further dissolution of Mg-rich secondary clay mineral in advanced weathering stage forms a decrease trend of δ26Mgsili with increase weathering intensity. Our weathering model is well applied in modern weathering profiles with different Mg isotope trend. The new Mg fractionation mechanism indicate δ26Mgsili-normalized Mg concentration, instead of previous δ26Mgsili, can be used as an effective weathering proxy in deep time, showing weathering stage, weathering intensity and other climate information.

E-mail: huxm@nju.edu.cn

Keywords: Paleocene-Eocene boundary, Carbon isotopes, Carbonate microfacies, Southern Tibet, Shallow-water carbonate platform

The Paleocene–Eocene Thermal Maximum (PETM, ~56 Ma) is a large negative carbon isotope excursion (CIE) that testifies to a massive perturbation of the global carbon cycle and has been considered to be an ancient, deep-time analogue for present and future climate change (Zeebe et al., 2016). This study presents new sedimentological, biostratigraphic, and carbon isotopic data from Yadong area in southern Tibet to evaluate the impact of the PETM on carbonate platform. The PETM beginning at the boundary between nodular and thin-bedded limestones is maintained up to the top of the thin-bedded limestone and calcareous marl interval, and is followed by recovery at the base of thick-bedded limestone interval. Microfacies analysis testifies to a regression at PETM onset from open to restricted shallow marine environments, and shallowing continued through the PETM core. Restricted lagoonal deposition was renewed during PETM recovery. These environmental changes were associated with two major turnovers of shallow-water biota, we infer that sudden biotic change at PETM onset may have been caused by the increased nutrient input related to intensified continental weathering and hydrological cycle. The smaller magnitude of the CIE observed in proximal, shallower-water strata than in distal, deeper-water strata is ascribed to enhanced primary productivity.

Paleosedimentary environment of upper Permian Linxi Formation in Zhalute Basin, Northeast China

Lei Sun[1*], Jian Zhang[1], Fei Su[1], XiongFei Bian[1], ShuWang Chen[1]
1. Energy geology, Shenyang Center of Geological Survey, China Geological Survey, Shenyang, Liaoning, CHINA
E-mail: 281270393@qq.com

Keywords: Paleosedimentary environment, the upper Permian Linxi Formation,Zhalute Basin

Zhalute Basin is located in the eastern ridge uplift zone of the Daxinganling Mountains and western subsidence zone of the Songliao Basin. The area mainly expose upper Permian Linxi Formation and late Jurassic volcanic rocks. Trace elements of dark fine clastic rocks of upper Permian Linxi Formation in Zhalute area are systematically analyzed to discuss the paleoclimate, paleosalinity and paleoredox condition. Samples are taken from Taohaiyingzi outcrop section and LD2 well in Zhalute Basin.

The ratio of Sr/Cu of the mudstone of Linxi Formation in the Taohayingzi outcrop section in Zalut Basin is 2.00~3.28 (n=12), and average value is 2.41; the ratio of Sr/Cu of the mudstone of Linxi Formation in LD2 well is 3.83~27.27 (n=12) with an average value of 10.9, and seven samples values are < 10. The results indicate that the sedimentary period of Linxi Formation in Zhalute area should be warm and humid climate(Deng et al. 1993).

The B/Ga ratio of samples from Linxi Formation in Taohayingzi outcrop section is 1.74~3.62, with an average value of 2.68, indicating freshwater environment (Wang et al. 1979); the B/Ga ratio of the samples from Linxi Formation of LD2 well is 3.31~11.74, with an average value of 6.14, indicating brackish water to saltwater environment with a tendency of dilution from bottom to top. It overall reflects the water environment of Linxi Formation is freshwater environment to brackish water and saltwater environment.

The ratio of V/(V+Ni) of mudstone samples of Linxi Formation in the Taohayingzi outcrop section in Zhalute Basin is 0.75~0.88 (n=12), with an average value of 0.79; The V/(V+Ni) ratio of mudstone samples of Linxi Formation of LD2 well is 0.67~0.81 (n=12), with an average value of 0.74. It overall reflects the water environment of Linxi Formation is anoxic and reductive environment (Jones et al. 1994).

To sum up, the analysis show that the sedimentary period of the upper Permian Linxi Formation in Zhalute Basin is warm and humid climate condition, the water environment is freshwater to brackish and saltwater, with anoxic and reductive environment.

Incision History of the Three Gorges, Yangtze River Constrained From Low-Temperature Thermochronology in the bedrock of Huangling Massif

Jianchao Su[1*]

1. School of Geography and Information Engineering, School of Geography and Information Engineering, WUHAN, Hubei, CHINA

E-mail: Alan1cug@163.com

Keywords: The Three Gorges, Yangtze River, detrital apatite, detrital zircon, AFT, AHe ZHe

Abstract: The evolution of the Yangtze River has a great significance for understanding the development of reorganization of the river networks and modern geomorphological patterns in east Asia. The Three Gorges as the key link between the upper and middle Yangtze River, and the incision history of the Three Gorges is an important part of the development of the river. Low-temperature thermochronology, such as apatite and zircon fission-track and (U-Th)/He, is one of the most important tools for uncovering the burial and erosional histories of sedimentary basins due to its relatively low closure temperatures of ~ 60 - 250°CIn this study, we use the fission track and (U-Th)/He thermochronology of apatite and zircon to calculate the exhumation rate, analyze the development of uplift in the bedrock of Huangling Massif. Based on the results of exhumation rate and cooling history, we can provide new evidence for the incision of the Three Gorges.

The spatial distribution of surface ocean primary productivity in the wake of Marinoan global glaciation

Chaochao Xing[1*]
1. School of earth and space sciences, Peking University, Beijing, CHINA
E-mail: shuofengxc@163.com

Keywords: Nantuo Formation, Microbial sulfate reduction, Microbial iron reduction, Pyrite, Iron isotope, Sulfur isotope

Termination of the Marinoan global glaciation (~650 – 635 Ma) was followed by the diversification of eukaryotes (e.g., early animals) and oxygenation of deep oceans in the early Ediacaran Period. Previous studies suggest recovery of marine primary productivity immediately before cap carbonate precipitation but after melting of the Marinoan global glaciation. Pyrite concretions from the topmost Nantuo Formation in the Yangtze Block, South China, decrease in abundance from shelf to basin facies, while their high positive S isotope values argued the development of oceanic euxinia, which required ample supply of organic matter, presumably reflecting the recovery of marine productivity. However, pyrite contents and pyrite S isotopes alone cannot uniquely constrain the extent and spatial distribution of the surface ocean organic matter production. In this study, we conducted in situ pyrite Fe (δ56Fepy) and S isotopes (δ34Spy) of pyrite concretions collected from four sections of the Nantuo Formation, spanning from shelf to basin environments. Pyrite from different sections has distinct δ34Spy and δ56Fepy values. In general, δ34Spy values display an increasing trend from shelf to basins, whereas δ56Fepy values demonstrate an opposite trend with the lowest values in the basin sections. The opposite δ34Spy and δ56Fepy onshore-offshore gradients strongly argue against hydrothermal origin, yet verify the diagenetic precipitation of Nantuo pyrite in sediment porewater. Numerical models were developed to quantify the microbial sulfate reduction (MSR), microbial iron reduction (MIR) and pyrite precipitation processes. The modeling results provide an explanation for the shallow-deep decreasing of δ56Fepy values, indicating that both the fraction of MIR (fMIR) and the fraction of Fe2+ consumed by pyritization (fpy) increase from shelf to basin sections. In addition, high δ34Spy values and pyrite contents in the basin sections also imply more intense MSR and higher supplies of H2S from sulfidic seawater. Both MSR and MIR are associated with organic matter degradation, thus suggesting that the surface ocean primary productivity displayed an unusual increasing trend toward the open ocean, which was different from the higher productivity in modern near-shore regions. We speculate that the reversed onshore-offshore gradient of surface ocean productivity might be attributed to high P concentration in the post-glacial ocean. Terrestrial riverine P supply, on the contrary, might have diluted seawater P concentration in the near-shore regions. Therefore, our result indicates that the recovery of marine productivity in the aftermath of the Marinoan global glaciation may be not controlled by the availability of nutrients, instead, the immediate recovery of productivity might have been prohibited by, e.g., low seawater pH at a high atmospheric pCO2 level in the initial melting of the Marinoan global glaciation.

Aqueous Medium Characteristics and Evolution of the Third Member of Shahejie Formation in Dongying Sag

He Zhao[1], Hongliang Wang[1*]
1. School of Energy Resources, China University of Geosciences, Beijing, Beijing, CHINA
E-mail: whliang@cugb.edu.cn

Keywords: Dongying Sag,Aqueous Medium Characteristics,Element Geochemistry, Sedimentary Environment Analysis

With the development of sedimentary geochemistry, the migration, accumulation and distribution of sediment elements and isotopes are important means to restore sedimentary environment. Element adsorption and exchange often occur between sedimentary rock and its surrounding water medium, so aqueous medium analysis can be used for paleo-environmental restoration. Through the element test of 8,721 samples from the third member of Shahejie formation in Dongying sag, the quantitative and semi-quantitative research on the paleo-sedimentary environment of the study area is carried out by core observation and geochemical data analysis. The single well aqueous medium database is established through key coring wells, which is used to analyze the relationship between the original geochemical parameters and the characteristics of aqueous medium. The method of sedimentary aqueous medium suitable for the study area is optimized. The element ratio method and element fitting method are applied to quantitatively analyze the characteristics and evolution of aqueous medium. The research shows that in the vertical direction, the element characteristics of the third member of the vertical from the bottom to the top are different. The gradually decreasing data include Ca, Mn, Sr/Ba, Ca/Mg, K/Na, V/Ni, Ni/Co, V/Cr, and etc; while the increasing one include Mg, Fe, Rb/K, Fe/Mn, and etc. It indicates a decrease in salinity and pH but an increase in Eh from bottom to top in the study area. In other words, the water body is desalinated, the alkalinity is weakened and the oxidation is enhanced. On the plane, the salinity presents the pattern of two low areas and one high area. The pH value presents two high value areas in the central strip and two low value areas on both sides. EH is distributed in a circular band, and the high value area is distributed at the edge of the depression. The central part of the depression has relatively large salinity, high pH and low eh, which indicates that the central area is in a saline, alkaline and strong reducing environment. The water medium environment with high salinity and strong reducibility is conducive to the preservation of organic matter. Most of the environment forms organic rich lithofacies and becomes a sweets spot. This study provides a method to quantitatively analyze the characteristics of aqueous medium through geochemical elements.

Geological characteristics and significance of source rocks of Mesoproterozoic Changchengian System in north of Guyang County of the northern margin of Ordos Basin

Juanping Feng[1*], Zhengjian Ouyang[2], Mengmeng Fan[1]
1. College of Geology and Environment, Xi'an University of Science and Technology, Xi'an, Shaanxi, CHINA
2. Bailie School of Petroleum Engineering, Lanzhou City University, Lanzhou, Gansu, CHINA
E-mail: fengjuanping@163.com

Keywords: North of Guyang County, Mesoproterozoic, Source rocks, Geological characteristics, Geochemistry

The development of effective source rocks is the key to Mesoproterozoic hydrocarbon accumulation in Ordos area. In this paper, the geological characteristics of source rocks in the Agulugou Formation of the Zhaertaishan Group of Mesoproterozoic Changchengian System in north of Guyang County were studied by means of field geological investigation, microscopic section identification and geochemical analysis. Researches show that the source rock is carbonaceous slate and a small amount of schist with quartz as the main mineral composition, followed by plagioclase, potassium feldspar and muscovite, and a small amount of siderite. The contents of organic carbon in the source rocks are high, and the value ranges from 0.17% to 21.62%, with an average of 5.53%. The type of organic matter is I kerogenand the second is II kerogen. The value of Ro ranges from 4.32 to 5.09, and the Tmax value is from 556℃ to 564℃. These results show that the thermal evolution of source rocks is highand is in the over-mature stage. Their NASC normalized REE patterns of the source rocks are characterized by LREE enrichment with obvious different value between LREE and HREE with distinctive negative Eu anomalies (δEu: 0.430.49). The content and ratio of trace elements indicate that the sedimentary environment of the source rocks of Agulugou Formation is an oxygen-deficient - anoxic closed environment with large water depth, weak hydrodynamic conditions and limited communication with the open sea and the sedimentary facies are desalinated lagoon facies in warm and humid climate.

Geochemical characteristics and geological significance of major elements in the lower paleoweathering crust of Benxi Formation, Ordos Basin

Yuan Zhen[1,2*], Li Qian[1,2], Dai Ya Wei[1,2], Chen Bing Bing[1,2]
1. School of Earth Sciences and Engineering, Xi'an Shiyou University, XI'AN, Shaanxi, CHINA
2. Shaanxi Key Laboratory of Petroleum Accumulation Geology, XI'an Shiyou University, XI'an, Shaanxi, CHINA
E-mail: cloud_yz@163.com

Keywords: Ordos Basin,Benxi Formation,weathering crust,major element,Paleoclimate feature

The geochemical composition of regolith can reflect its development processes and the background climatic characteristics of weathering processes, and geochemical compositions of the paleo-regolith formed in earth history can reveal the type of paleo-regolith and record paleoclimatic changes.Ordos Basin is a large petroliferous basin. After the Deposition of Ordovician, the basin was uplifted by caledonian movement, and the Silurian, Devonian and Lower Carboniferous deposits were missing. Moreover, the top of Ordovician experienced weathering leaching for 150 million years, forming a weathering crust karst zone with thickness of more than 50 meters. The development process of the weathering crust may record the paleoclimate characteristics from the late Ordovician to carboniferous of the Early Paleozoic. According to the compositions of major elements, enrichment in elemental migrations and coefficient of weathering distribution of the lower part of the Carboniferous Benxi Formation in the Ordos Basin, North China, this study suggests that: (1) The weathering crust belongs to aluminiferous bauxite type weathering crust. It is a type of rock rich in aluminum minerals and characterized by chemical deposition and mechanical deposition. The structure is coarse sugar, bean, clastic and oolitic and the main mineral composition of the rock is boehmite, boehmite and boehmite. The major element compositions of the weathering crust are dominated by the elements of SiO_2, Al_2O_3, TFe_2O_3, $CaOAl_2O_3$:$SiO_2$1.And the elements of Al_2O_3, TFe_2O_3, TiO_2, K_2O are relatively concentrated in the middle-toupper parts of the regolith while the SiO2 is slightly lost. (2) The vertical variations of geochemical proxies such as SiO_2/Al_2O_3, $SiO_2/(Al_2O_3+TFe_2O_3)$, chemical index of alteration (CIA) , residual coefficient and BA value indicate that the paleo-weathering crust formed in alkaline reduction "diving type" environment, controlled by the karst micro-topography, and the vertical upper sequence variation of aluminiferous rocks is complex . (3)The material source of the weathering crust is not only from the denuded strata above the ancient weathering crust, but also from the denuded ancient land around the basin. Comprehensive study area constant element geochemical characteristics of the ancient weathering crust, and combining to the late Carboniferous to the Permian ancient North China plate latitude migration characteristics, this paper holds that the weathering crust formed in warm humid subtropical to tropical climate and it's a silicon - aluminum clay weathering crust with low degree of desilication and aluminization. At the same time, this burial weathering crust structure plays an important role in the process of hydrocarbon accumulation, which is not only a good channel for oil and gas migration, but also an effective reservoir. Together with the overlying strata, the weathered clay layer forms a composite cap.

Keywords: volcanism,mass extincition, environmental change, mercury isotope

Intense volcanism is proposed as a driver for the mass extinction and environmental changes during the Ordovician-Silurian (O-S) transition (Lefebvre et al., 2010; Yang et al., 2019; Rasmussen et al., 2019), but evidence of a direct link was largely lacking. Mercury (Hg) enrichments in the O-S sediments have been used as a volcanic proxy to link the timing of volcanism with the record of environmental change and extinction (Gong et al., 2017; Jones et al., 2017; Bond et al., 2020; Hu et al., 2021), but it remains unclear whether these elevated Hg resulted from volcanic emission. Here we present mercury (Hg) concentrations and Hg isotope data for Upper Ordovician−Lower Silurian sedimentary strata in South China. Our new Hg data reveal two intervals of high Hg concentration coupled with generally near-zero or weak positive Δ^{199}Hg values and less negative δ^{202}Hg values, consistent with volcanic Hg source (Thibodeau and Bergquist, 2017). Both increased mercury intervals correlate with negative carbon and sulfur isotope excursions, and anoxia, supporting a link between them. The two observed episode of volcanism also correlate with the two Late Ordovician mass extinction pulses, suggesting that volcanism may have driven the end-Ordovician mass extinction. In addition, our Hg record suggests that previously unconstrained volcanism and associated environmental changes may also have played a major role in the delayed recovery in the aftermath of the Ordovician-Silurian mass extinction.

Study on sedimentary facies characteristics and sedimentary environment change of modern sedimentary body in Xi'an section of Fenghe River

Huan Meng Zhang[1], Ling Guo[1*]
1. Geological Department, Northwestern University, Xi'an, Shaan xi, CHINA
E-mail: guoling@nwu.edu.cn

Keywords: Based on the field survey, sample collection and analysis and google satellite image of modern river system in Xi'an section of Fenghe River, the river sedimentary system and geochemical element conte

Based on the field survey, sample collection and analysis and google satellite image of modern river system in Xi'an section of Fenghe River, the river sedimentary system and geochemical element content in Xi'an section of Fenghe River are analyzed, and the rock type, sedimentary facies type, sedimentary model and climate change of Fenghe river sedimentary body in this area are comprehensively studied. The results show that the lithology of the modern sedimentary body of Xi'an Fenghe river is mainly earthy yellow mudstone, gray white sandstone, argillaceous siltstone and a small amount of light gray fine conglomerate. It is a meandering river sedimentary system composed of three cycles. In this study, three subfacies were identified in the sedimentary body of Xi'an section of modern Fenghe River, namely channel filling subfacies, channel edge subfacies and flood basin subfacies; Four microfacies, i.e. riverbed retention sedimentation, point bar, estuarine fan and flood plain, develop three sets of different sedimentary sequences vertically: the lower sequence has anti rhythmic characteristics, and the middle and upper parts show obvious positive rhythmic sedimentation, indicating the process of hydrodynamic first increasing and then gradually weakening. By analyzing the changes of trace elements such as CO, Cr, Cu, Ni, Rb, Sr, V, Zn and Zr in sediments, as well as Sr / Cu, V / (V + Ni), V / Cr, Ni / Co and Sr / Ba, it is determined that the main environment during the deposition period is arid climate, accompanied by seasonal rainfall, and the water body is a brackish water environment with weak oxidation oxidation oxidation.

Differential paleogeomorphic changes in North China during the late Mesozoic: evidence from stable isotopes and clumped isotopes

Tianjie Jin[1], Laiming Zhang[1*], Katharine Huntington[2], Yixiong Wen[1], Andrew Schauer[2], Xue Gu[1], Chengshan Wang[1]
1. School of Earth Sciences and Resources, China University of Geosciences (Beijing), Beijing, CHINA
2. Department of Earth and Space Sciences, University of Washington, Seattle, Washington, UNITED STATES
E-mail: lzhang@cugb.edu.cn

Keywords: late Mesozoic, North China, topographic steps, paleoelevation, clumped isotopes

At present, the topography of China is characterized by prominent contrasts (i.e., topographic steps) in the east-west direction, which is particularly pronounced in North China (NC). Western NC is dominated by plateaus and high mountains with elevations generally >1000 m, while eastern NC is dominated by plains and low mountains with elevations generally <500 m. The topographic contrasts shape the modern climate and vegetation regionalization to some extent and also may have affected the paleoclimate and ecosystem in deep time. However, the timing of when the topographic steps in NC were established are unclear. Evaluating the surface topographic evolution of NC could provide a clue to this issue and promote the interpretation of the paleoclimate in Eastern China. In this study, we constrain the paleoelevation evolution of both western and eastern NC (i.e., Ordos Basin and Hefei Basin, respectively) during the late Mesozoic by applying clumped isotopes (Δ_{47}) and stable isotopes ($\delta^{18}O$ and $\delta^{13}C$) to paleosol carbonates. Our results suggest that the Ordos Basin maintained high paleoelevation (>1.5 km) throughout the late Mesozoic, while the Hefei Basin experienced significant paleoelevation reduction during the Early Cretaceous. Combined with paleogeographic, geophysical, and paleoecological evidence, these findings suggest that the differential paleogeomorphic changes may have formed the initial appearance of the present NC topographic steps no later than Aptian time. This topographic change may have affected the paleoclimate patterns of NC, or even the whole of Eastern China, and caused a climatic transition from dry to humid during this period.

Characterizing the occurrences of Phanerozoic marine oncoids and their secular response to paleoceanography and volcanism

Maode Wang[1], Huaguo Wen[1], Yuzhu Ge[1*], Longbin Wen[1], Huachuan Jiang[1]
1. Institute of sedimentary geology, Chengdu University of Technology, Chengdu, Sichuan Province, CHINA
E-mail: geyuzhu2021@cdut.edu.cn

Keywords: Phanerozoic oncoids, occurrence, formation process, paleo-seawater properties, volcanism

Throughout the Phanerozoic, marine oncoids, as microbially mediated carbonate coated grains, have been widely recorded in a variety of marine depositional environments. The marine oncoids are commonly thought as excellent indicators of paleoenvironmental and climatic conditions, and depositional settings. However, ambiguities still remain for the oncoids in terms of origins, formation processes and environmental meanings. To reach a better understanding of marine oncoids and their response to paleoenvironmental changes, we compiled Phanerozoic secular variation of the occurrence (abundance, size and morphology distribution) of marine oncoids, paleo-seawater properties ($\delta^{34}S$, $\delta^{13}C$, $^{87}Sr/^{86}Sr$, Mg/Ca. sea level,….) and volcanic activities, based on mass data from published literature. The initial results reveal a relationship between positive $\delta^{13}C_{carb}$ excursion and abundant occurrence of carbonate oncoids in the marine settings. Interestingly, associated and coeval with the positive $\delta^{13}C_{carb}$ excursion and abundant occurrence of onciods in marine settings, the $^{87}Sr/^{86}Sr$ and $\delta^{34}S$ can be increased or decreased. To interpretate the coupled features of $\delta^{13}C_{carb}$, $^{87}Sr/^{86}Sr$, $\delta^{34}S$ and oncoid abundance, we proposed two potential models related to continental weathering and volcanisms for the oncoid formation. In the first model featured by positive $\delta^{13}C_{carb}$, and increasing $^{87}Sr/^{86}Sr$ and $\delta^{34}S$, the oncoid formation may be related to enhanced continental weathering; while in the second model featured by positive $\delta^{13}C_{carb}$, and decreasing $^{87}Sr/^{86}Sr$ and $\delta^{34}S$, the oncoid formation may be related to volcanic activities. In the future work, more data (abundance, size and morphology) will be added to support the proposed models. We will also verify the models based on abundant occurrence of marine oncoids in the Cambrian and early Permian Period with different paleo-seawater properties.

ISOTOPE AND TRACE ELEMENT SIGNATURES OF PALEOENVIRONMENT OF GRYPHEA SHELL BANKS IN THE KALLANKURICHCHI LIMESTONE, ARIYALUR GROUP, CAUVERY BASIN, INDIA

SHILPA SRIMANI[1*], AMLAN KONER[1], ADRITA CHOUDHURI[2]

1. DEPARTMENT OF GEOLOGICAL SCIENCES, JADAVPUR UNIVERSITY, KOLKATA, WEST BENGAL, INDIA
2. DEPARTMENT OF GEOLOGY, BIRBAL SAHNI INSTITUTE OF PALAEOSCIENCES, LUCKNOW, UTTARPRADESH, INDIA

E-mail: shilpa.srimani@gmail.com

Keywords: Paleogeographic reconstructions, Kallankurichchi Limestone, Shell bank, O-isotope, Trace elements

To supplement the recent paleoenvironmental reconstruction of the Maastrichtian Kallankurichchi Limestone (KL) on the basis of field and petrographic data (Srimani et al., 2021), this paper adopts carbon and oxygen isotope geochemistry of successive growth laminae of LMg calcitic Gryphea species Pycnodonte. Thickness variation in the same lamina-successions is also taken into account. Sessile though the organisms were, their shells being highly convoluted were prone to postmortem rolling downslope. For that reason, the shells were collected only from shell banks cemented with micritic matrix to ensure that they surrogate for their endemic paleoenvironment. Samples were collected from shell banks at three different stratigraphic levels, two in the lower TST part and the other from the base of the upper HST part of the KL. The mid-level shell bank was sampled from two different localities, about 500m apart, to get an idea about lateral variation in paleoenvironment. δ13C strongly covaries with δ18O in all but one of the mid-level samples, ensuring unaltered δ18O isotopic signature from all the three shell banks. δ13C is most negative (up to -2.25PDB) in the oldest bank. This is well expected with highest influx of lighter C isotope at the base of the retrogradational part of the sequence. The pattern of age-related variation does not, however, match with lamina-thickness variation. This factor indicates that bioproductivity rate could not overcome the control of the then sea water isotopic composition. So, the observed C12 enrichment was possibly affected by the high rate of freshwater influx as indicated in already documented high content of detrital quartz in associated sediment. The shell bank paleotemperature, as calculated from the δ18O values (Median), was around 27.04^{o}C. In the mid-level the δ13C values tend to be more enriched in the heavier C isotope suggesting deepening and away from the carbonate basin margin. Concurrently the degree of dilution by detrital quartz dropped. As anticipated the temperature calculated from the shells is, on average, the lowest at the mid-level, around 23.5^{o}C (Md) on sea-bottom. At the topmost level, at the base of the HST, δ13C values again turns dominantly negative. Here too lamina-thickness variation in the targeted shell does not match, but detrital quartz content variation trend shows a strong spike. Hence the influence of fresh water influx on δ13C content seems overwhelming. Concurrently the shell bank paleotemperature increased considerably to about 24.53^{o}C (Md) because of shallowing. Depth-control on seafloor paleotemperature is thus apparent. Paleosalinity of sea water derived from the micritic matrix between the shells in the banks is generally considerably high, B/Ga and Sr/Ba ranging from 20.60-49.00 and 0.7-1.9 respectively. This high salinity of sea water, however, does not seem to correlate with the δ18O values of the shells.

Large volcanism during the Cryogenian interglaciation: Evidence for Hg and Hg isotopic from Datangpo formation black shales

Li Wang[1], Runsheng Yin[2*]
1. Institute of Sedimentary Geology, Chengdu Univerisity of Technology, Chengdu, Sichuan, CHINA
2. Institute of Geochemistry, Chinese Academy of Sciences, Guiyang, Guizhou, CHINA
E-mail: yinrunsheng@mail.gyig.ac.cn

Keywords: mercury, mercury isotope, Hg/TOC ratio, volcanism, Cryogenian interglaciation

Mercury to total organic carbon (Hg/TOC) ratios are a newly developed proxy of large volcanism in geological history. Here, we investigate Hg concentrations and isotopic composition of Cryogenian interglacial sediments in a drill core (ZK4411) collected from the Nanhua Rift Basin, South China, to understand whether large volcanism was a major driving force of the Cryogenian interglaciation. The anomalous high Hg/TOC ratios in the Datangpo black shales confirm the presence of large volcanism at the onset of the Cryogenian interglaciation. The near-zero to slightly positive Δ^{199}Hg values (0.04‰ ± 0.06‰, 1SD, n=21) in the Datangpo black shales support the deposition of volcanic Hg via wet Hg(II) deposition. Given large volcanism can emit large amounts of green house gases (e.g., CO_2) to trigger global warming and deglaciation, this study may provide a causal link between large volcanism and the termination of the Sturtian glaciation.

Zinc isotopes as a tracer for carbon cycle perturbations during onset of Carboniferous icehouse

Yutian Zhong[1], Jitao Chen[1*]

1. State Key Laboratory of Palaeobiology and Stratigraphy, Nanjing Institute of Geology and Palaeontology and Center for Excellence in Life and Paleoenvironment, Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences, Nanjing, Jiangsu, China, Jiangsu, CHINA

E-mail: jtchen@nigpas.ac.cn

Keywords: TICE, Zn isotope, paleoenvironment

The earliest Carboniferous cooling is thought to mark the onset of the Late Paleozoic Ice Age (Liu et al., 2019), which is consistent with one of the most significant variations of global carbon isotope (δ13C) record during Phanerozoic (named as 'mid-Tournaisian carbon isotope excursion', TICE, Mii et al., 1999; Saltzman et al., 2002; Yao et al., 2015; Maharjan et al., 2018a,b). Increased organic carbon burial was thought to be the cause of the δ13C positive excursion (Saltzman et al., 2000) and led to the CO2 decline. However, the possible mechanism remains controversial, including the rapid subsidence and sedimentation rate related to the Antler foreland basin (Saltzman et al., 2000), intensified ocean circulation and upwelling caused by cooling (Yao et al., 2015; Liu et al., 2019), expanded ocean anoxia (Cheng et al., 2020), and silicate weathering which was enhanced by the seed plants (Chen et al., 2021). Additionally, it is unclear whether TICE was caused by single or several triggers and the links between them.

Zn is a key trace element for lives, and the Zn-C cycle can well reflect marine primary productivity and organic carbon burial. Primary producers prefer to utilize 64Zn, and thus would result in higher zinc isotope composition (δ66Zn) (Maréchal et al., 2000; Little et al., 2014). In contrast, lower δ66Zn values correspond to a relative increase in the 64Zn-enriched input from riverine/volcanic sources or previously buried organic-rich sediments or shrink of 64Zn removal (Liu et al., 2017; Sweere et al., 2018; Chen et al., 2020). Carbonate δ66Zn has been widely used to reconstruct paleoenvironmental changes such as magmatism, silicate weathering, and burial and oxygenation of organic matter (Liu et al., 2017; Sweere et al., 2018; Chen et al., 2020; Lv et al., 2022). Here, we present the first carbonate δ66Zn record, in combination with other geochemical data (e.g., organic δ13C, δ238U, and major and trace elements), from a well-preserved, shallow-marine carbonate succession (the Malanbian section) from the northeastern Paleo-Tethys Ocean region. The Malanbian section of the South China Block was the target of previous high-resolution carbonate δ13C studies, showing a ~6‰ positive excursion in the mid-Tournaisian (Yao et al., 2015; Chen et al., 2020). We delineate the architecture (single or double peaks) and potential process of TICE during this critical climate transition through integrated geochemical proxies and careful biostratigraphic correlation.

Evidence of a Post-Shuram Recovery in Saudi Arabia? Insights from High-Resolution Geochemical Records

Muhammad Hammad Malik[1*], Ardiansyah Koeshidayatullah[1], Abduljamiu Amao[2], Adhipa Herlambang[2], Abdulwahab Muhammad Bello[2], Justin V Strauss[3], Khalid A. H Al-Ramadan[1,2]

Keywords: Ediacaran, Shuram, Gaskiers, Multiproxy, Isotopes

The Ediacaran Period records the rise of diverse metazoan assemblages coupled with profound environmental and geochemical events preceding the Cambrian Explosion. Despite numerous studies, the origin of these events, particularly the largest negative carbon isotopic excursion, also known as the “Shuram Carbon isotope excursion” remains enigmatic. In Saudi Arabia, Ediacaran carbonates are preserved in small, isolated half-grabens associated with the Ediacaran to early Cambrian Najd strike-slip fault system. However, these carbonates are relatively understudied compared to the prolific oil-bearing Phanerozoic carbonate successions in Saudi Arabia and other Ediacaran strata worldwide. Here, we examined a well-exposed up to 300 m thick Ediacaran carbonate exposure of Dhaiqa Formation in NW Saudi Arabia and conducted a high-resolution, geochemical study (δ13C and δ18O isotopes, mineralogical, elemental and TOC measurements) to decipher the occurrence, origin, and preservation of these events in Saudi Arabia and establish the possibility of correlating these events regionally and globally. Based on detrital zircon U/Pb geochronological data from interbedded diamictite strata (~570 Ma), the studied Ediacaran successions are thought to be deposited just after the Shuram-Wonoka negative δ13C anomaly event, following the Gaskiers glaciation. Overall, our results show a clear trend of recovery from the negative δ13C excursion, which has been reported in other basins across the Arabian Plate and other regions of the world. This finding highlights the possible preservation of post-Shuram recovery in Saudi Arabia and argues the origin of the Shuram excursion as a result of the Gaskiers glaciation. The correlation of these results with comparable data from different Ediacaran strata across Arabia and worldwide is promising in the sense of worldwide connectivity to the Ediacaran seas.

Keywords: stable isotopes, structural diagenesis, calcite vein

The Miocene post-rift sediments represent one of the thickest Red Sea Rift Basin deposits. Miocene sediments, historically grouped into the Raghama Formation, are exposed in the Umm Luj Basin, located in the northern part of the eastern coast of the Red Sea. The carbonates of the Raghama Formation were observed, in places, unconformably overly the Proterozoic basement and intensely fractured. Such fractures could provide insights into the structural evolution and paleo fluid flow of the Red Sea Rift Basin. However, little is known about the origin and timing of different structural-controlled diagenetic processes. This study focused on structural diagenesis of these post-rift carbonates by applying a multi-proxy geochemical analysis on calcite precipitated in veins and fault breccia and on the dolomitized host rock. The $\delta^{18}O$ and $\delta^{13}C$ isotopic compositions of calcite veins vary between -10.6 to -9.5‰ and -7.9 to -7.2‰, respectively. On the other hand, the precipitated calcite along the fault breccia indicates a heavier average isotopic composition of -6.8‰ for $\delta^{18}O$ and -4.8‰ for $\delta^{13}C$. Thus, we argue that the structural diagenesis history in the study area comprises two very distinct fluid circulation members. The first member is the deposition of lighter isotopic composition calcites, indicating vein precipitated at higher temperatures due to increasing depth or associated with hydrothermal fluids and followed by closed-system recrystallization, indicated by the high-magnesium vein that the dolomitized host rock may be buffered. The second member of a fluid flow corresponds to the heavier isotopic calcite member representing a brecciation on the near-surface regime. Our results bring a new understanding of paleo fluid circulation and also highlight the potential of the carbon and oxygen isotope proxy for structural diagenesis studies.

E-mail: bivingeo@gmail.com

Keywords: Chemostratigraphy, Geochronology, Ediacaran, Mesoproterozoic, India

The Kaladgi Basin is one of the several Proterozoic sedimentary basins of India. Located close to the current western margin of peninsular India, the basin has a binary evolutionary history with an angular unconformity separating the older deformed and younger undeformed rock sequences of the Kaladgi Supergroup, named the Bagalkot and Badami Groups respectively. Whereas the timing of deposition of the Bagalkot sediments is somewhat well constrained (>1150 Ma), that of the Badami sediments and hence, the age of closure of the basin remains tentative. Considering that the supergroup contains four marine carbonate formations which may have recorded some of the important global events of the Proterozoic, we carried out ^{206}Pb-^{207}Pb dating of the topmost carbonate horizon (Konkankoppa Limestone), and C-O-Sr isotope systematics in all the carbonate formations. The dating yielded a depositional age of 604 ± 25 (2σ) Ma for the Konkankoppa Limestone, thus pushing timing of active sedimentation in the basin well into the Ediacaran Period. The near primary $^{87}Sr/^{86}Sr$ of 0.70781 (Mn/Sr = 1.7) of the limestone is consistent with this age. These data also confirm the existence of a long duration hiatus, > 500 Ma, between the deposition of the Bagalkot and the Badami Groups. The extended sedimentation history of the Kaladgi Basin refutes a claim that the sedimentation in all the Proterozoic basins of peninsular India ended by 1000 Ma.

The $\delta^{13}C$ of all the carbonate formations appears to have preserved the primary marine signature as inferred from Mn/Sr <10, $\delta^{18}O$ > -10‰, and the absence of any relationship between $\delta^{13}C$ and $\delta^{18}O$. Limited (0 ± 2 ‰) variation of $\delta^{13}C$ of the Bagalkot carbonate horizons, suggests a steady state organic carbon burial, whereas, wide variation of $\delta^{13}C$ in the Konkankoppa Limestone, -3.5 to +2 ‰, hints at a dynamic organic carbon burial scenario; both being consistent with the C-isotope stratigraphy of the Meso-Neoproterozoic times.

Restoration of dolomite reservoirs process based on laser U-Pb dating technology: A case study of Ordovician Majiagou Formation, Ordos Basin

jingao zhou[1*], zhou yu[1], dongxu wu[1]
1. department of marin petroleum geology, petrochina Hangzhou institute of geology, hangzhou, zhejiang, CHINA
E-mail: zhoujg_hz@petrochina.com.cn

Keywords: U-Pb dating,Ordos Basin,Ordovician,dolomitization

Aiming at the problem of multiple solutions in the diagenetic pore evolution process of dolomite reservoir. Taking the Ordovician Majiagou Formation in Ordos Basin as an example, this paper studies the formation process of weathering crust karst type and mound-shoal type dolomite reservoirs of Majiagou formation by using laser ablated U-Pb in-situ dating technology and combined with carbon and oxygen isotope composition analysis and test data. The results are as follows: First, five groups of 14 age data were obtained from the dating test of 8 reservoir samples. The age of the first group of surrounding rock matrix dolomite is 444.0 ~ 494.0 Ma; The age of canine dental or leaffillings in the second group was 440.0 ~ 467.0 ma; The age of the third group of dolomite silt filler is 316.5 ~ 381.0 Ma; The age of the fourth group of grain dolomite fillings is 354.0 Ma; The age of the fifth group of grain calcite fillings is 292.7 ~ 319.0 ma; Second, the formation of matrix dolomite of Majiagou Formation is related to sedimentary or penecontemporaneous dolomitization, while the dolomitization of the cements is a little later, which is the origin of infiltration reflux-early burial dolomitization; Third, the weathered crust karst dolomite reservoir on salt has successively experienced diagenesis such as penecontemporaneous dolomitization, compaction, weathered crust karst, filling and fracture. The gypsum mold hole forms the supergene karst stage, which is filled with minerals such as seepage dolomite silt and calcite, and the porosity is reduced from 10-40% to 3-8%; Fourth, the subsalt dune beach dolomite reservoir has undergone diagenesis such as penecontemporaneous dolomitization, compaction, seabed cementation, penecontemporaneous dissolution, seepage and reflux dolomitization, filling and fracture. The primary porosity of the reservoir is 10 ~ 30%, which is reduced to 0 ~ 6% after seawater cementation. The porosity is restored to 5-15% by penecontemporaneous dissolution, and then filled with grain dolomite and calcite, The porosity finally decreases to 2 ~ 6%. The dolomitization and pore evolution restoration methods can be used as a reference for pore evolution restoration of other basins or reservoirs.

Dolomitic rock (dolostone) is a major topic in carbonate research and a complex archive of its palaeoenvironment and diagenetic pathways. Combining field and laboratory techniques (transmitted light- and cathodoluminescence microscopy, U-Pb dating, MicroXRF mapping, fluid inclusion analyses and clumped isotope thermometry, $^{87}Sr/^{86}Sr$, $\delta^{13}C$, $\delta^{18}O$), we assess the complex diagenetic succession and subsequent tectonic, hydrothermal and meteoric overprint of Paleozoic carbonates of the Middle-Late Devonian Massenkalk in Western Germany. The well-known geological and tectonic framework of the Massenkalk allows for an in-depth study of different alteration types in directly comparable lithologies. The aim is to better understand the impact of tectonic, hydrothermal and meteoric alteration events (Variscan and Post-Variscan) on multiple generations of hydrothermal dolostones and their precursors. Cathodoluminescence microscopy documents a complex paragenetic sequence ranging from marine calcite cements to multiple hydrothermal dolomites and meteoric/vadose calcites in partly dedolomitized carbonates. Fluid inclusion and clumped isotope analyses reveal temperatures between 20 and 230 °C representing individual events of fluid flow. Patterns in oxygen and carbon isotope data suggest a conservative behavior of precursor limestones and early hydrothermal dolomites during burial diagenesis. Later hydrothermal dolomites were altered by meteoric dedolomitization.

DOLOMITIZATION OF THE UPPER PERMIAN CHANGXING FORMATION IN YUANBA GAS FIELD, NE SICHUAN BASIN, CHINA

tian yongjing[1*]
1. Research Institute Co., Ltd.,, CNOOC Research Institute Co., Ltd.,, Beijing, CHINA
E-mail: tianyj10@cnooc.com.cn

Keywords: Geochemistry,Dolomitization,Reef-shoal Facies

The reef-shoal dolomite is the main reservoir of Upper Permian Changxing Formation in Yuanba gas field, NE Sichuan Province, Southern China. Dolomites vertically distribute in the upper member of Changxing Formation and laterally among reef cap, inter-reef shoal and back reef shoal facies. Different types of dolomites have similar ratios of 87Sr/86Sr(range from 0.7071 to 0.7075)which are consistent with those of dolomitic reef limestone, indicating dolomitizing fluids mainly came from synchronous seawater. Dolomitization occurred in a shallow burial low-temperature environment judged from the dolomitizing fluids temperature (40°-55°C) which is calculated from dolomite-water fractionation equation.

Even in an open-flow environment, different properties of dolomitizing fluids emerge because of the palaeogeomorphology and sea level fluctuation. (1)Relict bioclast medium-coarse crystalline reef cap dolomite has obviously negative δ18O, high Fe, Mn and slow crystal formation characteristics, suggesting the mixture of meteoric water and seawater involved in the reef cap dolomitization. (2)Microcrystal dolomite of inter-reef shoal has high δ18O, significantly high Fe, Mn, Sr and low order degree. It is closely related to the evaporated brines, though data may indicate a complex source of dolomitizing fluids. (3) Finely- medium crystalline dolomite of back reef (or shoal) owns a very low Fe, Mn value and high content of MgCO3, together with the rapid crystal formation, all of which demonstrate the normal water dolomitization features.

Early marine dolomites have been considered as potentially reliable archives for the reconstruction of past ocean physico-chemical conditions. However, this interpretation comes with significant challenges as not only can diagenetic alterations occur, but such dolomite frequently exhibits diverse fabrics with a consequent large geochemical variability. This study assesses whether the late Ediacaran dolomite (Hamajing Member, Dengying Formation) in South China can preserve geochemical representative of the original seawater in which they were formed. These dolomites contain five different fabrics (stromatolitic, micritic, oolitic, saddle dolomites and cements) and show a large variation in clumped isotopic values. Here, we aim to establish a diagenetic framework (closed versus open systems) for each dolomite fabric by combining clumped and oxygen isotopes. First, the influence of the solid-state reordering on such varied fabrics is evaluated by assuming two types of burial histories ("deeply buried" and "Hydrothermal pulse"). The results can not well account for the measured clumped isotopes in various fabrics. Therefore, the variability of clumped isotopes in the difference fabrics is mostly attributed to the alteration of diagenesis in the burial stage. In order to decipher the extent of diagenetic alteration, a quantitative framework has been established using variable water-rock ratios. Under such diagenetic framework, the micritic and stromatolitic dolomites show a closed-system behavior (low water-rock ratios = 0.06 – 0.3), while the fabrics of ooids, saddle dolomites and marine dolomite cements are buffered by hydrothermal fluids (high water-rock ratios = 1.4 – 5) during late diagenesis. This diagenetic framework highlights the extent of water-rock reactions plays a critical role in the fabric-specific variability of dolomite. This study indicates that the complex signals in early marine dolomite should be carefully evaluated when being considered as a palaeoproxy.

The in-situ U-Pb isotopic dating and clumped isotopeΔ47thermometry and their application in geological reconstruction for hydrocarbon accumulation history: A case study from Sinian Dengying FormationSichuan Basin

Anjiang Shen[1,2*], Anping Hu[1,2]
1. Department of Marine Petroleum Geology, Petrochina Hangzhou Research Institute of Geology, Hangzhou, Zhejiang, CHINA
2. /, CNPC Laboratory of Carbonate reservoirs, Hangzhou, Zhejiang, CHINA
E-mail: shenaj_hz@petrochina.com.cn

Keywords: laser-ablation in-situ U-Pb isotopic dating, clumped isotope thermometry, carbonate crystal with hydrocarbon inclusions, Sichuan Basin, Sinian Dengying Formation

Traditional methods for reconstructing hydrocarbon accumulation history in ancient marine carbonate reservoirs, such as geological analysis, fluid inclusion study, and speculation based on formation time of hydrocarbon-bearing palaeo-uplifts and traps, generally have large uncertainties and may result in ambiguous results. To upgrade the toolkit for the reconstruction of hydrocarbon accumulation history, we develop a new method by investigating samples from the Sinian Dengying carbonate gas reservoir in the central paleo-uplift of the Sichuan Basin, southwestern China. The key innovation of this method is to constrain absolute ages of hydrocarbon accumulation with the application of the carbonate mineral in-situ U-Pb geochronology. This new dating technique involves two key steps: investigate abundance and distribution patterns of liquid and gaseous primary hydrocarbon inclusions with optical microscopes; choose carbonate crystals appropriate for U-Pb geochronology, which are inclusion-free but contemporaneous with those containing hydrocarbon inclusions. In this study, three stages of hydrocarbon accumulation were identified in the Dengying gas reservoir by U-Pb dating of dolomites: late Silurian. The first stage of oil accumulation occurred at (416±23) Ma; late Permian to early Triassic. The second stage of oil accumulation occurred between (248±27) Ma and (246.3±1.5) Ma; Yanshan–Himalayan period. The third stage of gas accumulation occurred between (115±69) Ma and (41±10) Ma. The hydrocarbon accumulation history of the Dengying gas reservoir reconstructed in this study is consistent with the tectonic-burial history, basin thermal history and hydrocarbon generation history, indicating that the new method is a reliable way for reconstructing the hydrocarbon accumulation history.

Formation Mechanism of the Terminal Ediacaran Dolomite Cements: Implications for reconstructing Neoproterozoic seawater chemistry

Jiale Chen[1], Meng Ning[1*], Anjiang Shen[2], Xianguo Lang[1], Feng Liang[2], Yijiang Zhong[1], Pan Xia[1], Huaguo Wen[1]
1. Institute of Sedimentary Geology, Chengdu University of Technology, Chengdu, Sichuan, CHINA
2. Institute of Petroleum Geology, PetroChina Hangzhou, Hangzhou, Zhejiang, CHINA
E-mail: ningmeng@cdut.edu.cn

Keywords: Ediacaran, Dengying Formation, Dolomite Cement, Magnesium Isotopes, Seawater chemistry

The Ediacaran marine dolomite cement has been considered as the premium material that records seawater chemistry. However, with various types and debatable origins, dolomite cement was underutilized for reconstructing seawater chemistry. There are two viewpoints regarding the origin of the Ediacaran marine dolomite cements, one is primary precipitation from seawater, which holds clues of ancient seawater geochemical signals, and another is mimetic dolomitization of early unstable carbonate minerals. Thus, it is still controversial whether marine dolomite cement can be used as an effective proxy for reconstructing the ancient seawater geochemical compositions. In order to explore the formation mechanism of different types of dolomite cements in the Dengying Formation as well as deciphering the unique seawater chemistry of the Precambrian ocean, we investigated the dolomite cements from the Ediacaran Dengying Formation from the Sichuan Basin. The Ediacaran dolomite cement can be divided into two types, i.e., later diagenetic crystalline dolomite (including bladed dolomite, silty-fine dolomite, medium-coarse dolomite) and fibrous marine dolomite (including fascicular fast dolomite, fascicular slow dolomite and radial slow dolomite). The length-slow cements are considered as primary dolomite based on optical characteristics, well-preserved chemical bands and cathodoluminescent bands, while length-fast dolomites are speculated to be formed by mimetic dolomitization. The δ^{26}Mg values of micritic-micro dolomite matrix and fascicular fast dolomite cement are similar (-1.9 ~ -2.0‰), inferring a same origination by mimetic dolomitization of high-Mg calcite or aragonite precursors. The δ^{26}Mg values of the fascicular slow dolomite (-1.8 ~ -1.9‰) and radial slow dolomite (-1.9 ~ -2.0‰) show a certain difference about 0.2‰, suggesting different Mg isotopic fractionation caused by the change of precipitation rate. The δ^{26}Mg values of later diagenetic crystalline dolomite vary greatly, with enriched Fe, Mn and Sr contents, indicating alterations of diagenetic fluids during burial stage. Thus, the primary length-slow dolomite, directly precipitated from the Ediacaran "Dolomite Sea", can be used as robust seawater chemistry archives.

The response of Mg isotopes to dolomitization during sea-level fluctuations: Constraints on the hydrological condition of massive dolomitization system

Zhongya Hu[1*], Weiqiang Li[2], Zhiguang Xia[2]
1. School of Ocean and Earth Science, Tongji University, Shanghai , Shanghai, CHINA
2. School of Earth Sciences and Engineering, Nanjing Univerisity , Nanjing, Jiangsu, CHINA
E-mail: zhongyahu@tongji.edu.cn

Keywords: Edwards group, Cretaceous seawater chemistry, Albian, dolomites, Texas

Marine dolomitization processes are characterized by complex variations in hydrological conditions and pore-fluid chemistry. Deposition of massive dolomitized carbonates on the Comanche Platform of south Texas, USA, during the Albian coincided with multiple fluctuations in sea level, thereby providing an ideal setting to study the response of magnesium isotopes to dolomitization during eustatic sea-level change. In this study, we conducted Mg, C, and O isotope analyses and complimentary mineralogical and petrographic investigations of dolomitized massive carbonates of the Albian Edwards Group in the Comanche Platform. Petrographic observations indicate that the carbonate rocks in the studied units were not altered by deep burial diagenesis or hydrothermal fluids. Based on our petrographic observations and the trace element and C-O isotope data, we infer the dolomites were formed via syn-depositional dolomitization during a period of low sea level. The δ26Mg values of the dolomites increase rapidly from −2.5‰ to −1.8‰ in the basal part of the unit, reflecting a change in fluid chemistry caused by dolomitization in a restricted marine environment. Subsequently, δ^{26}Mgdolomite values gradually decrease back to their initial value of approximately −2.5‰ due to seawater replenishment during transgression. The observed variability in dolomite δ^{26}Mg values reflects changes in the connectivity of the platform with the open ocean during marine transgressions. However, the δ^{26}Mgdolomite values do not vary with the high-frequency eustatic sea-level change recorded in the lithological variations, indicating uniform hydrologic conditions of the massive dolomitization system despite the hydrodynamic variations in the sedimentary environment. Therefore, we propose that massive dolomitization systems are mostly fluid-buffered and, as a result, Mg isotopes of dolomites can be used to trace changes in the paleo-marine environment, such as basin connectivity.

Constraining selective dolomitization by Mg isotopes: A study of mottled limestone in the middle Permian Qixia Formation, Sichuan Basin

Yuting Wu[1], Meng Ning[1*], Huaguo Wen[1]
1. Institute of Sedimentary Geology, Chengdu University of Technology, Chengdu, Sichuan Province, CHINA
E-mail: ningmeng@cdut.edu.cn

Keywords: Mg isotopes, fabric-selective dolomitization, Qixia Formation, penecontemporaneous exposure

Traditional geochemical methods play important roles in understanding the enigma of 'dolomite problem', however, cannot provide unique constraint on the dolomitization process and sources of Mg^{2+}. Recent years, Mg isotopes have opened a new window in unraveling the 'dolomite problem'. To further promoting the application of Mg isotopes in the study of dolomite genesis, we measured Mg isotopic composition of selective dolomitized limestone from the middle Permian Qixia Formation in Sichuan Basin. Based on petrographic observation, dolomite mottle and calcite matrix were micro-drilled respectively for geochemical analysis. The carbon and oxygen isotopic compositions of the dolomite mottles ($\delta^{13}C$ = -0.12 ~ 3.48‰ and $\delta^{18}O$ = -10.26 ~ -3.2‰) are similar to calcite matrix ($\delta^{13}C$ = -1.54 ~ 3.52‰ and $\delta^{18}O$ = -8.71 ~ -3.69‰) indicating that the fabric-selective dolomitization might be penecontemporaneous with limestone deposition. The Mn, Fe and Sr concentrations of dolomite mottles show that fabric-selective dolomitization occurred at a subaerial oxidic environment. The $\delta^{26}Mg$ variation pattern supports penecontemporaneous exposure and early diagenetic dolomitization process. At the relatively high sea-level, the lime wackestone to packstone deposited, and then the sea-level dropped, subaerial exposure leaded to the formation of karstified cavities, where selective dolomitization was constrained. The limestone precipitation - subaerial dissolution - dolomitization cycle occurs repeatedly with the fluctuations of sea-level and results in the selective dolomitization of the mottled limestone.

Origin of dolomite in the lower Triassic Feixianguan Formation, Northeastern Sichuan Basin: Evidence from magnesium isotopes

Pan Xia[1], Meng Ning[1*], Anjiang Shen[2], Xianguo Lang[1], Feng Liang[2], Jiale Chen[1], Yuting Wu[1], Huaguo Wen[1]
1. Institute of Sedimentary Geology, Chengdu University of Technology, Chengdu, Sichuan, CHINA
2. Institute of Petroleum Geology, PetroChina Hangzhou, Hangzhou, Zhejiang, CHINA
E-mail: ningmeng@cdut.edu.cn

Keywords: Dolomite problem, magnesium isotope, the Feixianguan Formation, Sichuan Basin

The origin of the dolomite from the lower Triassic Feixianguan Formation(FXG Fm.), Sichuan Basin remains controversial. Previous studies suggested the FXG dolomite was formed by multiple dolomitization processes, e.g., meteoric mixing zone dolomitization, seepage-reflux dolomitization and burial dolomitization. Here, We analysed the third member of the FXG Fm. at the Hekou section, NE Sichuan Basin, which is composed of oolitic dolomite, sandy dolomite and micrite dolomite. Based on detailed sedimentary facies analysis, we recognized three lithofacies and two sedimentary facies associations (ooid shoal and back-shoal lagoon), suggesting a shallow carbonate platform margin environment with periodic eustatic change. Meanwhile, multiple shallowing upward cycles of sedimentary sequences can be recognised by facies assemblage. We also measured the major and minor elements (e.g., Ca, Mg, Fe, Mn, Sr, Al, etc.), carbon and oxygen isotopes ($\delta^{13}C$: -1.3 to 0.7‰; $\delta^{18}O$: -9.1 to -4.5‰) and Mg isotopic compositions of the dolomite ($\delta^{26}Mg$: -2.23 to -1.93‰). The stratigraphic variation of $\delta^{26}Mg_{dol}$ is coincident with the depositional cycles, suggesting the dolomitization might be periodic and coupled with the sea-level oscillation. As dolomitization fluids experience changes in $\delta^{26}Mg$ values during dolomitization processes, the intra-cycle stratigraphic $\delta^{26}Mg_{dol}$ profile reflects the dolomitization processes. Our study indicates that the dolomitization pattern of the FXG dolomite is penecontemporaneous sabkha model coupled with seepage-reflux dolomitization model. When sea-level fell, the ooid shoal facies gradually evolved as back-shoal lagoon facies, and with the intensified evaporation, microcrystalline dolomite began to formed via penecontemporaneous sabkha model. Such process is characterized by a downward decreasing $\delta^{26}Mg_{dol}$ profile of the lagoonal dolomite. Meanwhile, the dense porewater flowed back and infiltrated downwards, resulting in the dolomitization of the underlying oolitic dolomite layers. Such process is collectively known as seepage-reflux model, supported by a downward increasing $\delta^{26}Mg_{dol}$ pattern of the shoal facies. In sum, our study provides a testable approach to investigating the formation mechanism of the lower Triassic FXG dolomite.

Origins of the Lower Ordovician Dolomite and Main Controlling Factors for Reservoir Formation in the Tarim Basin

Xunyun He[1,2*], Anjiang Shen[1,2], Ran Xiong[1,2], Lili Huang[1,2], Tianfu Zhang[1,2]
1. Hangzhou Research Institute of Geology, PetroChina, Hangzhou, Zhejiang, CHINA
2. Key Laboratory of carbonate reservoirs, CNPC, Hangzhou, Zhejiang, CHINA
E-mail: hexunyun@sina.com

Keywords: origin of dolomite, geochemical proxies, petrological observation, main controlling factors of the development of the dolomite reservoir, Lower Ordovician, Tarim Basin

The Ordovician in the Tarim Basin, NW China is rich in oil and gas resources. Limestone and related reservoirs are mainly developed in the Middle and Upper Ordovician, and a large amount of oil and gas has been proved and produced. However, a massive dolomite occurred in the Lower Ordovician (including the Penglaiba Formation and the third and fourth member of the Yingshan Formation (collectively referred to as the Lower Yingshan Member), which have been confirmed by exploration to be able to form large-scale reservoirs, but no massive oil and gas discoveries have been made. In order to further clarify the origin of the Lower Ordovician dolomite and the main controlling factors of the development of the dolomite reservoirs, a systematic petrological and geochemical analysis was made. The results show that the Lower Ordovician dolomites are mostly distributed in thick layers and blocks in a large area, and vertically the lower strata are mostly dolomite, while the proportion of dolomite in the upper strata decreases; the lithology is mainly medium-fine crystalline dolomite, a small amount of very fine crystalline dolomite and grain dolomite. The residual grain structures or phantoms are usually observed in the medium-fine crystalline dolomite and very fine crystalline dolomite; combined with geochemical parameters such as carbon and oxygen isotopes, strontium isotopes, trace elements, rare earth elements, fluid inclusion measurements, and cathodoluminescence, it is believed that the Lower Ordovician dolomite in the Tarim Basin was formed in the early diagenetic period, and the middle and late diagenetic periods were superimposed with buried dolomitization; the development of the dolomite reservoirs is mainly controlled by high-energy facies, exposure dissolution and dolomitization.

Linking penecontemporaneous subaerial exposure and dolomite formation: Evidence from modern dolomite crusts forming in Brejo do Espinho, Brazil

Meng Ning[1*], Judith A. McKenzie[2], Crisogono Vasconcelos[2,3], Chenqing Li[4], Bing Shen[4]

4. School of Earth and Space Sciences, Peking University, Beijing, CHINA
E-mail: ningmeng@cdut.edu.cn

Keywords: dolomite crust, Mg isotopes, early diagenesis

The occurrence of modern microbial dolomite crusts in Brejo do Espinho (LBE), a hypersaline coastal lagoon located approximately 100 km east of Rio de Janeiro, Brazil, has been well documented in surficial deposits exposed aerially during dry periods when lagoon water levels are lower. This lithified dolomite serves as an exceptional modern analogue for decoding the penecontemporaneous diagenetic lithification processes and associated dolomite formation mechanisms. A previous study proposed that the early lithification of the crust during subaerial exposure under intensified semiarid conditions promotes the formation of well-ordered stoichiometric dolomite (Bahniuk et al., 2015). However, very limited information exists on the penecontemporaneous subaerial exposure and its influence on biogeochemical processes that are favorable for dolomite formation.

In this study, three samples of modern dolomite crusts with different lithified states (well lithified and less lithified) were collected from the border of LBE. All of the crusts had experienced repeated penecontemporaneous subaerial exposure during the annual dry season. Petrological analysis indicates that the crusts comprise co-occurring high-Mg calcite (HMC) and poorly to well-ordered dolomite. These lithified crusts mainly consist of micritic dolomite peloids or clotted peloids, as well as discrete aphanitic micro-laminae, whereas microsparitic dolomite crystals are predominantly distributed in well-lithified crust and surround the micritic peloids. In order to investigate the geochemical fingerprints recorded during the early diagenetic process, we measured elemental compositions and the C-O-Mg isotope values of the crusts. Low Fe and Mn concentrations reflect the formation of dolomite under aerobic conditions (Land, 1980), while higher Sr concentrations of well-lithified crust (mean value ~3000 ppm), which are contrary to Sr loss during the dolomitization process, indicate primary bacterial induced dolomite precipitation (Sánchez-Román et al., 2011). In general, the Mg isotopic composition (δ^{26}Mg) of the LEB crust (mean value -3.02‰) is lighter than other published values (Shalev et al., 2021), possibly indicating different dolomitization processes and Mg sources (including EPS bonded Mg^{2+}, porewater and dissolved HMC) for the different dolomite samples. The average ^{18}O value for the three different LBE crusts is 1.1‰ VPDB, indicating equilibrium with a relatively evaporated water. Additionally, there is no significant difference in the δ^{13}C values among the three different LBE crusts, which show more negative δ^{13}C value (mean value -8.6‰ VPDB) than the unlithified carbonate mud in LBE (δ^{13}C = -1.2‰ VPDB) (Bahniuk et al., 2015), suggesting the incorporation of ^{13}C depleted organic carbon during early biogeochemical diagenesis.

Thus, we propose that the biogeochemical processes related to decaying microbial mats under oxic conditions played an important role in the diagenetic dolomite formation. During the penecontemporaneous subaerial exposure, the respiration of aerobic bacterial communities produces CO_2 which lowers pH (Sánchez-Román et al., 2008) and increases the dissolution of primary HMC. Meanwhile, microbial degradation of EPS liberates bonded Mg^{2+}. At the same time, supersaturation due to strong evaporation and evaporative pumping of porewater represent different steps towards the enrichment and stabilization of Mg^{2+}. Finally, these combined

processes induce the transition of HMC to dolomite (micritic dolomite) or direct dolomite precipitation (microsparitic dolomite).

Evidence for primary organogenic dolomites in the late Ediacaran Dengying Formation, South China

Qian Xiao[1], Zhenbing She[1,2*]

1. School of Earth Sciences, China University of Geosciences, Wuhan, Hubei, CHINA
2. State Key Laboratory of Biogeology and Environmental Geology, China University of Geosciences, Wuhan, Hubei, CHINA

Keywords: Shibantan Member, microbial mats, organic matter, massive dolostone, microbialites

Dolomite forms massive dolostones in Paleozoic and Precambrian sequences but rarely occurs in Holocene sediments which are commonly associated with microbial mats in highly evaporitic and alkaline environments such as coastal sabkhas, hypersaline lagoons and inland saline lakes. Although dolomite is difficult to precipitate at low temperatures under abiotic conditions, previous laboratory experiments have demonstrated that extracellular polymeric substances (EPS) can break the kinetic barriers for dolomite nucleation. However, unlike modern dolomites that have been extensively reported, confirmed occurrences of ancient primary dolomite are rare, likely due to poor preservation of primary sedimentary textures in Precambrian dolostones. In this work, we conducted a comprehensive mineralogical study of Late Ediacaran carbonates of the Shibantan Member, Dengying Formation in the eastern Yangtze Gorges area, South China. The Shibantan carbonates are characterized by calcite layers intercalated with millimeter-thick, dolomite-rich layers that contain up to 50% dolomite and exhibit an anastomosed structure akin to microbial mats. The dolomite-rich layers typically contain well-ordered, micritic-microlitic dolomite rhombs that are closely associated with organic matter. Microstructures resembling EPS were found between the dolomites within microbial mats, while small amounts of Mg-containing carbonate mineral nanoaggregates were also preserved, which closely resemble primary dolomites in modern microbial mats. Based on these observations, we propose that the Shibantan dolomites were formed by the gradual ordering of proto-dolomite or high magnesium calcite through a microbially induced transformation. The positive correlation between the occurrences of microbialite and dolostone abundance in both the Precambrian and the Phanerozoic supports the involvement of microbial mediation in the formation of massive dolostones. In microbially-dominated, anoxic oceanic environments with a relatively high Mg/Ca ratio, growth of organogenic primary dolomite in microbialites, along with subsequently superposed dolomitization events, likely have controlled the formation of some massive dolostones in the geological history.

U-Pb dating, elements, and C-O-Sr-Nd isotopes of dolomite veins and rock acoustic emission in the Sichuan Basin, China: Implications for genetic mechanism of natural fracture in carbonate reservoirs

Shaohui Wang[1], Chen Zhang[1*], Huaguo Wen[1]
1. Chengdu University of Technology, Institute of sedimentary geology, Chengdu, Sichuan Province, CHINA
E-mail: zhangchencup@163.com

Keywords: Fracture, Carbonate reservoirs, fracture dolomite cement, U-Pb dating, C-O-Sr-Nd isotopes

Natural fractures in carbonate reservoirs can significantly improve the permeability of the carbonate reservoir by acting as seepage channels. Moreover, the fractures themselves can provide space for oil and gas storage and control the development of solution pores and caves. Therefore, they are important to the evaluation of the distribution of hydrocarbon sweet spot sites in carbonate reservoirs. The Deng IV Member of the Gaoshiti-Moxi Block in the Sichuan Basin is a typical carbonate reservoir with large natural gas reserves. Since the Paleozoic, the Gaoshiti-Moxi Block has experienced multi-stage tectonic movement and many natural fractures have developed. Previous studies on the gas bearing property of the Dengying Formation in the Sichuan Basin mainly focused on the regional structure, reservoir lithology, pore structure, and sedimentary characteristics, paying little attention to natural fractures. Moreover, the formation time and mechanism of the natural fractures remain unknown, restricting the efficient development of gas extraction in the Dengying Formation. Using fluid inclusions of fracture dolomite cement, C-O-Sr-Nd isotope, rare earth elements, and U-Pb dating and combined with rock acoustic emission test, the present study accurately traced the origin of fluids filling these fractures, and constrained the time of fracture formation. Based on high temperature and high pressure triaxial rock mechanics experiment, the history of paleotectonic stress in the Gaoshiti-Moxi Block was reconstructed to reveal the fracture formation mechanism of carbonate reservoirs in the Deng IV Member. Micron CT imaging was used to clarify their contributions to the reservoir capacity and connectivity. The results show that tectonic fractures in the study area developed in three stages: Stage I, the Early Cambrian Yangtze Plate was extensively uplifted. The central Sichuan paleo-uplift was under the strong dynamic background of NEE-trending extension, leading to the oblique crossing of fault strikes along the NEE principal stress direction, existing SEE direction, and near-EW direction and the occurrence of a local dextral shear stress field near the fault zone. This further led to the formation of NWW-trending relaxed shear fractures within or near the existing fault zone. In this context, fluids from the Deng IV Member invaded NWW-trending relaxed shear fractures during ~558–550 Ma. Stage II, the Late Silurian Yangtze Plate collided with the Cathaysia Plate, forming compression-torsion stress field and then NEE-trending shear fractures in the Gaoshiti-Moxi Block. In this context, fluids from the Deng IV Member and the underlying Dengying III Member invaded NEE-trending relaxed shear fractures during ~425–420 Ma. Stage III, the Late Permian Sichuan Basin was wholly uplifted under the influence of the Emei taphrogeny, where the central Sichuan paleo-uplift was under an EW-trending tensile stress environment. Consequently, near NS-trending tensile fractures formed in the Gaoshiti-Moxi Block under the near EW-trending tensile stress field. In this context, high temperature fluids related to basaltic magma of Mount Emei invaded near NS-trending tensile fractures during ~258–250 Ma. Micron CT imaging revealed that the development of fractures increases the reservoir capacity and connectivity of carbonate reservoirs, which are important factors for the formation of high-quality hydrocarbon bearing reservoirs.

Early diagenesis and dolomitization of island carbonates in the South China Sea: Lessons from Calcium isotope signature

Yangrui Guo[1*]
1. State Key Laboratory of Isotope Geochemistry, Guangzhou Institute of Geochemistry, Chinese Academy of Sciences, Guangzhou, Guangdong, CHINA
E-mail: guoyr@gig.ac.cn

Keywords: Reef carbonate, calcium isotope, carbonate diagenesis, dolomitization

Carbonate rocks in reef islands can be used to investigate how their isotopic compositions are modified by water-rock interactions during diagenesis, which is an important consideration when using these rocks as archives of paleo-environmental conditions. We investigated the diagenetic history of reef carbonate sediments in a core (well NK-1) from the margin of Meiji Reef in the South China Sea using stable Ca isotopes (δ44/40Ca). We present a model for diagenetic alteration that quantitatively explains the observed δ44/40Ca variations under different diagenetic conditions (i.e., meteoric versus marine diagenesis). The model can account for changes in the fluid advection rate, sedimentation rate, carbonate recrystallization rate, and seawater δ44/40Ca values. Our results identified significant stratigraphic variability in carbonate δ44/40Ca values, which are the consequence of variable types of diagenesis or the relative importance of seawater- versus sediment-buffered diagenetic conditions. An extreme excursion to lower δ44/40Ca values, along with low δ13C and δ18O values, was likely caused by a low advective fluid flow rate when the carbonate sediment was deposited, exposed at the surface, and diagenetically altered. The observed Ca isotopic fractionation was associated with regional tectonism and sea-level changes during reef development. Our results also suggest that the δ44/40Ca fractionation factor between carbonate and seawater for dolomite may be lower than that of its precursor calcite by up to 0.6‰. As such, the Ca isotope systematics of dolomite in reef island settings may be not close to equilibrium during its formation. This study has significant implications for the δ44/40Ca variations in ancient carbonates that have been used to document secular changes in seawater δ44/40Ca values, as well as paleo-environmental reconstructions based on reef limestone and dolostone archives.

Formation mechanism of selective dolomitization in stromatolites from the Tonian Weiji Formation, North China

Junyao Kang[1,2], Chenqing Li[1], Lin Dong[1*]
1. School of Earth and Space Sciences, Peking university, Beijing, CHINA
2. Department of Geosciences and Interfaces of Global Change IGEP, Virginia Tech, Blacksburg, VA, UNITED STATES
E-mail: lin.dong@pku.edu.cn

Keywords: selective dolomitization, stromatolite, Tonian

Selective dolomitized carbonates are common in the Phanerozoic, especially in the Cambrian and Ordovician carbonates. Previous studies conclude that selective dolomitization is related to diagenetic process. Bioturbation, Mg2+ bearing fluids reflux and depositional environment change may induce selective dolomitizations. In the Precambrian, the selective dolomitic carbonates are also recorded in stromatolite from the Tonian Weiji Formation. The Tonian Period marks a critical interval of Earth history as it connects the relatively static Mesoproterozoic Era and the extremely dynamic Neoproterozoic Era. Dolomitic stromatolites from the Weiji Formation are possible archives for decoding selective dolomitization and paleoenvironmental changes. In this study, we applied systematic petrological and geochemical analysis to stromatolitic carbonates in the Weiji Formaiton, Jiangsu Province.

In the Weiji Formation, three types of dolomitization are recognized on the basis of petrographic and geochemical data. Types I and II are selective dolomitization in dolomitic limestones. In Type I, dolomitization occurs selectively in the matrix. In Type II, dolomitization preferentially occurs in dark stromatolitic laminae. In Type III dolomitization, both the matrix and stromatolites are pervasively dolomitized to form dolostones. Under the guidance of petrographic observations, sample powders were collected by using a hand-held micro-drill for elemental compositions analysis, carbon and oxygen isotopes analysis. Magnesium to calcium ratios (Mg/Ca, mol/mol) of dolomitic samples show positive linear relationships with carbonate associated ferrous iron (Fecarb) and manganese (Mncarb). Carbon (δ13Ccarb) and oxygen (δ18Ocarb) isotopes also have a positive linear relationship. Rare Earth Elements of dolomitic samples are characterized by LREE depletions, MREE enrichments, positive yttrium anomalies, and a lack of europium anomalies. Geochemical results suggest an early diagenetic dolomitization, which possibly occurred in the iron reduction zone and under the influence of bottom seawater. The selective dolomitization processes are mainly controlled by heterogeneous compositions and primary structures of stromatolites. Iron-bearing rings in dolomite of dark-layers in type II stromatolites indicate that organic matter degradation and microbial activities may play an important role in dolomitization processes. Fecarb, Mncarb, δ13Ccarb and δ18Ocarb data of stromatolites show that dolomitization fluids in the Weiji Formation may have originated from mixed bottom seawater and pore water, indicating that early Neoproterozoic seawater or pore water may be enriched in ferrous iron.

Solid evidence suggests Neoproterozoic fibrous dolomite cement precipitation postdated matrix dolomitization

Lei Jiang[1*], Anjiang Shen[2]
1. Key Laboratory of Cenozoic Geology and Environment, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, CHINA
2. PetroChina Hangzhou Research Institute of Geology, PetroChina Hangzhou Research Institute of Geology, Hangzhou, OTHER - NON USA, CHINA
E-mail: lei.jiang@mail.iggcas.ac.cn

Keywords: Dolomitization, fibrous dolomite cements, carbonate U-Pb dating, clumped isotopes, diagenesis, Neoproterozoic "dolomite sea"

The higher abundance of dolomite in the Neoproterozoic compared to that of the Phanerozoic has been linked to elevated marine Mg/Ca ratios, and a hypothesized "dolomite sea" that promoted widespread syn-sedimentary fibrous dolomite cements precipitation. Here we provide new uranium-lead (U-Pb) chronology, clumped isotope thermometry ($T_{\Delta47}$), combined with $\delta^{13}C$ and $\delta^{18}O$, and trace element geochemistry measurements for different types of dolomites, include bulk dolomite matrix (BD), fibrous dolomite cement (DC1), and late sparry dolomite cement (DC2 and DC3), in three Neoproterozoic dolostone profiles from China. The Ediacaran U-Pb ages coupled with nearly identical, low $T_{\Delta47}$ temperatures (average at ~50 ºC) for BD and DC1 dolomites, imply that these dolomites were either syn-depositional or early diagenetic. Some DC1 dolomites yield slightly younger (~20 to 50 Ma) U-Pb ages than the BD dolomites, suggesting that they were early diagenetic products formed after matrix dolomitization. The estimates of $\delta^{18}O_{water}$ values for dolomitizing fluids suggest that both DC1 and BD dolomites were precipitated from highly evaporated seawater. In contrast, DC2 and DC3 dolomites filling in vugs and fractures have much younger U-Pb ages (mostly <525 Ma), higher $T_{\Delta47}$ temperatures (>95 ºC), and lower Sr and U contents, consistent with the paragenetic sequence based on petrographic evidence that they were deeper burial diagenetic products. A synthesized diagenetic model with evaporative dolomitizing water evolved from anoxic, ferruginous to sub-oxic and/or oxic, non-ferruginous conditions is responsible for the decrease of Fe and Mn concentrations in global DC1 and BD dolomites throughout of the Neoproterozoic time. This study suggests that the widely distributed Neoproterozoic fibrous dolomite cements may be a later diagenetic feature, and thus calls into question their use in paleoclimate reconstruction, and as a principle line of evidence for the Neoproterozoic "dolomite sea" hypothesis.

E-mail: uditabansal.geo@gmail.com

Keywords: Authigenic Fe-silicate, Glauconite, Precambrian, Shallow-marine, Geochemistry, 'Pseudomorphic' replacement

Authigenic Fe-silicates are a rare occurrence in Precambrian and therefore holds significant information about the ocean geochemistry. An integrated approach involving petrography, mineralogy and geochemistry reveals the origin of authigenic shallow marine-originated glauconitic sandstones of Proterozoic Gandikonta Formation, Cuddapah basin, southern India. X-ray diffractograms confirm the Fe-silicate as 'glauconite' with characteristic basal reflection (001) at 10.03Å. Petrography reveals dark green colour glauconite in two modes of occurrence as completed 'evolved' and a partially 'evolved' varieties. Partially 'evolved' variety exhibits the replacement texture within K-feldspar, mica and quartz grains while completely 'evolved' variety leaves no trace of substrate. Mica-replaced glauconite exhibits effects of pressure solution. A thin rim of iron oxides often concurs the glauconites. Geochemical studies further reflect the 'evolved' to 'highly-evolved' stage of maturation with K_2O content of glauconite ranging from 6.72% to 9.56% while the Fe_2O_3 (total) content varies from 4.56% to 18.87%. The avg. Al_2O_3 content of glauconite is 21.18% and the avg. SiO_2 content is 50.56%. The chemical composition of glauconite in Gandikonta Formation are comparable to many Precambrian equivalents. The high K and Si content reflects the replacement of K-feldspar and quartz by glauconite respectively. The simultaneous addition of Fe with constant K corroborate the 'pseudomorphic' replacement of substrate. The low Fe_2O_3 (total) content of glauconite may be related to either non-availability of Fe Precambrian shallow seas or weakly sub-oxic depositional condition. In either case, Precambrian glauconites differ from their Phanerozoic counterparts by the significantly lower content of Fe_2O_3 (total) and shallower depositional setting.

Keywords: Mid-Proterozoic, Gaoyuzhuang, North China, Cr isotope, Sulfur isotope, Eukaryote

Oxygen availability is crucial for the evolution of eukaryotes in geological history, but the redox conditions of the mid-Proterozoic atmosphere–ocean system remains vigorously debated. Previous geochemical studies suggested a very low mid-Proterozoic atmospheric oxygen level probably below 0.1–1% of the Present Atmosphere Level (PAL) with weakly oxygenated surface ocean, which may have suppressed the early evolution of eukaryotes in the ocean. A recent study, however, revealed a pulsed oxygenation event that was recorded in shallow marine carbonate of the middle Gaoyuzhuang Formation (at ~1.57 Ga, North China) with atmospheric pO_2 up to ~4% PAL based on iodine speciation, and is associated with the earliest known multi-cellular eukaryotic fossils. To elucidate whether this pulsed oxygenation was limited to local shallow seawaters or could also reflect an increase in atmospheric oxygen, chromium (Cr) and carbonate-associated sulfate (CAS) sulfur isotopes in the middle Gaoyuzhuang Formation were studied in two sections of the North China Platform. The results show a positive shift in authigenic Cr isotope from -0.18‰ to +0.66‰, followed by a decline to -0.16‰. This suggests a rise in atmospheric oxygen sufficient to initiate oxic Cr cycling and isotope fractionation (pO_2 > 0.1–1% PAL). This positive Cr isotope excursion was associated with a transient positive shift in $\delta^{34}S_{CAS}$ from ~20‰ to ~50‰, and a subsequent decline to ~10‰, providing independent evidence of atmospheric oxygenation. This oxygenation may have enhanced oxidative terrestrial weathering, increasing sulfate input to the ocean, and thus stimulated bacterial sulfate reduction and pyrite burial in deep anoxic seawaters. This is broadly consistent with previous results of carbonate I/(Ca+Mg) and Ce anomaly, but also reveals a lag between shallow seawater and atmospheric oxygenation. Fluctuated redox conditions and decoupled oxygenation between shallow seawater and atmosphere during the mid-Proterozoic may help to account for the current debate.

Ultrafine fabrics and organominerals as indicator of microbial dolomite in deep time: An example from the Mesoproterozoic of North China

Yali Yuan[1], Xiaoying Shi[1,2*], Dongjie Tang[2,3], Qing Shi[2,3], Xinqiang Wang[1,2]

Keywords: Mesoproterozoic dolomite nucleation, Extracellular polymer substances (EPS), Nanoglobules, Utrafine fabrics, Organo-mineralization, Anoxic-suboxic conditions

Both laboratory experiment and modern environment studies show that primary dolomite can precipitate at low temperature (≤ 60°C) only when microbes were involved. Vast dolomites in mid-Proterozoic have long been suspected to be the results of microbial mediation, but direct evidence is rare. To reveal their origin, an integrated study was conducted on dolostone of the Mesoproterozoic Wumishan Formation (~1.48 Ga) of North China using multiple techniques. The results show that the Wumishan dolostone contains abundant multiscale organominerals that associated closely with fossilized extracellular polymeric substances (EPS) and putative bacteria. These micro-fabrics are strikingly similar to those recognized in dolomite precipitates produced in laboratory culture and modern sabkha environment, suggesting microbial origin. In the Wumishan samples, nanoglobules (60–200 nm) are well preserved, they preferentially attach to EPS filaments and tend to merge into polyhedrons (3–8 μm) that in turn coalesce into microspheres (20–60 μm). EDS analysis revealed a successive decrease in carbon from nanoglobules to microspheres with the increases of Mg and Ca contents, implying an increased mineralization. Nanoglobules may have derived from EPS degradation in nucleation, and served as seeds for subsequent growth of polyhedrons. Microsphere, as a basic building block in dolostone, can transform into rhombohedral crystal via neo-morphogenesis. Petrographic and XRD analyses show that the dolostone is dominated by ordered dolomite and was formed in peritidal environments with thriving microbial community. Iodine species, redox sensitive elements, Ce anomalies, and C−O isotopes suggested that the environment was dominated by anoxic to suboxic conditions, with low P but high Si contents in seawater.

Our study offered direct evidence of microbial origin for the Mesoproterozoic dolostone, providing new insights into the “Dolomite Problem”. The massive development of microbial dolostone in the Mesoproterozoic points to a specific ocean chemistry, where low oxygen and active bacterial metabolisms may have played crucial roles in precipitating dolomite. The coexistence of abundant microbial components and multiscale organominerals can be taken as textural evidence for microbial dolomite and signatures of life-environment interactions in deep time.

Constraining the redox landscape of Mesoproterozoic mat grounds: A possible oxygen oasis in the 'Boring Billion' seafloor

Tianyi Jia[1], Bing Shen[1*]
1. School of Earth and Space Sciences, Peking University, Beijing, CHINA
E-mail: bingshen@pku.edu.cn

Keywords: Pyrite, Sulfur isotope, DAR model, Wumishan Formation, North China

The Earth's middle age or the 'Boring Billion' (~1.8 to ~0.8 Ga, billion years ago) represents one of the most enigmatic intervals in Earth's history, characterized by the absence of significant carbonate carbon isotope excursions and the sluggish evolution of eukaryotes. It is widely accepted that the atmospheric O_2 level was extremely low (<1% PAL or <10% PAL) and the ocean remained predominantly anoxic with the development of sulfidic (H_2S-enriched) continental margins. It is suggested that 2-10% of seafloor euxinia was sufficient to deplete some micro-nutrients in the ocean inventory, such as Mo and Cu, which are essential for nitrogen-fixation for eukaryotes. However, recent studies report multicellular fossils and episodic/sporadic inception of oceanic oxidation in Mesoproterozoic. These findings imply the possible occurrences of oxygen oasis that provided habitable niches for eukaryote evolution. Such oxygen oasis likely developed at shallow marine seafloor covered with microbial mat, where O_2 produced by benthic cyanobacteria resulted in the oxygenation of seafloor. Therefore, in order to constrain the habitability of Mesoproterozoic oxygen oasis, it is essential to reconstruct the O_2 fugacity in the seafloor. In this study, we analyzed pyrite sulfur isotopes and pyrite contents of the Mesoproterozoic Wumishan Formation (~1.4 Ga). The Wumishan Formation is composed of cyclic deposition of, in a shoaling upward sequence, the subtidal calcareous shale, massive thrombolitic dolostone, and microbial laminated dolostone. Both microbial laminated dolostone and thrombolytic dolostone precipitation involved with microbial activities, and thus might record the redox condition of putative oxygen oasis in the Mesoproterozoic oceans. We apply the One-Dimensional Diffusion-Advection-Reaction (1D-DAR) model to simulate syndepositional pyrite formation in sediments. Sedimentation rate can be well constrained by the sedimentary cycles. The modelling results indicate that more than 60~80% of H_2S that was generated in microbial sulfate reduction (MSR) was reoxidized, and that organic matter supply, both from surface water and seafloor, was limited. Thus, our study indicates that the seafloor could be substantially oxygenated in Mesoproterozoic, even when the atmospheric O_2 level was extremely low. Shallow marine seafloor covered with microbial mat may function as the oxygen oasis, providing habitable niches for the evolution of eukaryotes.

The Mesoproterozoic Oxygenation Event

Huajian Wang[1], Shuichang Zhang[1*]
1. Key Laboratory of Petroleum Geochemistry, Research Institute of Petroleum Exploration & Development, Beijing, CHINA
E-mail: sczhang@petrochina.com.cn

Keywords: Mesoproterozoic, Oxygen, North China, Yanliao Basin, Xiamaling Formation, Gaoyuzhuang Formation

Oxygen, one of the most essential elements for the survival of eukaryotes, plays a crucial role in the emergence and evolution of eukaryotic life. The accumulation of oxygen is one of the most important characteristics that distinguish Earth from other planets in the solar system, which is also considered to be the key factor influencing the birth and evolution of complex life forms. The oxygenation process of the Earth surface has long been viewed to be episodic with two critical intervals occurring in the early Paleoproterozoic (2.45–2.10 Ga) and the late Neoproterozoic (0.80–0.54 Ga), with a 1.3-billion-year-long low oxygen period in between. Recently, increasing independent works carried out by different scientific teams in the Yanliao Basin, North China are demonstrating that the atmospheric oxygen concentrations had reached >4% PAL (present atmospheric levels) at least during 1.59–1.56, 1.44–1.43, and 1.40–1.36 Ga. These estimated values are higher than the previously recommended values of <0.1–1% PAL. Such a scenario discovered in the Yanliao Basin is consistent with the synchronously deposited strata in Australia and Siberia, pointing to a Mesoproterozoic oxygenation event (1.59–1.36 Ga) between the two major oxygenation intervals during the Proterozoic. This Mesoproterozoic oxygenation event is coupled with the break-up of the Columbia (Nuna) supercontinent, the formation of organic-rich shales and Fe-Mn deposits, and the early innovation of eukaryotic algae, indicating that the geological and biological co-evolutionary processes control the Earth surface system.

Keywords: Shennongjia Group, micro-Raman, I-1350/I-1600, degradation of organic matter

Microbial degradation of organic matter is one of the main drivers of the biogeochemical cycles and provides principal insights into the sedimentary environment. However, it is a big challenge to identify the different microbial degradation processes of organic matter in deep time. Here, we illustrate that micro-Raman spectrometry of organic matter collected from limited strata intervals would provide insights into microbial degradation. Over 800 individual micro-Raman spectra of organic matter and 10 micro-Raman imaging are acquired from the Taizi formation (~1250 Ma) of the Shennongjia Group in South China. The Raman spectra data suggest that the organic matter is typically disordered but substantially different in the Taizi Formation. Specifically, the intensity ratio of *I*-1350/*I*-1600, a parameter reflecting the structure of organic matter, displays distinct temporal variations. The upper Taizi Formation is characterized by lower *I*-1350/*I*-1600 values, varying from ~0.8 to 1.0, relative to those of the lower Taizi Formation, which is located from ~1.0 to 1.8. No correlation is observed between the *I*-1350/*I*-1600 ratios, peak metamorphic temperatures, $\delta^{13}C_{org}$, and TOC contents. We attribute the diverse forms of kerogen structures observed in the Taizi Formation to different microbial degradations, which alter the functional groups of organic matter. The higher *I*-1350/*I*-1600 values indicate more recalcitrant organic matter, which might be caused by more severe aerobic microbial degradation.

Keywords: Mesoproterozoic, north China, Milankovitch cycles, Gaoyuzhuang Formation, negative carbon isotope excursion, oxygenation event

Earth oxygen concentration is closely interrelated to tectonic activity, biodiversity and climate evolution. The Mesoproterozoic earth, which between the GOE (ca. 2.43-2.22 billion years ago) and NOE (in late Neoproterozoic), experienced frequent redox environmental fluctuations. Recent studies of the upper part of Gaoyuzhuang Formation (Fm) (ca.1.60-1.54 Ga) in north China suggested that the Earth then experienced an oxygenation event that is characterized by a negative carbon isotope excursion, and it may have caused the expansion of eukaryotic life. But the duration of the events, which hint their origin mechanism, remains uncertain. Here we report a floating astronomical time scale based on the extracted Milankovitch cycles from the carbonate-dominated strata of the Member three of the Gaoyuzhuang Fm, in which the oxygenation event was reported. High-resolution magnetic susceptibility (MS) and anhysteretic remnant magnetization (ARM) series were obtained from the stratigraphic sections in the Jixian and Yanqing regions, north China. Rock magnetic experiments suggest that the magnetic parameters were dominated by input flux of the exogenous paramagnetic minerals, flux of which was likely controlled by the orbital-forced climatic changes. Our results demonstrate that the negative $\delta^{13}C_{carb}$ excursion and the interpreted transient oxygenation event had a duration of ~1.7 myr and ~ 6.2 myr, respectively. In the Yanqing section, the calculated duration of this corresponding pulse oxygenation event detected by I/ (Ca+Mg) is ~6.2 myr, and the short-term oxygen-filled atmosphere period is ~1.5 myr. By comparing Yanqing and Jixian Section, the large multicellular eukaryote fossils appear in the strata that is ~6.7 myr younger than the beginning of oxygenation event, ~3.3 myr younger than the oxygenation of deep water, and ~2.2 myr younger than the $\delta^{13}C_{carb}$ curve reaches its minimum.

E-mail: hguo@cug.edu.cn

Keywords: Mesoproterozoic, Gaoyuzhuang Formation, Redox, Sulfur isotope

The early Mesoproterozoic (1.6 - 1.4 Ga) is a critical stage for oxygenation of Earth's surface and early eukaryote evolution. However, the relationship between both is vague. Here, we provide new carbonate associated sulfate (CAS) sulfur isotopic compositions ($\delta^{34}S_{CAS}$) and trace elements from the 1.6 to 1.55 billion-year-old Gaoyuzhuang Formation in multiple sections, Yanshan Basin, North China, to investigate the temporal and spatial variation of ocean redox conditions. New and collected $\delta^{34}S_{CAS}$ data from four sections (Pingquan, Kuancheng, Qianxi and Jixian sections) reveal similar sulfur isotopic excursions, but the differences in absolute values indicate spatial heterogeneity of sulfur isotopic compositions, which may link to marine low-sulfate concentrations and oceanic redox stratification. The most elevated $\delta_{34}S_{CAS}$ values appeared at the top of the Second Member of the Gaoyuzhuang Formation, followed by distinct negative excursions at the bottom of the Third Member, suggesting a dynamic sulfur cycle and seawater redox status during this period. Combined with previous reported carbon and sulfur isotopes and some redox proxies (e.g., Ce anomalies, manganese-rich deposit, I / (Mg + Ca) and Fe speciation), we suggest that at least two oxygen rising events occurred in the Gaoyuzhuang Formation: (1) the bottom of the Second Member and (2) the bottom or middle part of the Third Member. Different sections show asynchronous oxygenation pulse, indicating that the redox status was spatial heterogenous within the Yanshan Basin. The spatial heterogeneity may be controlled by facies and paleogeographic locations. Considering the decimeter-scale multicellular eukaryote occurred in the middle part of the Third Member, it is consistent with the oxygenation pulse, we argue that oxic bottom water condition may be a critical factor for early eukaryote evolution.

Pulsed oxygenations during Mesoproterozoic in North China Platform

Sun Longfei[1*]

1. School of Earth Sciences and Resources, China University of Geosciences (Beijing), Beijing, China, CHINA

E-mail: sunlongfeijkl@163.com

Keywords: Wumishan Formation, pulsed oxygenation, I/(Ca+Mg), C-S isotopic

Mid-Proterozoic (1.8–0.8 Ga), the critical stage for the origin and early evolution of eukaryotes, is a transitional period in the Earth oxygenation. However, the oxygen levels in the atmosphere-ocean system during this period remain debated, and thus limited our understanding to the co-evolution of life and environment. Recent studies revealed several episodes with “high” oxygen levels during mid-Proterozoic, but the possible causes for these short-lived oxygenations are still controversial. In order to further constrain the redox conditions in mid-Proterozoic atmosphere and shallow seawaters, thick peritidal carbonate successions (up to ~3000 m) in the Wumishan Formation (ca. 1.52–1.47 Ga) on the North China Platform have been chosen as target. Using petrographical and multiple geochemical proxies on three well-exposed sections, two pulsed increases of I/(Ca+Mg) (>2.6 mmol/mol) in Member I (~1.52 Ga) and lower part of Member IV (~1.48 Ga) were identified, respectively. Accompanied with the two intervals, negative Ce anomaly (~0.7) and low Mn/Sr ratio were also recognized, indicative of pulsed oxygenation in shallow seawater. This interpretation is also supported by sedimentological evidence that shows abundant water-column precipitated carbonate muds in the oxygenated intervals but rich seafloor precipitated aragonites in the neighboring intervals. The former requires moderate oxygenated conditions to remove carbonate inhibitors from water column through oxidation (e.g., Fe2+), while the latter requires the presence of Fe2+ under more anoxic conditions to inhibit carbonate precipitation from water column. The increase of δ34SCAS by ~30‰ during the latter stage of each pulsed oxygenation, possibly indicates atmospheric oxidation events, which led to the increase of sulfate input from oxidative weathering on land, and promoted elevated bacterial sulfate reduction and pyrite burial. According to the high I/(Ca+Mg) ratios (much higher than the Precambrian baseline 0.5 mmol/mol), and a semi-quantitative calculation, an oxygen level of >2.5% PAL was estimated for these two intervals. The negative shift in δ13Ccarb by 1.5‰ associated with the late stages of the intervals are likely caused by rapid remineralization of dissolved organic carbon with the expansion of oxygenated seawater, which is one of the significant causes to push the oxygenated seawater back to anoxic. The pulsed oxygenations identified in this study (~1.52, ~1.48 Ga), together with previously recognized short oxygenations (e.g., ~1.64, ~1.58, and ~1.44 Ga), likely imply that the mid-Proterozoic redox conditions were highly dynamic, with several intervals of high oxygen levels against an overall low backdrop. This study may shed light on oxygenation processes and give new perspectives on co-evolution of life and environment in mid-Proterozoic.

Keywords: Seismic sedimentology,Seismic attributes,Channel sand body,Multi-attribute clustering,RGB fusion

Shallow water delta is a special sedimentary system in the interactive environment of rivers and lakes. The lithology combination changes rapidly in space and is sensitive to the change of water depth, which often forms the coexistence of thin interbeds and thick sandstone deposits. It is a key and challenging work to accurately identify and characterize channel sand body using seismic data under the condition of no enough wells in the sea area. In this study, the shallow water delta deposition of Paleogene Hua Gang Formation in T gas field area of East China Sea Basin is selected as an example. The author explores the method of using seismic multi-attribute fusion technology to accurately characterize the river channel in shallow water delta system. Six types of thirty-eight seismic attributes reflecting different geological information are extracted for river channel identification in the target area, and the most sensitive attributes to geological conditions are selected in each class of attributes. The physical meaning of various attributes is analyzed to identify the differences between different river structures. The multi-attribute clustering analysis based on FCM algorithm is used to reduce data dimension and reduce redundancy. Three seismic attributes that reflect the boundaries of geological bodies and lithological characteristics are selected for RGB fusion to highlight the overall characteristics of river distribution in this area, and enhance the characterization of the boundaries of channel sand body. It provides practical value for the next favorable target prediction of channel sand body.

Various structural slope-breaks types and their petroleum geological significance

Weidong Xie[1*], Hua Wang[1], Si Chen[1], Xiaopeng Li[1]
1. School of Earth Resources, CUG, Wuhan, Hubei, CHINA
E-mail: xwd@cug.edu.cn

Keywords: Structural slope-break, Sequence architecture, Sedimentary features, Reservoir distribution

Yinggehai Basin is a Cenozoic transition-extension petroliferous basin in the orientation from northwest to southeast that has experienced multi-stage tectonic movements, by which the accommodation space evolution has been controlled. The long-term activity of syn-sedimentary faults formed complex and diverse types of structural slope-break, which affects the sedimentary processes and infills. Five types of structure slope-break have been classified with the discussion of their control on petroleum accumulation. The slope-breaks are developed controlled by the No. 1 boundary fault of the Yingdong slope zone, which includes: flexure slope-break, multi-step flexure slope-break, flexure fault terrace slope-break, multi-step fault terrace slope-break, and fault-controlled steep slope-break (Fig. 1).

Type is developed in MeishanFormation, Huanliu Formation, and Yinggehai Formation. The sedimentary infills are similar to type , which is featured by lowstand slope fans, basin fans, and highstand distal gravity fans. Type is mianly developed in Huangliu Formation during the accelerated thermal subsidence period, and the boundary faults are inactive. The whole Huangliu Formation is characterized by large-scale axial gravity flows and submarine fans. Type is developed in Sanya Formation and Meishan Formation. During the sedimentary period of the Meishan Formation, the study area is also in the thermal subsidence period, but the boundary fault activity is further weakened, and the sedimentary infilling is composed by the lowstand gravity flow fans and highstand deltas. Type is mainly developed in Sanya Formation within the thermal subsidence period, boundary fault activity is weakened, and the secondary small faults are sporadically developed, which controls the distributions of lowstand fan deltas. Type is mainly developed in Lingshui Formation, which is in the fault-depression transition period, the boundary fault activity is relatively strong, and the fan delta deposits are dispersed in lowstand, highstand, and transgressive systems tracts.

The research results present a case reference for the classification of structural slope-break types and have a certain significance for the distribution and prediction of oil and gas reservoirs in the study area.

Research on provenance and sedimentary system of Qintong Sag, Subei Basin, China

Rui Jiang[1], Zhen Liu[1*]
1. College of geoscience, China university of petroleum(Beijing), Beijing, CHINA
E-mail: liuzhenjr@163.com

Keywords: seiemic frequency division technology,provenance,seismic facies,seismic attributes,sedimentary system,Qintong Sag

In order to meet the demand of oil exploration in Qintong Sag.It is necessary to understand provenance and sedimentary facies. Previous studies believed that the provenance of the 3rd Member of the Funing Formation of Qintong Sag came from the Western Wubao low uplift, the southern Taizhou uplift and the southwestern slope do not provide provenance, the exploration potential in the middle and southeast of the sag has been neglected. But we found that the sedimentary facies and sand body distribution in central Qintong Sag,are quite different from previous views, so as to determine the provenance and sedimentary system, firstly, the sequence division model is determined based on logging and 3D seismic which was managed by frequency division technology. Sedimentological methods such as the distribution characteristics of sandstone composition maturity, heavy mineral content and sandstone granularity, the variation tendency of the angle of progradational reflection and seismic facies distribution are used to qualitatively or semi-quantitatively characterize provenances at different times. Combined with the distribution of seismic facies,seismic attributes, loggingand logging lithology combination characteristics to determine the sedimentary facies distribution, and finally determine the sedimentary system. The 3rd Member of the Funing Formation is divided into two third-order sequences, the lower sequence can be divided into LST, HST and TST, the upper sequence is divided into LST. Provenance studies showed that the compositional maturity and heavy mineral content are low in northwest, southeast and north, but high in central and southwest,the granularity of sandstone distribution showed that The granularity of sandstone is lower in northwest, southeast and north, and higher in central and southwest.The angle of progradational reflection is the largest,when the seismic survey line of low TST about 15° , the seismic survey line of the HST and LST strikes about 310°~330°30° and 60°. Those analysis suggests that there are three provenance systems in Qintong Sag,the provenance of the central Qintong sag comes from the Taizhou uplift in the south of the study areanot the Wubao low upliftthe provenance of the north sag comes from the Liangduo uplift. There are six types of seismic facies. In general, progradational reflection and filling reflection are only found in the south and southeast of the study area, continuous,high to moderate amplitude,medium frequency parallel reflection are mainly developed in the northwest, the scale of progradational reflection and filling reflection gradually decreases from the early stage to the end stage of strata, it shows that this period is a process of lake level rise and hydrodynamic weakening.Fan delta and shallow lake subfacies are mainly found in the central area of Qintong Sag. Combined with the research of provenance and sedimentary facies, the multi-source sedimentary system of Qintong Sag was established for the first time.It is pointed out that the southern direction of the study area is the development area of high-quality reservoirs. The fan delta sedimentary system in the southeast is a favorable area for exploration.

Prediction of high-quality clastic rock reservoirs under the constraint of source and sink in the middle and deep layers of the Paleogene, Bohai Sea

xiaojun pang[1,2*], guanmin wang[1], xiaofeng du[2], qingbin wang[2], puyuan cui[2]
1. School of Geosciences, China University of Petroleum, Qingdao, Shandong, CHINA
2. Bohai Petroleum Research Institute, Tianjin Branch of China National Offshore Oil Corporation Limited, Tianjin, CHINA
E-mail: pangxiaojunupc@163.com

Keywords: High-quality reservoir, source-sink, clastic rock, Paleogene, middle-deep layer, Bohai Sea

In recent years, the middle and deep layers have gradually become the focus of oil and gas exploration in the Bohai Sea. Middle-deep reservoirs are characterized by deep burial and strong physical heterogeneity. Especially for reservoirs buried deeper than 3000m, the porosity is generally less than 15%, the permeability is less than 10mD, and it has entered the stage of low porosity and low permeability. However, there are also a large number of high-quality reservoirs with porosity greater than 15% and permeability greater than 10 mD in low-porosity and low-permeability reservoirs. Such reservoirs have become the key targets for oil and gas exploration in the middle and deep layers (over 3000m deep) in the Bohai Sea. Accurate comprehensive seismic interpretation data is particularly important. Various types of clastic rock deposits such as delta and sublacustrine fans are developed in the middle and deep layers of the Bohai Sea. Based on the analysis of cast thin sections, physical properties, and various analytical and laboratory data, the conditions for the development of high-quality reservoirs in the middle and deep layers are as follows: (1) coarse-grained parent rock rich in potassium feldspar is the material basis for the formation of high-quality reservoirs; (2) relatively Large-scale convergence system-long extended main valley-steep provenance area is the paleogeomorphological condition for the formation of large-scale thick sandstone; (3) delta distributary channel/underwater distributary channel/mouth bar microfacies and sublacustrine fan main Channel/proximal channel microfacies are the main types of sedimentary facies for the development of high-quality reservoirs; (4) Atmospheric freshwater leaching (early dissolution pores) - dissolution (diagenetic dissolution pores) - reservoirs and source rocks are connected by faults (Enhanced dissolution and development of fractures) are the main diagenetic conditions for the formation of high-quality reservoirs after burial. On the basis of clarifying the development conditions of high-quality reservoirs, a set of methods for predicting high-quality clastic rock reservoirs has been formed: (1) Restoration of parent rock and paleogeomorphology in the provenance area to obtain the real parent rock and paleogeomorphology of the provenance area; (2) Use the seismic structure to characterize the elements of the source-sink system and quantitatively count the parameters, classify them according to the size of the paleogeomorphic conditions that form high-quality reservoirs, and finely characterize the distribution and thickness of sedimentary microfacies of various sedimentary bodies, and carry out sand-rich analysis. (3) Use seismic data to find and characterize all kinds of faults running through sandstone and source rocks; (4) Combine the above-mentioned parent rock-paleomorphology-sedimentary microfacies-faults together to predict high-quality reservoirs .

An active-learning-based lithology prediction technology and its application in seismic sedimentary analysis

Su Mingjun[1], Yuan Cheng[1*]
1. NWGRI, CNPC, Lanzhou, Gansu, CHINA
E-mail: 13772539515@139.com

Keywords: seismic sedimentary, active-learning, lithology prediction

Seismic sedimentology based on stratigraphic slices has greatly improved the accuracy of the analysis on thin sedimentary layers. However, conventional attribute slices from the data set of 90-degree phase shift or wave impedance inversion can not reflect the thickness, but the morphological characteristics of a sedimentary body. This affects the sedimentary facies maps and results to share.

A lithology prediction method based on active learning is proposed to improve the accuracy of sedimentary analysis. The active learning method is generally divided into two parts: a learning engine (or a basic learning model) and a selecting engine (or a query function). The learning engine is responsible for maintaining a benchmark classifier and learns from the labeled sample set provided by the system with the help of a supervised learning algorithm to improve the performance of the classifier. The selecting engine is responsible for selecting a sample set that has not unlabeled using a committee-based query function, and then send the set to a human annotator to label. The samples after labeled by the human annotator will be added to the labeled sample set. The learning engine and the selecting engine work alternately. After many cycles, the performance of the benchmark classifier will be gradually improved, and the whole process will be terminated when the preset conditions are met. Model prediction results show that the method we proposed can provide good prediction results in the case of less samples, and its prediction accuracy is better than the conventional semi-supervised learning method.

Meandering river deposits were developed in the Keshang Formation in the Fengnan area of the Junggar Basin, where drilling data found that the oil-bearing sandstone layer is 2-10 m thick. When analyzing the seismic sedimentary characteristics of the target layer, we used the active learning method to predict the lithology. By using the lithologic body, we obtained the stratal slice of the oil-bearing sandstone layer. In order to make the stratal slice reflect both the shape and the thickness of the sandstone layer, we improved the stratal slice technology. In other words, we first determine whether the seismic attribute of slice is sandstone or mudstone. If the attribute indicates sandstone, we further analyze whether the lithology of sampling points above and under the slice is sandstone. If so, the thickness of the sandstone can then be calculated. On the improved stratal slice, both the shape and the thickness of the sandstone body can be clearly characterized. We employed the active learning method and novel stratal slice technology to predict the thickness of the sandstone layers drilled in 9 wells in the study area, and obtained an accuracy of 80%.

Identification of seismic architectural characteristics of onshore meandering river reservoir based on Seismic Sedimentology

Bin Yang[1], Liqiang Zhang[1*]
1. School of Earth Science and technology, China University of Petroleum (East China), Qingdao, Shandong, CHINA
E-mail: liqiangzhangwxm@163.com

Keywords: Seismic sedimentology, Seismic architecture, Meandering river reservoir, Chengdao Oilfield

Reservoir architecture is an important basis for studying the sedimentary evolution of underground reservoir and the distribution of remaining oil. Taking meander-river reservoir of Guantao Formation in Chengdao Oilfield as an example, characteristics of the evolution of subsurface meander-belt deposits were studied by seismic sedimentology. Seismic lithology is performed using 90° phase wavelet and frequency fusion; lithofacies are classified by combining seismically derived lithology (shaliness) and core and wireline-log description of lithology, grain size, and sedimentary structures; seismic geomorphology is conducted on seismic stratal slices. Five meandering belts were defined in the target layer, and the sediment at the bottom is characterized by the transformation from braided river to meandering river. Five fluvial architectural elements are recognized, including fluvial valley, floodplain, meander belt, sand fan, chute channel. According to logging while drilling technology of Schlumberger, the shape model of underground point bar is established. The seismic architecture, which reflect the shapes of the point-bar sandbodies in the superimposed regions between point bars, are identified by seismic forward models. Based on the seismic architecture between point bars, distribution characteristics of point bars in the meandering belt are identified and predicted by numerous continuous seismic profiles. The identified superimposed architecture between point bars and morphometric parameters of point bars are useful for the model of the target reservoir and streamline adjustment of well site.

Seismic sedimentary interpretation and sedimentary evolution analysis of Jurassic Shaximiao Formation in Qiulin area, central and western Sichuan Basin

1*

1. , , , , CHINA
E-mail: 174427283@qq.com

Keywords: Seismic sedimentary,Fluvial facies,High resolution sequence,Sedimentary evolution, Sichuan Basin

The channel sand bodies of Jurassic Shaximiao Formation in Qiulin area of central Sichuan and western Sichuan are frequently superimposed in longitudinal period and interlaced in transverse direction. In this study, seismic sedimentology was used to characterize the sedimentary system types and temporal and spatial evolution law of Shaximiao Formation in this area, and to clarify the spatial distribution characteristics of channel sand bodies. Firstly, the isochronous interface in Shaximiao Formation is identified and the sequence stratigraphic framework is established based on high-resolution sequence stratigraphy. On the basis of establishing isochronal framework, the sedimentary facies types in this area were identified by integrating core, logging, analysis and seismic information. Then, the sandbody distribution of Shaximiao Formation was accurately characterized by using high-precision 3D seismic data, 90° phase transformation, stratigraphic section, frequency division pixel imaging, and three-dimensional interpretation of superimposed channel, and the depositional system and temporal and spatial evolution law of the area were clarified. The results show that :(1) the Shaximiao formation can be divided into two third-order sequences and five fourth-order sequences based on the widely developed phyllolimic shale in Sichuan basin as isochronous interface; (2) The Shaximiao Formation in this area is dominated by fluvial facies with obvious dual structure characteristics of fluvial facies. Delta facies and lacustrine facies are developed at the bottom and top of the first member of Shaximiao Formation. (3) Two river geomorphic types, strip-straight river and arched medium-low bend meandering river, were mainly identified in several stratum sections, and the coexistence of multiple river types was found in some stratum sections. The channel developed in high accommodating space is relatively isolated and small in scale. Low capacity allows rivers to interweave and become larger. The variation of the tolerable space controls the superposition patterns of sand bodies in different system tracts. The top of Shaximiao 1 submember and the top of Shaximiao 2 submember are in the lowest period of accommodating space, the development scale of channel sand body is relatively large, and they are the most favorable exploration and development intervals.

Seismic Sedimentology of Shallow Water Delta of Lianggaoshan Formation in Wubaiti Area, East Sichuan

1*

1. School of Earth Science and Technology, Southwest Petroleum University, Chengdu, Sichuan, CHINA
E-mail: 707776171@qq.com

Keywords: Lianggaoshan Formation, shallow water delta, seismic sedimentology

The Jurassic strata have been stripped away in the anticline areas of the east Sichuan tectonic zone, but the Lianggaoshan Formation is well preserved in the widely syncline areas. The giant thick sand mudstone of the overlying Shaximiao Formation can serve as a good cover. Frequent hydrocarbon shows are seen in the Jurassic Lianggaoshan Formation in east Sichuan, but the exploration of the Lianggaoshan Formation in the east Sichuan syncline area is seriously under-recognized, which restricts the next exploration direction of the Jurassic. The old shallow seismic data have low coverage times and serious acquisition footprints; the sand body is thin, the impedance difference with the surrounding rock is small, and the geophysical response characteristics are hidden, making it difficult to characterize the sand body and quantitatively predict and describe the reservoir. To this end, on the basis of high-fidelity and high-resolution "double-high" target processing, using frequency division interpretation, multi-attribute RGB fusion, waveform classification and technology based on neural network control, and quantitative prediction of geostatistics, the research on Seismic sedimentology of the Lianggaoshan Formation in eastern Sichuan. The research results show that: (1) The two-division lake transgression-regression system tract division method is used to identify the shale with the largest lake flooding surface; The Lianggaoshan Formation is divided into two third-order sequences, and the upper section of Liangshan is further divided into four fourth-order sequences. It is determined that the Lianggaoshan Formation in the Wubaiti area mainly develops a shallow water delta system. (2) Adopt a comprehensive research idea from macroscopic to microscopic, qualitative to quantitative, and from fine characterization of appearance to insider heterogeneity evaluation. Imaging, depicting the boundary of the distributary channel sand body; The shallow water delta of Lianggaoshan Formation in Wubaiti area is mainly composed of fine-medium sandstone with high maturity, and the overall sand body is characterized by thin thickness and tight lithology. There are various distribution types of sand bodies, that is, there are distributary channel-type sand bodies dominated by river-controlled deltas, and there are also distributary sand bars controlled by lake waves. (3) Using the "sparse pulse" blind well algorithm and the "co-simulation" geostatistical algorithm, the inside of the channel sand body is finely described, and the evaluation idea of facies-controlled sand search, finding the best in the sand, and selecting the rich in the best is formed. It is concluded that the use of seismic sedimentology technology has clearly described the shape and inner reservoir characteristics of the delta distributary channel and distributary sand bar in the eastern Sichuan area, and achieved fine characterization of thin sand bodies less than λ/8. Well-configured delta front sand bodies formed by faults are favorable exploration and development targets. It points out the direction and provides technical and theoretical support for the exploration of Lianggaoshan Formation sand bodies in the eastern Sichuan area.

Source-Sink Sedimentary Characteristics Analysis and Sandbody Identification of Deep-water Gravity Flow System

gao xiong xiong[1*]
1. Project Department, Chengdu Jingshi Petroleum Technology Co., Ltd, chengdu, sichuan, CHINA
E-mail: gaoxx@chinarockstar.com

Keywords: Deep-water gravity flow deposition, Source-conduit-sink, Wheeler transform, Seismic configuration; Sedimentary paleogeomorphology

Deep-water gravity flow deposits and their huge oil and gas exploration potential are the hotspots in the exploration of lithologic oil and gas reservoirs. The Baiyun deep-water area is located in the continental slope deep-water area of the northern continental margin of the South China Sea, where gravity flow channels and deep-water fan deposits are developed under the control of the continental shelf slope break. Gravity flow sand reservoirs have strong lateral heterogeneity, and are affected by the strong reflection of overlying limestone, making it difficult to define lithologic trap boundaries. In addition, thin sand bodies are affected by tuning effects, making it difficult to accurately predict the reservoir characteristics by conventional inversion methods. In this paper, the three-level "source-conduit-sink" coupling analysis is used to explore and study the gravity flow deposition in the Baiyun deep water area to guide the identification of gravity flow sand bodies. Firstly, the seismic data obtains multiple frequency division data volumes through wavelet transformation, performs F-X filtering, optimizes frequency bands for frequency reconstruction, highlights stratigraphic interface, carries out stratigraphic interpretation of key sequence interfaces and system and system domain interfaces, conduct research on the response of relative sea level and sequence interface, establish the sequence stratigraphic framework in the Baiyun deep water area, and describe the gravity flow deposition model of the deep water continental slope. Secondly, on the basis of Wheeler transformation, the seismic configuration analysis in the Wheeler domain is carried out, and the well-seismic combination is carried out to correlate the sedimentary lithology of the well with the paleospace seismic configuration, and establish a quantitative version for the seismic configuration interpretation of the reservoir sand body. Finally, Finally, through the analysis of sedimentary paleogeomorphology, continuous stratigraphic slice analysis, gradient structure tensor attributes, etc., study the sequence sedimentary interior and the "source-canal-sink" sedimentary structure response relationship, and analyze the supply background, transportation pipeline, depositional microscopic interior, depositional process, storage conditions and trap properties of the lobes of the continental slope gravity flow channel and the deep-water fan, to identify the distribution of gravity flow sand bodies. The third-level "source-canal-sink" coupling study of deep-water gravity flow deposition organically combines the profile configuration elements of sequence stratigraphy, the paleogeomorphic elements of source-sink analysis, and the plane seismic configuration elements of seismic deposition. Analyzing the distribution of depositional systems and reservoir architectural units from the perspective of depositional process and depositional origin provides a new idea for depositional analysis and reservoir sand body identification.

Application of "source-canal-sink" ternary seismic sedimentary analysis in thin interbedded reservoir prediction——Taking A gas field in Xihu sag as an example

wang yanan[1*]

1. Project Department, Chengdu Jingshi Petroleum Technoligy Co.,Ltd, Chengdu, Sichuan, CHINA
E-mail: wangyn@chinarockstar.com

Keywords: source-canal-sink, thin-layer interference, K-means clustering, Huagang Formation

The Huagang Formation of the A gas field in the central and southern part of the central inversion structural belt in the Xihu Sag has a fluvial-delta depositional environment and is a typical facies-controlled low-permeability gas reservoir. The favorable reservoir is the distributary channel. The gas abundance is higher, so the fine characterization of reservoir traps is of great significance to increase the reserves and production of the A gas field. The study area has thin interbedded sediments of sand and mud, with low seismic vertical resolution, severe interlayer interference, strong heterogeneity of planar channel reservoirs, and difficulty in identifying sand body boundaries. In view of the above problems, this paper adopts the "source-canal-sink" ternary seismic sedimentary analysis idea on the basis of previous research, firstly analyzes the paleogeomorphology and provenance of the study area through Wheeler domain transformation, and establishes a seismic configuration template. Two types of geological targets, such as distributary channels and distributary bays, were identified; secondly, surface block slices were used to eliminate interlayer interference, and 3 slices reflecting the distribution characteristics of river channels in different stages were extracted, and K-means artificial intelligence multi-attribute clustering technology was used to make research. Finally, combined with the seismic configuration template, the topography and semi-quantitative sand body configuration interpretation were carried out to clearly describe the early, middle and late channel sedimentary plan of the H5 sand formation in the target area. The results show that the Huagang Formation in the study area was flat during the depositional period, and developed two provenance areas, axial and lateral; the H5 sand formation in the target layer as a whole is a vertical superimposed complex of migratory channels, and three early, middle and late are identified. Period channel: In the early stage, the NW-trending source crossed channel was developed, converging to the southeast, in the middle stage, the lateral migration channel was developed, which was vertically stacked, and the axial single channel was developed in the late stage.

Seismic sedimentology fine characterization of deep-lake turbidites in continental lacustrine basin based on genetic knowledge --taking 3rd member of Shahejie Formation in Niuzhuang Sag of Jiyang Depression in China as an example

Li Fenglei[1*], Lin Chengyan[1], Zhang Xianguo[1]
1. School of Geosciences, China University of Petroleum, Qingdao , China, Shandong, CHINA
E-mail: lfl_winter@163.com

Keywords: deep-lake turbidites,Seismic sedimentology,Jiyang Depression,Sedimentary characteristics

Geological knowledge gained through years of exploration and development suggests that there are three types of gravity flow deposits in Niuzhuang Sag: slump, detrital flow and turbidity current.The development location and scale of different types of gravity flow are different. On the basis of understanding the sedimentary law of deep-lake turbidites in this area, combining with drilling, logging, logging and seismic data, the main sand body in Niuzhuang oilfield is divided and compared.By means of fine calibration of well seismic synthetic record, selection of regional well backbone profile and fine interpretation of regional marker layer sand group, the major cycle correlation of turbidite deposition is carried out to complete the work of regional stratigraphic series.The deep-lake turbidites types, lithologic assemblage characteristics and distribution of different sand body genetic models are defined:In the northern fault trough belt, clastic channel and turbidity fan are mainly developed. The lithologic assemblage features are thick interbedded sand and thin interbedded sand respectively.In the southern restricted step-fault zone, slump sand bodies are mainly developed, and tThe lithologic assemblage features is isolated thick sand bodies.In the southern open fault step, the inner fan of debris flow and outer fan of turbidity flow are mainly developed, which are characterized by the lithologic combination of sand and mud thin interbedding. Based on actual seismic data and forward modeling, the seismic facies characteristics of different sand body genetic models are clarified.The typical seismic profile of gravity flow in the northern fault trough zone has the characteristics of strong amplitude, continuous and parallel reflection.The gravity flow in the southern restricted step-fault zone is characterized by strong amplitude and pod-like intermittent reflection.The gravity flow in the southern open step-fault zone has the characteristics of weak amplitude, medium continuity and disorderly reflection.Further, according to the characteristics of seismic data in the study area, the seismic data that can best reflect the sedimentary characteristics of turbidite sand body is selected. By analyzing the quality of seismic data, the forward model of turbidite sand body is designed according to the genetic type.Therefore, appropriate processing parameters are defined to obtain better quality seismic data. Through the well-seismic combination method, multi-well sand body is fully used to fit and match the optimal seismic attributes, and seismic sedimentology technology is used to complete the fine characterization of turbidite sand body combined with inversion prediction results.

E-mail: zhangxianguo@upc.edu.cn

Keywords: fluvial-deltaic system,seismic sedimentology, seismic lithology,AVO attributes

Abstract: The acoustic impedance contrast between sandstone and mudstone is the basis for using 3-D seismic data to predict lithofacies and interpret sedimentary facies, but in sandstone reservoirs in complex sedimentary environment, the spatial variation of the acoustic impedance contrast between sandstone and mudstone brings multiple solutions to seismic lithology prediction. In this study, we took the ancient fluvial-deltaic system in the East China Sea Basin as the main object to conduct the research where had three types of sandstone with different acoustic impedance from mudstone: low-AI (type A) sandstone, overlapped-AI (type B) sandstone, and high-AI (type C) sandstone. The spatial variation law of the acoustic impedance relationship between sandstone and mudstone is summarized by the petrophysical analysis of well logs. And then a seismic lithological prediction method was proposed by the identification ability of different elastic parameters on the above three types of sandstone. The study found that: 1) The burial depth controlled the acoustic impedance relationship between sandstone and mudstone, and with the burial depth increasing three types sandstone were developed sequentially (type A - type B - type C);2) The western part of the study area was dominated by A-type sandstone. The central and eastern parts were dominated by B-type sandstone, and C-type sandstone was developed in the deep southeast; 3) AVO attributes G was used for interpretation of B-type sandstones, and seismic attributes from post-stacked seismic -90° phase shift data was used for interpretation of A-type sandstones ,and seismic attributes from post-stacked seismic 90° phase shift data can interpret C-type sandstones better;4) The ‘stratification- Partition’ seismic lithology prediction method was established to interpret the planar distribution of fluvial-shallow water delta sedimentary system in the study area. The results show that a river-dominated area developed in the northern part of the study area was characterized by stable skeleton drainage system and large channel sand body, and in the south shallow-water deltaic deposits was developed characterized by multistage superimposed and contiguous sand bodies. The sedimentary model of the fluvial-deltaic system was established to predict the reservoir in study area, and the reservoir prediction results were verified by drilling.

2D convolutional neural network driven seismic multi-attribute method for sand thickness prediction in sparse well area

Feiyue Chu[1], Xianguo Zhang[1*]
1. School of Geosciences, China University of Petroleum (East China), Qingdao, Shandong, CHINA
E-mail: zhangxianguo@upc.edu.cn

Keywords: 2D convolutional neural network,shallow water delta,seismic multi-attribute, sand thickness, sparse well area

The prediction of sand thickness by seismic attributes is an important method for the study of sedimentary facies in oilfield exploration, but the lack of effective methods to construct the nonlinear relationship between seismic attributes and sand thickness and the lack of samples in sparse well areas restrict the prediction accuracy and reliability. Tianwaitian area in the Xihu Sag is taking as an example to explore the method of seismic multi-attribute prediction of sand thickness distribution in shallow water delta in sparse well area. Cluster analysis is used to optimize seismic attributes; the method of two-dimensional image valuing is taken to improve the reliability of seismic attribute value; virtual samples obtention from image rotation symmetry is used to expand the sample set. Based on the above process, 2D convolution neural network model is built to predict the plane distribution of sand thickness in the study area. The result is compared with BP neural network and SVM. The results show that the two-dimensional image value and virtual sample construction method of well point seismic attributes effectively solve the problem of insufficient sample size in sparse well area. On this basis, the 2D convolution neural network method can significantly improve the prediction accuracy. This method provides an effective solution for the prediction of sand thickness of complex clastic rock reservoir combined with well seismic in sparse well area.

Study on sedimentary microfacies and sand body prediction of tight reservoir based on well seismic reservoir data

Jie Wang[1*], Ting ting Zhang[1], Zhu Xia[1], Yin tao Cai[1], De sheng Sun[1], Kai Li[1]
1. geological Research Center, research institute, zhuozhou, hebei, CHINA
E-mail: wangjie_eu@163.com

Keywords: high-resolution 3D VSP and 3D seismic, sedimentary microfacies, Waveform indicating inversion, sweet sand body

The study area is located in an oil field in a basin in eastern China. It belongs to a low porosity and low permeability structural lithologic reservoir with tight sandstone under the sedimentary background of the lower Cretaceous delta front. Structure controls reserves, sedimentation controls reservoir types, and facies belts and physical properties control reservoir quality. Due to the low density of actual well pattern (well spacing greater than 400m), large spatial variation and uneven distribution of sedimentary microfacies, tight sand thickness (3-20m), physical parameters (porosity 11% - 23.4%, permeability 0.5-206md), and insufficient resolution of previous seismic data, it is very difficult to accurately describe tight sandstone reservoir.

Joint acquisition and processing based on the high-resolution 3D VSP and 3D seismic, this paper adopts the "well seismic reservoir" integrated reservoir fine description technology series, that is, the well point logging sedimentary microfacies (based on core thin section, logging facies analysis, etc.) calibration constrained seismic sedimentary facies technology, high-resolution seismic reservoir feature interpretation technology (fine structural analysis, paleogeomorphic restoration, multi-attribute analysis, etc.) Waveform indicating thin reservoir inversion prediction technology, sweet sand body distribution optimization technology based on production data, etc., qualitatively + quantitatively identify and predict four types of reservoir sedimentary microfacies, and characterize the spatial distribution of (3-10m) thin sand body and effective sweet sand body.

Based on the geological results and production data of structure, sedimentary microfacies, sand body prediction, the sweet sand bodies of the tight reservoir of the target strata in this area are finally classified and zoned, and 13 sweet sand body distribution areas above 5m are newly delineated, with the geological reserves of 25 million tons. Penetration rate of sweet sand body in horizontal well increased from 45% to 95%, which well guided the horizontal well drilling; The coincidence rate of well seismic of reservoir sedimentary microfacies and thin sand reservoir characteristics has increased by 30%.

Precise Depicting Thin Fluvial Channel Sand Bodies Based on High-Precision Frequency Division Technique

Siyuan Cao[1], Yaoguang Sun[1], Siyuan Chen[1*], Yankai Xu[2]
1. College of Geophysics, China University of Petroleum (Beijing), Beijing, CHINA
2. College of Information Science and Engineering, China University of Petroleum (Beijing), Beijing, CHINA
E-mail: 344491362@qq.com

Keywords: Thin fluvial channel sand body, Frequency division, Zero-crossing time, Tuning frequency, Thickness

Prediction of thin-bed geometry and stacking patterns using seismic data is always a challenge. The identification of thin fluvial channel sand bodies in the complex sedimentary environment and the lateral heterogeneous depiction of reservoirs are key issues in the current seismic processing. In this paper, based on the comprehensive analysis of high-precision frequency-divided seismic data and high-precision horizon data, a case study of predicting thin fluvial channel sand bodies is carried out. At the zero-crossing-time points, a thin bed's reflection makes no contribution to the composite response. Therefore, for different frequency-divided seismic data volumes with 90° phase, we find out the stratigraphic slices that can reflect the distribution characteristics of single sand body from consecutive amplitude slices. Different thicknesses of fluvial channel sand bodies correspond to different tuning frequencies. Based on the frequency division by using high-precision wavelet transform and ZCTs at the tuning frequencies, we can estimate the thin sand bodies thickness and obtain the lateral distribution of each thin bed according to different tuning amplitudes in seismic reflection corresponding to components of tuning frequencies. Two synthetic examples (one simple model with two sand bodies and one complex model with six sand bodies) and field data examples justify the feasibility and reliability of the proposed method in characterizing interbedded fluvial channel sand bodies.

In this paper, we first perform the high-precision frequency-division process to obtain the seismic data volumes with different dominant frequencies. Then, we introduce the zero-crossing-time (ZCT) amplitude slice with its potential in depicting thin fluvial channel sand bodies. Next, the thickness of fluvial channel sand bodies at their tuning frequencies can be accurately estimated from their ZCTs. Finally, we use two sets of synthetic 3D seismic data and one field data set to discuss the identification of thin sand bodies from consecutive amplitude slices. Notably, more precise horizons will help us obtain better results.

Study on Sedimentary Model and Quantitative Reservoir Prediction of J Oilfield in Bohai Area

Jiatao Wen[1*], Zongbin Liu[1], Ya Wang[1], Yongping Wang[1], Chao Liu[1]
1. Bohai Oilfield Research Institute, CNOOC China Limited, Tianjin Branch, Tianjin, CHINA
E-mail: wenjt@cnooc.com.cn

Keywords: sedimentary model, regularity of reservoir distribution, seismic facies; seismic attributes, reservoir prediction, increase reservoir production

In the early stage of development, the J Oilfield in Bohai Area is faced with problems such as few exploration well data, large well spacing, unclear understanding of provenance direction and sedimentation model, and rapid lateral changes in reservoir, which seriously restrict the implementation of development plan. Making full use of core, drilling and logging data to carry out sedimentary facies research, it is considered that the second member of Shahejie Formation in the J Oilfield mainly develops braided river delta front subfacies with far provenance in the northwest direction. Four types of sedimentary microfacies are identified, including underwater distributary channel, tributary bay, mouth bar, and distal bar. Through seismic facies, seismic attributes and seismic forward modeling technology, the superimposed characteristics of the braided river delta front sedimentary sand bodies with five different branch provenances on the plane of the J Oilfield and the plane distribution range of the sand bodies in each period are finely described. Then the fine sedimentary model of the study area is established. Based on the constraints of the sedimentary model and through the optimization and correlation analysis of seismic attributes, a set of techniques and methods for quantitative prediction of reservoir thickness by fusion of multiple seismic attributes are explored. The error range between the predicted reservoir thickness and the actual drilled reservoir thickness of the development wells is within 6 meters, which improves the accuracy of mid-deep reservoir prediction in J Oilfield. Through the study of fine deposition model and quantitative prediction of reservoir thickness, the risk and potential of oilfield are fully recognized, which guides the implementation of well location deployment and development plan to successfully realize the high efficiency evaluation of oilfield potential. Oilfield development practices have confirmed that the newly-added proven petroleum geological reserves in the J Oilfield exceed 8 million cubic meters, and more than ten new development wells have been added. The average productivity of a single well exceeds the pre-drilling design by 1.7 times, and a double harvest of reserves and production has been obtained. This research result has a good reference significance and enlightenment for the development of similar oilfields.

Reservoir prediction of channel sublacustrine fan in the third member of Shahejie Formation, Laizhouwan Depression, Bohai Sea

Wang Zhiping[1*], Guan Dayong[1], Zheng Jinggui[1], Yu Xitong[1], Wang Qiming [1]
1. Bohai Oilfield Research Institite, CNOOC Ltd., TIAN JIN, CHINA
E-mail: wangzhp9@cnooc.com.cn

Keywords: channel sublacustrine fan, deposition and reservoir prediction, faulted lacustrine basin, the middle sub-member of the third member of Shahejie Formation, Laizhouwan Depression

Large channel sublacustrine fan lithologic traps are in the third member of Shahejie Formation in Laizhouwan Sag, Bohai Bay Basin, with good reservoir forming background and great exploration potential. However, the sedimentary characteristics of sublacustrine fan are not clear, and the reservoir distribution is difficult to be delineated, which restrict the exploration process.

Therefore, under the guidance of seismic sedimentology and sedimentology theory, a method of optimizing attributes based on seismic facies analysis of different gravity flow channel types was proposed, and the distribution of sublustrine fan was described in detail with plane section, and favorable reservoir development area was finally established. It is recognized that the sublacustrine fan channel has the chaotic characteristics of medium and weak amplitude, which is obviously different from the parallel and continuous strong amplitude reflection of lacustrine mudstone. Based on this, coherent properties of frequency division dip angle, seismic structure attribute based on gray level co-occurrence matrix and waveform classification technique of neural network were selected to characterize the boundary of sublustrine fan and the inner channel.

The development of sublacustrine fan was mainly controlled by fault slope break and palaeogeomorphology.The gravity flow formed a watercourse fan body spreading NE, which advanced and extended to the low potential direction of palaeogeomorphology perpendicular to the strike of fault slope break.The gravity flow advances and extends to the low potential direction of the palaeogeomorphology perpendicular to the fault slope break, forming a watercourse fan body spreading in the northeast direction.The microfacies from south to north shows as "confined channel complex →superimposed channel complex and flank edge → interchannel → deep lake mud".Under the slope break of F1 fault, influenced by the pre-existing limited geomorphology, two restricted channel complexes developed in the first slope break zone, which were wide and thick..A plurality of single channels with small width are developed in the interior, and the single channels are superimposed and cut each other.Under the slope break of F2 fault, the landscape gradually slow, with the increase of transportation distance, the channel's effect on the fluid is gradually weakened, Sandy debris flow gradually diffuses to both sides and transforms into high-density turbidity current.Moreover, the diverging effect of the internal waterway gradually increases, and the main waterway gradually changes from a relatively straight branch waterway with flanks to a curved branch waterway.The thickness and availability of the reservoir also deteriorate from south to north.

The sedimentary distribution characteristics of sublacustrine fan reservoir in this area are clarified, which provides a basis for exploration and well distribution.The bohai channel sublacustrine fan sedimentary model was established, which enriched the sedimentary types of paleogene sublacustrine fan in Bohai Sea.The technical combination of this kind of reservoir prediction is established, which will guide the reservoir prediction of related types in Bohai sea area effectively.

Application of Cauchy constrained inversion method in microfacies characterization of shallow water deltas - Taking Pinghu Formation in a depression in the East Sea as an example

Weizhe Yu[1*]

1. Research Institute, CNOOC China Limited, Shanghai Branch, Shanghai, CHINA

E-mail: yuwzh4@cnooc.com.cn

Keywords: Sea-land transition, Weak reflection coefficient,Cauchy constrained inversion, Sedimentary microfacies characterization

Shallow water deltas are developed in a depression slope belt in the East China Sea. Under the background of sea-land transition, the lithology changes quickly in lateral direction under the influence of rivers and tides. Meanwhile, due to the impedance superposition of middle-deep sandstone and mudstone, the difference of seismic reflection coefficient is small, which makes it difficult for conventional inversion technique to meet the requirements of fine characterization of the lithology. Therefore, fine characterization of sedimentary microfacies in the study area is difficult.In this paper, Cauchy constrained inversion method is applied to lithology identification that contributes to describe the sedimentary microfacies, which firstly combines the longitudinal low-frequency trend of rock physics with the transverse sensitive seismic information of different lithofacies, to establish optimized model that is more consistent with regional geological knowledge. As to solve weak seismic reflection coefficient problem, forward three-parameter Cauchy prior distribution was put to regularize the inversion parameters and the long tail feature of Cauchy distribution was used to protect the weak reflection information, which can improve the prediction accuracy of thin reservoir inversion. The application of three-parameter Cauchy constraint inversion in the target area indicates that the technique can effectively improve the vertical and lateral resolution of lithology prediction. Finally, based on the data of core, single well and interwell, Cauchy constrained inversion results are used to describe the sedimentary microfacies in each system tract of Pinghu Formation and analyze their evolution characteristics.

Early Cretaceous Sequence Stratigraphy and Sedimentary System in Doseo Basin, Chad

Hongkui Chen[1], Xiaomin Zhu[1*], Xiaoxue Wang[1], Yebo Du[2], Xinshun Zhang[2], Zhiyun Yuan[2]
1. State Key Laboratory of Petroleum Resources and Prospecting, China University of Petroleum,Beijing, Beijing, CHINA
2. Africa Institute, PetroChina Research Institute of Petroleum Exploration & Development, Beijing, CHINA
E-mail: xmzhu@cup.edu.cn

Keywords: Doseo Basin,Early Cretaceous,Sequence stratigraphy,Seismic sedimentology,sedimentary system

Seismic sedimentology is an emerging fringe subject that uses seismic data to study sedimentary rocks and their formation processes. It is an effective tool for high-frequency sequence and sedimentary system research in the stage of oil and gas exploration and development. Exploration of Chad's Doseo Basin is currently in early stages. Under the guidance of the theory of seismic stratigraphy and seismic sedimentology , We carry out seismic facies analysis in the 2D seismic data area, and 90° phase conversion, stratigraphic slicing, frequency division interpretation, etc. in the 3D seismic data area. Combined with drilling and coring data, the sequence stratigraphy, sedimentary system types and distribution of the Lower Cretaceous in the Doseo Basin are systematically analyzed. The research results show that the Doseo Basin is a narrow and long dustpan-shaped fault depression characterized as “northern fault besides southern stratigraphic overlap”, and can be divided into two depressions , an uplift and two slopes. Eight sequence boundaries can be identified in the Lower Cretaceous, and seven third-order sequencesSQ1~SQ7can be devided, which are represented by two water transgrassive-water regressive cycles. During the depositional period of SQ1 and SQ2, the topography of the basin fluctuated greatly, the sediment supply was sufficient, and the grain size of the sediments was relatively coarse. The sediments mainly came from the northern, central and southern paleo-uplifts. The sedimentary system of alluvial fan-fluvial-braided river delta was mainly developed in the southern fault terrace belt. In the northern steep slope zone, there were nearshore subaqueous fans and fan delta deposits, but no sublacustrine fans. During the depositional period of SQ3 and SQ4, the paleo-geomorphology tended to be flat, and the sediments mainly came from the east and south of the lake basin, extending a long distance to the northern steep slope zone. Normal delta deposits were developed in the southern fault terrace belt. The northern steep slope zone was dominated by the development of fan delta and nearshore subaqueous fan deposits which were superimposed with semi-deep lacustrine mudstone, and sublacustrine fans developed in front of the fan delta. The northeastern part of the basin developed braided river delta deposits that flow into the lake along the long axis of the basin. During the depositional period of SQ5 and SQ6, the lake deposition further expanded, and the delta depositional system took the dominant position. During the deposition of SQ7, the lake gradually shrank, and the lake basin was dominated by fluvial coarse clastic deposits. The sedimentary filling evolution of the basin shows that the delta front sand bodies in the central low uplift belt and the southern fault terrace belt, the fan delta front and nearshore subaqueous fan sand bodies in the northern steep slope belt are the most favorable reservoir for oil and gas exploration. Using seismic stratigraphy and seismic sedimentology methods to study the sequence framework and the distribution of sedimentary systems in the new exploration area provides an important basis for the subsequent exploration and development of the Doseo Basin.

Keywords: Thin-interbedded reservoir, Seismic sedimentology, Seismic meme inversion, Spacial distribution of sandbody, Reservoir thickness prediction

Seismic sedimentology is a new multidisciplinary subject, which develops on seismic stratigraphy and sequence stratigraphy, and plays an important role in the prediction of thin reservoirs in terrestrial rift basins. Zhuangxi area is a typical terrestrial rift sub-basin with strong tectonic activity, multiple sediment source areas and rapid lateral change during the sedimentary period of the Dongying Formation. The thin sand-mud interbed reservoir is the main one of the Dongying Formation. The scouring and overlaps of multi-stage sandbodies cause complex internal reservoir architecture and seriously restrict the development of this area. The present study successively employes sequence stratigraphic framework building, sandbodies plane distribution analysis and reservoir thickness prediction to explore the thin sand-mud interbed reservoir whose total thickness is less than the limit of the vertical seismic resolution. The resolution of the original seismic data of the study area is 25 meters (the dominant frequency is 25Hz), which is challenging to carry out the fine stratigraphic division. Therefore, the sequence stratigraphic framework builds on the frequency raising and widening data, and the sedimentary face types in this area are identified by combining with logging and core data. The results show that the Dongying Formation in Zhuangxi area is divided into five third-order sequences (SQ5, SQ4, SQ3, SQ2, SQ1 from bottom to top), which mainly developes braided river delta, shallow braided river delta and gravity flow sedimentation. Controlled by the paleotopography of rift sub-basin, the sedimentary genetic types of sand bodies in steep slope zone are mainly underwater distributary channel of braided river delta, river mouth bar and slump turbidite fan, and the sedimentary genetic types of sand bodies in gentle slope zone are mainly underwater distributary channel of shallow braided river delta and beach bar. Then the spatial geometry of sandstone and evolution of the sedimentary system are defined by reservoir seismic sedimentology analysis through 90°phase conversion, stratigraphic slicing and color blending. The results indicate that the lake level decreases gradually during the period of the Dongying Formation and accompanies by the sedimentary evolution from prodelta to braided fluvial river delta front or shallow braided river delta front from bottom to top. The sandbodies of SQ2 and SQ1 sequences are distributed in sheet shape with a large scale. The sandbodies of SQ4 and SQ3 sequences are roughly distributed in a banded shape in the trend of the NE-SW direction. The sandbodies of the SQ5 sequence are distributed in point shape with the smallest scale. Based on the present results, five to ten meters thin sandbodies are accurately predicted longitudinally through seismic sedimentology and seismic meme inversion which can make full use of the lateral variation information of seismic waveform to establish a crosswell model and has good inter-well prediction ability to predict the thickness of thin interbed.

Application of Seismic Sedimentology in the Study of the Shallow Water Delta in the Kangning Gas Field, Ordos Basin

LE SUN[1*], YU QI[1], BO WANG[1]
1. research institute, CNOOC, Beijing, BEIJING, CHINA
E-mail: 15101148905@163.com

Keywords: sedimentary evolution,seismic sedimentology,shallow water delta,Ordos Basin

Kangning Gas Field is located in the eastern Ordos Basin, at present, the Kangning Gas Field has entered the stage of full-scale development, with strong reservoir heterogeneity and frequent vertical stacking of sand bodies. The drilled production wells reveal that the gas layer thickness in the Kangning Gas Field changes rapidly, and the drilling productivity varies greatly. However, the resolution of the seismic data in the study area is low, and the main frequency is about 32 Hz, which is difficult to meet the requirements of sedimentary microfacies analysis. In response to the above problems, this paper takes sequence stratigraphy, modern sedimentology, seismic sedimentology and other disciplines as the theoretical basis, and takes the fourth member of the Permian Shihezi Formation (H4) as the research object to carry out a fine characterization of the shallow water delta sedimentary system and guide the efficient exploration and development of the Kangning Gas Field.

Seismic sedimentology research is an important means for the exploration and development of lithologic reservoirs and the fine carving of sedimentary microfacies. Using seismic sedimentology in the fine study of the shallow water delta sedimentary system in the Kangning Gas Field, this study established a technical system for the characterization of shallow water delta channel sand bodies. That is, (1) the well-seismic combined sequence stratigraphic framework is constructed under the guidance of sequence theory, (2) the seismic lithologic stratigraphic significance is given by the phase adjustment technology, (3) the distribution law of sand bodies is clarified by means of seismic stratigraphic slices, (4) the frequency division attribute finely describes the distribution of sand bodies with different thicknesses.

From bottom to top, H4 Member is divided into three sand layer groups, corresponding to the lowstand, water transgression, and highstand system tracts respectively. The H4 Member developed shallow delta plain facies, mainly including braided distributary channels, sand bars and inter-channel deposits. A channel sand body characterization technology system based on seismic sedimentology, and a corresponding sedimentary evolution model had been established. The distribution of sedimentary facies has the characteristics of " distributary channel dominates, developed sand bars, and lateral migration". The superposition of multi-stage sand bodies during the low-stand and water-transgressive periods is the core cause of the distribution of thick sandstone and glutenite in the H4 Member. Distributary channel microfacies and sand bar microfacies are the main sedimentary facies belts contributing to productivity, providing favorable storage space for the formation of lithologic reservoirs. The study of shallow water delta sedimentary system based on sedimentology and seismic sedimentology is of great significance for guiding the exploration and development of lithologic reservoirs.

Discussion of seismic diagenetic facies of deep reservoir in the East China Sea Basin

Wenguang Wang[1*], Chengyan Lin[1], Xianguo Zhang[1], Chunmei Dong[1], Lihua Ren[1], Jianli Lin[1]
1. School of Geosciences, China University of Petroleum (East China), Qingdao, Shandong, CHINA

Keywords: Seismic diagenetic facies, Stratal slicing, Seismic sedimentology, Supervised learning, Tight sandstone, Xihu sag

Evaluation of seismic diagenetic facies is an effective interpretation procedure to characterize the spatial distribution of diagenetic facies in deep tight sandstones in offshore sparse well areas. Based on petrographic and seismic data, research on seismic diagenetic facies was used in the proposed workflow to predict the spatial distribution and distribution characteristics of seismic diagenetic facies for the third (H4c) sub-member of the fourth (H4) member of the E3h Formation in the Xihu Sag, East China Sea Basin, Eastern China. Herein, two discriminant functions between the core-derived diagenetic facies and the seismic elastic parameters of shear modulus, p-wave impedance, and porosity data volume were established using the supervised learning method, and seismic data X and seismic data Y containing diagenetic facies information were evaluated. Based on the linear function between seismic data X and seismic data Y, a new seismic data volume was calculated and a comprehensive index of diagenetic facies was proposed to describe the distribution of diagenetic facies. The comprehensive index of diagenetic facies can better identify the spatial distribution of diagenetic facies. The results of seismic diagenetic facies research mainly focused on (1) the spatial distribution of diagenetic facies and (2) the distribution characteristics of diagenetic facies. Based on core-derived diagenetic facies, typical stratal slices, and sedimentary microfacies, the spatial distribution of seismic diagenetic facies in the two sublayers of the H4c sandstone was accurately interpreted. The northern part of the H4c1 and H4c2 sublayers mainly developed quartz-cemented facies and a small amount of chlorite-coated quartz facies. The southern part and the surrounding areas of the H4c1 and H4c2 sublayers primarily developed tightly compacted facies. The area near four (F1, F2, F3, and F4) faults in the H4c1 sublayer mainly developed a small amount of dissolution facies, whereas the area near the F2 and F4 faults in the H4c2 sublayer primarily developed a small amount of dissolution facies. Furthermore, the distribution characteristics of seismic diagenetic facies were investigated from the perspective of sedimentary microfacies and diagenetic facies. The chlorite-coated facies is mainly distributed in the subaqueous distributary channel sedimentary microfacies. The dissolution facies is primarily distributed in the subaqueous distributary channel and sheet sand sedimentary microfacies near the faults. This study shows that the research of seismic diagenetic facies using petrographic data and seismic data can better predict the spatial distribution of diagenetic facies of deep tight sandstone.

Seismic sedimentology study of Shihezi Formation in Kangningxi areaOrdos Basin, China

Ruixing Zhao[1], Xiaomin Zhu[1*], Yanlei Dong[1]
1. College of Geosciences, China University of Petroleum (Beijing), Beijing, CHINA
E-mail: xmzhu@cup.edu.cn

Keywords: Ordos Basin, the west of Kangning Area, Shihezi Formation, seismic sedimentology, shallow braided river delta

The thin sand body reservoir of Shihezi Formation in Ordos Basin is rich in natural gas resources. Traditional research methods are difficult to depict its sedimentary microfacies and predict the distribution of favorable reservoirs while seismic sedimentology can accurately characterize the temporal and spatial distribution and evolution of its thin sand bodies. Integrating data from the comprehensive study of seismic sequence and drilling and logging sequence shows that Shihezi Formation in the west of Kangning area can be divided into four third-order sequences and nine fourth-order sequences under the guidance of sequence stratigraphy theory. Guided by sedimentology theory, it is clear that the sedimentary period of Shihezi Formation was basically in shallow water environment, and the sedimentary facies was mainly shallow braided river delta in the study area after a detailed investigation of regional geological background data as well as core data, drilling and logging data and seismic facies analysis. The seismic sedimentology research on key sequences is carried out under the guidance of seismic sedimentology. Firstly, we use the spectral inversion technology to increase the frequency of three-dimensional seismic data, and then establish the good correspondence between thin sand body and seismic reflection by 90 degree phase shift. Finally, we use frequency division, stratal slices, RGB attribute blending techniques and lithology calibration to study and depict the sedimentary facies of key sequences (SQh6, SQh4, SQh3 and SQh2). During the depositional period of SQh6 and SQh4 of Shihezi Formation, the lake level decreased slowly and underwater channels bifurcated and merged and oscillated frequently; in SQh3 sedimentary period, the inner front of shallow Braided River Delta continued to develop, but the underwater channel widened; In SQh2 sedimentary period, the delta advanced as a whole. Combined with the study of gas testing data, porosity and permeability data and stratal slices, we predict the zone of favorable sand bodies of key sequences, which is mainly determined by the distribution area of favorable sedimentary microfacies and thicker single sand body thickness (generally greater than 3m).

Geological modeling of fan Delta Reservoir guided by seismic sedimentology and constrained by evolution and origin information --A case study of the upper fan-delta front subfacies of Es31 in Gangzhong Oilfield

chao jiang[1*]
1. School of Geosciences, China University Of Petroleum (Huadong), Qingdao, Shandong, CHINA
E-mail: b21010055@s.upc.edu.cn

Keywords: fan delta, Seismic sedimentology, geologic modeling, gangzhong oilfield, origin and evolutionary information

The ES31 formation in the eastern Gangzhong area of beidagang secondary structural belt in Huanghua Depression is characterized by fan-delta deposition, rapid change of sedimentary facies, significant difference of lithologic assemblage, unclear understanding of the law, and strong heterogeneity within the reservoir, which restricts the understanding of uneven distribution of oil and gas and seriously affects the formulation and implementation of subsequent development plans. Therefore, taking gangzhong area as an example, the fan delta distribution in the study area was characterized by integrating core, well logging and seismic data. Under the guidance of depositional model, strata sections were extracted to analyze the evolution process of genetic units. This information is transformed into probability body to control geological modeling, and the geological model constrained by genetic and evolutionary information is established with the identification results of well data as hard data. Six lithofacies and four lithofacies combination types are identified. There are two fan delta groups in the study area, which are formed by the convergence of several channels. The two fan delta groups are gradually connected laterally along the provenance direction, forming the continuous distribution of fan Delta front sedimentary belt. By analyzing the sedimentary model of the study area and extracting the genetic and evolutionary information from the well and seismic data, the three-dimensional geological model of braided river reservoir is constrained to improve the rationality of the geological model.

Thin bed prediction from interbeded backgrounda new approach base on seismic sedimentology

Changkuan Ni[1*], Mingjun Su[1], Cheng Yuan[1]
1. Research Institute of Petroleum Exploration and Development-Northwest, China National Petroleum Corporation, Lanzhou, Gansu, CHINA
E-mail: nck@petrochina.com.cn

Keywords: thin-bedded reservoir, stratal slicing, seismic sedimentology, AVF, Junggar basin

Thin inter-bed< λ/4 in thicknesswhere λ is the length of waveform reservoir is important in non-marine postrift basins. However, thin bed prediction from the interbedded background is a challenging work for the seismic interpreters because of the limitation of seismic vertical resolution. Interference from other thin layers in seismic reflections has great negative impact on the thin-bedded reservoir prediction. To deal with this, Zeng proposed to analyze the changes of thin inter-bed by using slice sequence and then obtain the distribution of each thin layer. Li analyzed the interference process of thin interlayer and predicted the thin layer by decreasing slice interval to 0.2ms for searching zero-value slices without interference. Based on the zero-value slicing idea, we propose two novel approaches that can improve the accuracy of thin-bedded reservoir prediction by suppressing the interference with the help of seismic sedimentology. The proposed methods can accurately predict the plane distribution of an individual sand body within thin-bedded strata which is indistinguishable from a seismic profile. By using the amplitude versus frequency (AVF) attribute estimated by wavelet transform, the first method, named as Minimum Interference Frequency (MIF) slicing, can find a constant seismic frequency by which the adjacent layers show the minimum influences on the stratal slice of target layer. An optimal slice can be then obtained by dividing seismic data with the constant frequency mentioned above in frequency domain. Moreover, the second method, superimposed slicing, can suppress the interferences of thin beds by weighted stacking the multiple stratal slices of neighboring layers. The weight coefficients are estimated based on the spatial relation between the adjacent and target layers. A field example from Junggar Basin, Northwestern China, is carried out to validate the effectiveness of the two proposed methods in detecting an oil-bearing layer with a thickness of 6m from a thin-bedded reservoir with three sets of thin layers. A comparison with the well-log curves suggests that the proposed methods bring us a better prediction of thin-bedded reservoir than the traditional slicing approach.

Recent progresses in seismic sedimentology: improving thin bed prediction in lacustrine basins

Hongliu Zeng[1*]
1. Bureau of Economic Geology, The University of Texas at Austin, Austin, Texas, UNITED STATES
E-mail: h_zeng@yahoo.com

Keywords: Seismic sedimentology, seismic geomorphology, seismic lithology, stratal slicing

Depositional systems in lacustrine basins are dominated by seismically thin sand bodies. Most of hydrocarbon plays contain a large number of interbedded, thin (1-10 m) sandstone reservoirs. Standard seismic sedimentology uses seismic lithology (shaliness, relative impedance, etc.) to generate seismic-geomorphologic (stratal slice) volume for sedimentary study at seismic scale. In the thin-bed domain, however, seismic sedimentology faces challenges. In thin-bedded sequences, seismic geomorphology is compromised if chronostratigraphic assumption of seismic reflections and stratal slices is violated; seismic lithology is limited by seismic resolution (for geologists, it is typically restricted to dominant seismic resolvable limit at a quarter wavelength).

In recent years, there have been notable progresses in both aspects of seismic sedimentology. The most significant development in stratal slicing is the hybrid stratal slicing, i.e., to combine auto-tracking and proportional slicing (Wang et al., reviewing). In the seismic lithology side, progresses have been seen in reducing sidelobe and tuning effects and in improving resolution. Ni et al (personal communication) Tested stratal slicing at the minimum interference frequency and by suppressing interference by subtraction. Frequency fusion (Zeng, 2017; Zeng et al., 2021) reduces tuning with higher resolution (at least double the dominant frequency) and a wider sandstone body imaging range (1/16-1 wavelength). Seismic wavelet effect can be partially reduced by model-based seismic inversion. The Most promising development, however, is machine-learning based inversion or estimation (e.g., Hampson et al., 2001; Das et al., 2019), which train seismic traces for lithology logs (e.g., gamma ray) with many benefits. Models and field-data applications in lacustrine basins will be presented to support this study.

Sand supply mechanism and its hydrocarbon significance in Paleogene of the northern Huanggekou Sag, Bohai Bay basin, China

haifeng yang[1*], geng qian[1], meng zhao[1], xiaojun pang[1], weiyan lu[1]

1. Bohai Petroleum Research Institute, Tianjin Branch of China National Offshore Oil Corporation Limited, Tianjin, CHINA

E-mail: yanghf3@cnooc.com.cn

Keywords: the Bonan Upliftbasin evolution, parent rock recovery, provenance evolution, reservoir cap assemblage

The Bonan Uplift is a submarine low uplift located between the Huanghekou Sag and the Bozhong Sag. In Paleogeneas the parent rock areathe parent rock type and distribution of the Bonan Uplift were not clear, making it difficult to understand the reservoir forming conditions of the northern Huanggekou Sag. Firstly, the uplift's evolution history and provenance characteristics were recovered based on different main fault depression periods of the two adjacent sages. Secondly, the provenance direction and the deposit range were studied and predicted using the paleogeomorphology characteristics and well seismic data. Finally, the Bonan Uplift's provenance evolution and its favourable role on hydrocarbon accumulation were discussed. The results suggested: (1) From Paleocene to Eocene, a large area of the Bonan Uplifted was denuded and supplied sediments southward to the Huanghekou Sag; (2) From Late Eocene to Early Oligocene, as the Bozhong Sag rifted strongly, the Bonan Uplift rotated, tilted and subsided, resulting in weakened sand supply capability; (3) The Bonan Uplift's provenance role varied in different geological periods, forming superior Paleogene reservoirs in the northern and central parts of the Huanghekou Sag, which is favorable for the vertical petroleum preservation.

Application of seismic sedimentology to characterize the S2S and thin sandbodies in Chinese continental basins

Xiaomin Zhu[1*], Yanlei Dong[1], Lei Ye[1], Ke Yang[1], Reixin Zhao[1], Huanghui Xie[1]
1. College of geosciences, China University of Petrleum, Beijing, CHINA
E-mail: xmzhu@cup.edu.cn

Keywords: Seismic sedimentology, Key technology, Sequence framework, Source to sink, Thin sandbodies, reservoir architecture

Seismic sedimentology is a new interdiscipline of sedimentary geology and geophysics based on seismic stratigraphy and sequence stratigraphy. It revolutionizes the research perspective of sedimentologists and petroleum exploration scientists: from interpreting conventional seismic facies with seismic vertical resolution to studying sequence stratigraphy, source-sink systems, sandbodies distribution and reservoir architecture by making full use of seismic horizontal resolution (with stratal slices).

Different types of continental basins are developed in China, and multiple source-sink systems and thin sandbodies of multiple genetic types are developed under the complex sequence framework. It has been proved that seismic sedimentology plays an irreplaceable role in characterizing the source-sink systems elements, depicting thin sandbodies, predicting lithologic traps and exploring and developing oil and gas resources in thin sandbodies in continental basins.

The key technologies of seismic sedimentology include wavelet phase and seismic frequency adjustment, frequency division processing, rock physical relationship analysis, seismic parameter selection, stratal slice processing, RGB fusion, comprehensive analysis of seismic geomorphology and sedimentology. According to the characteristics of seismic lithology and seismic geomorphology reflected by stratal slices, the distribution and evolution process of system tracts in different sedimentary sequences, the characteristics of various elements of source-sink systems, the distribution of sedimentary systems and thin sandbodies, reservoir architecture, and the prediction of reservoir quality and the distribution of stratigraphic lithologic traps can be explained.

Seismic sedimentology is helpful to establish high-precision stratigraphic framework, characterize sequence framework, architecture and evolution of system tracts, and indicate the spatial and temporal distribution of lowstand systems tracts, transgression systems tracts and highstand systems tracts. It also can characterize the elements of source-sink systems, depict the catchment area and geomorphic characteristics of the source area, the types and scale of transport channels, and the relationship between the development of sedimentary sandbodies and the source area and transport channels. Seismic sedimentology can show the spatial and temporal distribution of thin sandbodies of genetic types such as rivers, deltas, beach bars, subaqueous fan and gravity flow deposits developed in continental rifted basins in different geomorphic units and different tectonic stages, and it is helpful to predict potential sand-rich units. Seismic sedimentology can characterize the sandbodies architectures of different sedimentary types, depict the sandbodies morphology and its association with mudstone interlayer, which lays a geological foundation for the precise exploration and development of oil and gas fields.

Inspirations of seismic sedimentology from shear wave 9-component 3D seismic data in Qaidam Basin, NW China

Zhaohui Xu[1,2*], Zeyu Shao[2], Yan Wang[3], Dekang Song[2]
1. Department of Petroleum Geology, RIPED, Beijing, CHINA
2. Research Institute of Exploration and Development, Qinghai Oil Field, Jiuquan, Gansu, CHINA
3. Research Institute, BGP, Zhuozhou, Hebei, CHINA
E-mail: tadxu@126.com

Keywords: Shear wave 9-Component 3D seismic, Seismic sedimentology, Seismic geomorphologic microfacies, Seismic lithologic reservoir property, Qaidam Basin

The first large-scale (82.5km^2) shear wave 9-component 3D (9C3D) seismic survey in the world was conducted by Qinghai Oil Field and BGP in Taidong area, Qadam Basin. The 9C3D seismic survey offers an opportunity to investigate structural, stratigraphic, and lithologic gas reservoirs for its super high quality. Comparing with conventional P-wave seismic data, the 9C3D data can reflect real structural features despite of interference from the unconsolidated sediments and the natural gas. Furthermore, the vertical resolution of the 9C3D data is doubled than the conventional P-wave data.

Seismic sedimentology, i.e., seismic geomorphology and seismic lithology, is firstly performed on the 9C3D seismic data. In the aspect of model-driven seismic geomorphology, a lacustrine-fluvial system is firstly recognized in the Taidong area, and then the evolution of sedimentary microfacies from K13 to K3 is reconstructed as well. In the aspect of data-driven seismic lithology, some key factors e.g., reservoir thickness, porosity, permeability, gas saturation, are calculated for the current target layer by the 9C3D seismic data and 28 wells (20 wells for calculating and 7 wells for verifying).

In the seismic geomorphology, -90° phase rotation, frequency decomposition, RGB blending, and stratal slicing are used. Water level deepens from K13 to K6, and then become shallow from K6 to K3. Microfacies change from underwater fluvial system with numerous channels in K13, to fluvial-lacustrine with a few channels, to shore-shallow lake with few channels, to shallow lake with no channel but beach and/or bars in K6. From K5, lateral heterogeneity become strong with the water level decline. It changes from lake to fluvial in the top of K5 with an obvious channel, and then to probably semi-restricted environment in K4 with a concentric circle phenomenon in the east area, which is quite similar with Salar de Uyuni in Bolivia.

In the seismic lithology, seismic attribute generation, principal component analysis, machine learning, and random fitting are utilized to calculate reservoir thickness, porosity, permeability, and gas saturation by the 9C3D seismic and well data for the sand layer numbered 4-1-4cd. It seems that reservoir thickness and porosity distribution obey microfacies, while permeability and gas saturation are controlled not only by microfacies but also by other factors e.g., digenesis and/or natural gas generation and migration.

Combination of seismic geomorphology and seismic lithology helps us to understand the facies evolution qualitatively, and the reservoir property and gas distribution quantitatively. In the meanwhile, combination of the new data (i.e., shear wave 9C3D seismic) and the new techniques (i.e., seismic sedimentology) enables us to reveal the forming environment of the world-wide renowned biogas in Sanhu area. The study is beneficial not only for the technique (shear wave and seismic sedimentology) progress and application, but also for the natural gas exploration and development in Qaidam Basin.

Machine Learning Based Proxy Model for Reactive Transport Modeling: Workflow and Implementation Example in Dolomitization Process Study

Yupeng Li[1*], Peng Lu[1]
1. Beijing Research Center of EXPEC ARC, Saudi Aramco, Beijing, CHINA
E-mail: yupeng.ua@live.com

Keywords: proxy modeling, Machine Learning, dolomitization model

Proxy-modeling (also known as surrogate modeling or meta-modeling) is widely used as a computational inexpensive alternative to the intensive numerical simulation in various applications, such as assisted history matching in reservoir simulation in petroleum industry.

In this study, the proxy modeling method is implemented in process-based reactive transport modeling (RTM). The conventional RTM integrates thermodynamic and kinetically controlled fluid-rock interactions with fluid flow through porous media in the subsurface and surface environment. RTM is usually conducted through numerical programs based on the first principle of physical processes. Thus, the calculation for complex chemical reactions in most available programs is in general computationally intensive.
Multiple RTM simulations are usually required for input parameter sensitivity analysis and model calibration. Therefore, it is highly desired to develop a computational efficient proxy modeling method with sufficient accuracy in an automated fashion to complement the process-based RTM and assist the sensitivity analysis or model calibration.

In this study, multiple machine learning methods, including neural network, Gaussian process and support vector regression methods are implemented as candidate methods for proxy modeling. The over all proxy modeling includes (1) base case RTM design and training model design, (2) proxy model construction based on machine learning, (4) surrogate model validation and evaluation, (5) prediction and other analysis work with the best calibrated proxy model.

The proposed workflow is illustrated with a simple 1D dolomitization model. Although different machine learning model procedures require different tuning and modeling efforts, the final well-trained proxy model can replace the original RTM with a satisfied accuracy and can be safely implemented in the task of sensitivity analysis or model calibration. Comparing with the conventional RTM, using proxy model can significantly reduce the computational time. It greatly improved the work efficacy such as rank the sensitivity of the parameters and to search the optimal solution for model calibration.

Automatic classification of microbial carbonate thin sections based on convolutional neural network

Ping Zhang[1*], Jing Wang[1]

1. Basin Experimental Research Center, PetroChina Research Institute of Petroleum Exploration & Development -- NorthWestNWGI, Lan Zhou, Gansu, CHINA

E-mail: zhangping_xb@petrochina.com.cn

Keywords: rock thin section, convolution neural network, microbial carbonate, image classification

Microbial carbonate is formed by inorganic or organic induced mineralization associated with microbial activity, different types of microbial carbonate have different macroscopic and microscopic structures, rock thin sections are usually manually identified by professionals, there are some problems such as low appraisal efficiency, disunity of judgment criteria and subjective factors. Therefore, an automatic classification method of microbial carbonate thin sections based on convolutional neural network is proposed.

Firstly, 200 microbiological carbonate thin sections from the northwest of Qaidam Basin were used as sample data, the thin section image can be divided into three types, including: clotted structure, granule structure and laminated structure. The image is preprocessed by multiple random transformations (rotation Angle, tangent Angle, random scaling, random horizontal flipping, etc.) , it is used to increase the number of samples and improve the generalization ability of neural network model training. Secondly, the convolutional neural network structure was established. The feature extraction part was composed of three convolutional layers and three pooling layers, and the classifier consists of two full connected network. The ReLU activation function is applied, the dense layer is classified by Softmax classifier. Finally, Adaptive gradient algorithm is used to optimize losses, the initial learning rate is 0.0001, K - fold cross - validation is used to train the dataset, After 400 iterations, The accuracy of training set is 95.3%, The classification accuracy of the test set was 91.2%, It is proved that convolutional neural network can replace manual to obtain efficient, accurate and reliable thin sections classification results.

The thin section data in this paper are only obtained from drilling in the Qaidam Basin, and the sample data are few. In the future, microbial carbonate rock thin section data for each basin will be added, the convolution neural network model with stronger applicability is established to achieve better classification effect.

Multi-factor karst reservoir evaluation based on paleogeomorphological reconstruction, a case study from the 4th member of the Dengying Formation in the Sichuan Basin, China

Zikun Zhou[1], Xingzhi Wang[1], Long Wen[2], Xiyan Yang[1*], Wenzhi Wang[2]

1. School of Geoscience and Technology, Southwest Petroleum University, Chengdu, Sichuan, CHINA

2. Exploration and Development Research Institute, PetroChina Southwest Oil and Gas Field Company, Chengdu, Sichuan, CHINA

E-mail: yxysgst@163.com

Keywords: Reservoir evaluation, Paleogeomorphological reconstruction, Random forest algorithm, Factor analysis, Deng IV member, Gaoshiti-Moxi area

The evaluation of reservoirs is of great importance in exploration practices, distribution of which is subjected to multiple geological factors. The carbonate platform of the 4th member of the Dengying Formation (Deng IV member) in the Gaoshiti-Moxi area (GMA), was uplifted above sea level during the episode II of Tongwan Movement and underwent prolonged karstification by meteosssric freshwater in the terminal Sinian, leading to a strong heterogeneity in reservoirs. Paleogeomorphic relief reflects hydraulic gradients that affect intensities of surface karstification to an extent, and the hydraulic gradients can be approximated by terrain slope gradients. Karst products (especially solution vugs and caverns) exist prevailingly in the Deng IV member, development of which mirrors internal dissolution intensities. Based on paleogeomorphological reconstruction in elevation method, the slope angles of single boreholes are calculated through digital elevation model (DEM). In accordance with single-borewell formation microscanner image (FMI) logging data, four electrofacies (viz. host rock, vug, fracture and cave) were identified in boreholes possessing FMI data. Matching the identified electrofacies with corresponding conventional logging curves as the training data, a model generalized for other boreholes without FMI data is established employing random forest algorithm, and thicknesses of the four electrofacies in each borehole are obtained to characterize the karstification intensity. Slope gradients and electrofacies thicknesses, together with multiple physical parameters depicting reservoirs in boreholes, are utilized for factor analysis. Four factors were obtained and fused into one comprehensive score in the light of their ratios of variance proportions. The favorability of reservoirs is described with the comprehensive scores of each borehole. It turns out that the most advantageous reservoirs are distributed in the vicinity of the platform margin in the west of the GMA, at which superimposition of several advantage factors may account for this. First is differentiation of deposition, porous mound-shoal complexes with rigid frameworks erect majorly in the platform margin. Karstification difference is the second, large scale caves are more developed in the mixing karst zone of seawater and freshwater in platform margin, complexes constructed upward with seaward steep slope may promote surface erosion and the developed matrix porosity of which can be preferential conduits of karst fluids for internal dissolution. The last reason is the transmeridional lateral migration of hydrocarbons from regional hydrocarbon-generating centre abutting the west of the GMA, contributing to earlier entrapment and accumulation in the mound-shoal complexes in the platform margin.

Petrophysical facies prediction using a LDA-assisted SSOM method for Paleogene Shahejie Formation in Bohai Oilfield

Zongbin Liu[1*], Ya Wang[1]
1. Bohai Oilfield Research Institute, CNOOC China Limited, Tianjin Branch, Tianjin, CHINA
E-mail: liuzb@cnooc.com.cn

Keywords: Petrophysical facies prediction, supervised self-organizing map, sedimental and diagenetic variations

The Shahejie Formation is an important oil and gas exploration and development target in Bohai Oilfield. It is composed of the superposition of multi-stage underwater distributary channel sand bodies. However, due to the differential carbonate cementation, the physical properties of the reservoir have strong heterogeneity within and between layers, which brings great difficulty to the deployment of injection-production wells in oilfields. Prediction of complex sedimental and diagenetic variations in sandstones are critical for hydrocarbon development. Integrated petrographic and petrophysical analyses are served here to categorize five petrophysical facies representing distinct mineralogical compositions, diagenetic processes, and pore systems. To upscale petrophysical features through correlating core petrophysical facies with geophysical well logs, linear discriminant analysis (LDA) was first employed to obtain eigenvectors that can best describe and distinguish petrophysical facies. The well logs that have stronger influence on the first and second eigenvectors and have less correlations with each other are selected to compress the feature space dimensions. The supervised self-organizing map (SSOM) predicable model was trained using dimensionally reduced well log database as input and core petrophysical facies as supervision to determine the nonlinear mapping relations between log response combination features and petrophysical facies group membership. The results showed that LDA assisted SSOM model yielded higher accuracy as compared with commonly employed linear and non-linear predictable model. The supervised LDA-assisted SSOM method as provided here can be gainfully used to predict petrophysical facies via conventional well logs.

Intelligent automatic identification instrument for rock slice

1*

1. , , , , CHINA
E-mail: yuxl.syky@sinopec.com

Keywords: rock slice identification, Intelligent identification, identification instrument, Deep learning, Molecular spectrum

Rock thin section identification is the forerunner and basis of all research in geology and energy industry, but the traditional manual identification methods requires high experience and is greatly affected by subjective factors.

In this study, the method of establishing a mathematical model is proposed to analyze and simulate the process of geologists' identification of rock slices, and the model is calculated and solved based on various technical methods to obtain the identification results. On this basis, through the deep integration and digital synthesis of image recognition technology and mineral optical characterization technology, an intelligent automatic identification instrument of rock thin section is developed. For a given sample of ordinary thin slice or casting thin slice of clastic rock, The micro panorama is first automatically obtained, and then each segmented area of the panorama and its corresponding AI identification results are gradually realized, which is followed by the fingerprint identification and correction of single minerals in the thin slice sample through intelligent molecular spectrum. Finally, based on the overall processing and calculation of the AI & molecular spectrum identification results of each segmented area of the panorama, the thin section identification report and grain size thin section identification report of clastic rock are completed (including porosity value). 21 coarse sandstone thin section samples in HangJinQi area of Ordos Basin were selected and the stability, speed and accuracy were tested by using the intelligent automatic identification instrument of rock slice. The results show that the overall stability of the instrument system is good, the average identification time of each sample is 40-50 minutes, the average accuracy of image recognition part is 37-91% (weighted value), and the average pricision of image segmentation part is 16-83% (iou0.50). Compared with traditional manual identification, the identification instrument uses molecular spectrum to make the identification results of minerals more reliable. The micro panorama makes the field of view larger and more comprehensive, and the parameter calculation is more meaningful. If the accuracy of micro panorama segmentation and identification can be guaranteed, the rock and mineral identification instrument will have absolute advantages over manual identification.

Through the effective intersection and integration of multiple disciplines, this study makes it possible to use the instrument to test rock slices in standardized process, which provides a new development idea for the traditional research and has important scientific significance.

Keywords: Upper Triassic, Chang 7 section, Ordos Basin, Geostatistic decision tree, Shale facies, Black shale

The Ordos basin in North China may be one of the nonmarine basins with highest hydrocarbon generation per volume of sedimentary fill. It has great potential for unconventional oil and gas exploration, especially shale oil. When evaluating and predicting shale oil resources, the difference between different regions and different layers of shale is very obvious, so it cannot be calculated simply by average. A geostatistic decision tree was constructed based on a training set of 22 parameters (geochemistry, petrology, and sedimentology) for 110 shale samples from the basin, which can be used to implement genetic classification of subsequently collected shale samples. Three shale facies are identified by the decision tree. The properties of each facies are different, such as TOC, kerogen type and sulfur content. Genetic properties indicate formation conditions and provide base for the geostatistic assignments. The differential distribution of shale facies in the basin reflects their origins from different formation mechanism. Elements ratios, isotopes and biomarkers can be used to infer the sedimentary environment for each shale facies. Facies 1 mainly occurs in the upper Chang 7 section and shows evidence of quartz-rich source rock deposited under suboxic–anoxic condition. Facies 3 occurs at the lower Chang 7 section and shows evidence of clay-rich and pyrite-rich shale deposited under reducing dysoxic conditions with numerous higher plants input. Facies 1 and 2 constitutes the upper Chang 7 with interactive thick layers; Facies 2 and 3 constitute the lower Chang 7 with interactive thin layers.

Petrology, geochemistry and sedimentology of the shale facies suggest: Facies 1 represents the suboxic–anoxic upper Chang 7 proximal quartz-rich shale, which has lower TOC and sulfur content than other facies. The organic lamina is straight but rare. Kerogen is type I and dominated by sapropel. The content of saturated hydrocarbon in chloroform asphalt “A” extract is the highest. Facies 2 has higher TOC value, sulfur content and soluble hydrocarbon content than facies 1. It was formed in unstable hydrodynamic environment under weak anoxic condition. It is characterized by abundant laminas with various deformation structures and more alginite and vitrinite in kerogen. Anoxic lower Chang 7 distal sulfur-rich shale source rock make up organic-rich facies 3 (~7.0–17.0 wt. % TOC). This facies received more higher-plant input than the other facies. Well preserved algae shells are common in numerous and flat laminas. The content of chloroform asphalt of facies 3 is higher than that of other facies, but among which the saturated hydrocarbon content is the lowest, the aromatic, non-hydrocarbon and asphalt are the highest, suggesting the fluidity of hydrocarbon is the worst. Compared to others, this facies was formed in the environment where temperature is relative lower, water is relative deeper, productivity and salinity are relative higher, and the reducibility is relative stronger. A deeper understanding of shale classification and distribution is important for the accurate resource evaluation and optimal exploration planning of shale oil.

Intelligent Identification And Application Of Imaging Logging Facies In Carbonate Reservoir

Zongyan Han[1,2], Guiwen Wang[1,2*]
1. Collage Of Geosciences, China University Of PetroleumBeijing, Beijing, CHINA
2. State Key Laboratory of Petroleum Resources and Prospecting, China University Of PetroleumBeijing, Beijing, CHINA
E-mail: wanggw@cup.edu.cn

Keywords: Carbonate Reservoir,Image Log Feature,Image Log Facies,Feature Extraction,Deep Learning

As an important part of petroleum exploration, carbonate reservoir has become the focus of research at present. Imaging logging technology plays an irreplaceable role in the study of carbonate reservoir sedimentation and structure. The imaging logging data have the characteristics of high longitudinal resolution and strong continuity. Therefore, the changes of rock mineral composition and structure model caused by the difference of deposition and tectonic action have obvious response characteristics in the imaging logging facies. In recent years, domestic and international identification and interpretation of imaging logging facies are mostly carried out by manual method. It is not only of huge workload, but also strongly influenced by human factors and large errors. With the development of artificial intelligence technology, automatic interpretation of imaging logging data by computer has become the development trend of logging in the future. But at the same time, how to improve the automatic identification accuracy of imaging logging facies by computer, in order to study the sedimentary and structural characteristics of carbonate reservoir based on imaging logging better is also the key problem to be solved urgently at this stage. In this study, the Tarim basin, Ordos basin and Sichuan basin are chosen for carbonate reservoir research and summarize in imaging logging characteristics. A set of suitable for Chinese typical carbonate reservoir of imaging logging facies identification chart is established for the follow-up contrast research of different carbonate reservoir sedimentary and tectonic characteristics. The features include fractures, caves, striations, stripes and gravels, and the logging image patterns are divided into 28 types, including light block, dark block, light and dark block truncation, etc. In addition, JAVA language and CIFLog software is used as the platform to realize the identification and extraction of imaging logging features and phase patterns. The carbonate reservoir imaging logging phase pattern database suitable for computer deep learning is formed, and convolutional neural network (CNN) technology is used to realize computer deep learning of imaging logging phase pattern samples. According to the classification of logging phase patterns, the feature extraction of 128 wells of electrical imaging logging data of carbonate reservoirs was completed, and a total of 5647 logging features were extracted and 20802 logging phase patterns were calibrated using image segmentation technology, and a database of typical imaging logging features and logging phase patterns of carbonate reservoirs was established. Based on this, the imaging logging facies of carbonate reservoirs in Changxing Formation, Maokou Formation, Qixia Formation, Longwangmiao Formation and Dengying Formation in Hechuan-Tongnan area of Sichuan Basin were identified. The identification accuracy reached 84% after comparison and verification, which has high practical application value.

E-mail: songjinmin@sohu.com

Keywords: Sichuan basin,Mao1 Member,sepiolite-talc combination,2-dimensional distributions

The Middle Permian Maokou Formation is an essential exploration target in Sichuan Basin. With the discovery of unconventional natural gas in Maokou-1 Member (Mao1 Member), Mao1 Member is a new exploration heat in Sichuan basin. Researches unravel that sepiolite-talc combination is a crucial factor for unconventional natural gas in Mao1 Member (Song et al., 2022). However, the distribution of sepiolite-talc combination in Sichuan basin is still ambiguous and constrains the exploration in Mao1 Member. To delicately predict the distribution of sepiolite-talc combination in Sichuan basin (composing of (1) the existence of sepiolite-talc combination; (2) the contents of sepiolite-talc combination; (3) the geometric type of sepiolite-talc combination), this work collects and utilizes 1.8 million well-logging data from 245 wells. Training data are obtained from well Xt1 by microscopic, SEM, XRD analysis with coring samples. Strict comparasion of CatBoost, XGBoost, LightGBM, Random Forest, SVM, KNN, ANN incidactes that SVM and CatBoost models have excellent performances in the prediction of the existence of sepiolite-talc combination, XGBoost and ANN have excellent performances in the prediction of the contents of sepiolite-talc combination, and CatBoost is most suitable for the prediction of the geometric type of sepiolite-talc combination. Based on the results of best models, this work acquires 2-dimensional distributions of sepiolite-talc combination in Mao1 Members in Sichuan Basin. Code and technical details are accessible via https://github.com/KeranLi/multixgb.git.

Fracture identification in tight sandstones : Ensemble learning method with conventional well logs

JianWei Lin[1], WanZhong Shi[1*]
1. School of Earth Resources, China University of Geosciences, China, Wuhan, Hubei, CHINA
E-mail: 1202020040@cug.edu.cn

Keywords: Fracture identification, Tight sandstone reservoirs, XGBoost, Particle swarm optimization, Conventional well log

Fractures are of great significance to tight oil and gas reservoirs. Fracture recognized by using conventional well logs data is an economical and effective method for fracture zones identification. The classic approach to identify the fractures is crossplot. However, crossplot is not effective due to the weak and complex well log responses that fractures in tight sandstone reservoirs. To solve these problems, an ensemble learning method termed XGBoost (extreme gradient boosting) is introduced in this work, which is an improved algorithm of GBDT (gradient boosting decision tree). XGBoost has been proved to be powerful in classification, but limited by the setting of hyper-parameters. Therefore, PSO (particle swarm optimization), a heuristic algorithm, is introduced to optimize the hyper-parameters of the model. In addition, the XGBoost model is combined with an autoencoder to reduce the dimension of logging data to eliminate data redundancy. Consequently, the fracture identification method based on ensemble learning can be described as autoencoder-PSO-XGBoost. The wells of Chang 8 member in Binchang area, southwest of Ordos Basin is taken as validation. Caliper (CAL), acoustic log (AC), compensated neutron log (CNL), density (DEN) and resistivity log (ILM, ILD and LL8) were selected to evaluate the method. In order to highlight the superiority of the method, PSO-SVM (support vector machine) and MLP (multilayer perceptron neural network) are used as the comparative experiments. By comparing the experimental results with the prediction accuracy and F1-score, the proposed model is more reliable, the prediction accuracy is more than 85%, and has greater applicability in fracture identification.

AUTOMATED CORE DESCRIPTION SYSTEM APPLICATION FOR SEDIMENTOLOGICAL ANALYSIS

Evgeny E. Baraboshkin[1*], Evdokiya A. Panchenko[2], Andrey E. Demidov[1], Yana D. Sharipova[2], Nadezhda N. Gatina[2], Dmitry A. Koroteev[1,3]

Keywords: automation, core description, deep learning, computer vision, sedimentology, convolutional neural networks

The automated methods for core description have been developed for a long time. Different approaches have been used to meet the desired result: color distribution analysis and computer vision [1–5], machine learning [6–8], or deep learning [9–13] application. Recent developments in computer vision and machine learning allowed the creation of a system for automated core image extraction and description [14]. The system works with daylight core box images. Algorithms based on computer vision and deep learning have been applied to extract core column images from a core box with semantic segmentation [15] and automatically depth-reference them. These algorithms also helped to classify rocks into different rock and structure types [16]. The system works as a cloud solution. It was applied to various oil and mining industries' tasks — the system allows changes to the data produced by segmentation and classification algorithms. The speed of classification is about 10m\s. In this study, we overview the system application for sedimentological description. The quality of the images can be low (the minimum requirement is around 100dpi, which is about 390px for a 10 cm core column width).

After a classification algorithm was developed for 14 different types of rocks (3 rock types: sandstone, siltstone, shale\argillite, and five structures: bioturbated, rippled, laminated, massive, and cross-bedded) [17], it was uploaded to the system, and an expert applied it for a description of 10 different wells. An expert sedimentologist checked each well after classification and made some changes. The automated classification results have been reviewed and statistically analyzed compared to the expert's results. The classification accuracy on new data demonstrated a good accuracy\speed ratio. With a 7 - times well analysis speed increase, the minimum accuracy gained is 70%. Most lithologies have been detected correctly, but the structure was sometimes mixed. Also, some lithologies have not been included in the model (e.g., coal). The number of samples in the training set was small (less than 40 10x10 cm images), so the expert added these types to the system. The difference in NTG value measurement on the expert and algorithm classification results with a 1m sliding window is only 5%.

The automated core description application results are valuable for the industry in terms of their speed and NTG calculation. Also, it makes the life of an expert much easier. It allows him to concentrate on the results instead of the description. The overall description speed based on daylight core box images was 7-times increased. Another benefit of such a system application is automated depth referencing for the core images – the expert can interactively see the depth. The applied classification models help increase classification speed, improve the overall description quality, and be used as the first mandatory stage of initial preparation before the trip to the core storage or as a stand-alone stage for a quick core description. Even an untrained person can learn to classify different rock types while examining the results produced by an algorithm.

Instance segmentation method to assist the identification of mineral particles in rock slices under microscope

Lihe Yang[1], Zhaohui Xu[2*], Yining Gao[2]
1. College of Artificial Intelligence, China University of Petroleum - Beijing, Beijing, CHINA
2. College of Geosciences, China University of Petroleum - Beijing, Beijing, CHINA
E-mail: xuzh211@163.com

Keywords: Rock slice, Artificial intelligence, Convolutional neural network, Mineral identification

In recent years, a variety of artificial intelligence algorithms have achieved many results in solving regression problems and classification problems in the field of geoscience. The identification of mineral particles in rock slices is a classification problem in nature, and has good applicability with artificial intelligence algorithms. In the observation process of rock slices, the conventional method is to classify according to the experience of mineralogists. This manual classification method based on empirical statistics is very similar to the method of database comparison. The traditional rock slice classification method is limited by the experience of interpreters, which is a time-consuming and labor-intensive method. In this paper, an intelligent classification method is proposed. By segmenting different particles of rock slices under the microscope, each particle is marked, and then a database of mineral particles in rock slices is constructed. Then, the faster R-CNN algorithm is used to segment the rock slices image under the target mirror. Through verification, it is found that the model can quickly and accurately identify minerals such as quartz and feldspar. And the other side is more sensitive to calcite minerals. The experiments have achieved good identification results.

ML assisted sedimentological descriptions of core

Wolfgang Hujer[1], Jörg Peisker[1], Kanchan Dasgupta[1*], Astrid Metz[1], Thomas Kuffner[1]
1. TECH Center & Lab, OMV Exploration & Production GmbH, Gänserndorf, Lower Austria, AUSTRIA
E-mail: Kanchan.Dasgupta@omv.com

Keywords: Sedimentology, Core Description, Machine Learning

Sedimentological descriptions of core are often the crucial input for developing subsurface geological models as it provides numerous hard facts through direct measurements, observations, and interpretations. These core-based datasets typically are integrated with well logs and/or seismic for a better understanding of the geological/depositional model. Traditional manual core descriptions require significant amount of time and demand considerable experience of a sedimentologist. In order to reduce time and increase standardisation/ automatization, a project has been set up to develop a workflow using artificial intelligence (AI) and machine learning (ML) techniques for sedimentological data collection and core description. The main advantage would be collection of critical data from cores in a much faster and standardised format.

Over the recent years, several publications have documented the applicability of image recognition methods using AI, however, the sole dependency on core images ignores the vast amounts of measurements usually done on cores. The approach of this study is, therefore, to combine core images with a suite of diverse analytical datasets such as sedimentological, mineralogical, geochemical and geomechanical.

In the first phase of the study, the following sets of data have been used: slabbed white-light core images, tabulated analytical data comprising sedimentologial core description (lithology, texture, grain-size, sedimentary structures, bioturbation, lithofacies), spectral core gamma, routine core analyses data, XRD data and CoreDNA data (©Epslog Engineering). The main challenge in this approach was to combine the datasets with different dimensionalities. Nevertheless, preliminary results and learners from this ongoing study would be shared. Furthermore, the way forward would be discussed in order to achieve the ultimate goal of developing an automatized ML-based workflow that delivers core description/data such as lithology, texture, physical rock properties and lithofacies.

Ideally, depending on the complexity or heterogeneity of the rock, the resulting core description would only need minor revisions by senior staff for the basic sedimentological interpretation. A secondary aim of the project is also predictions of rock and reservoir properties.

Sedimentary Characteristics, Sediment Accumulation and its Geological Significance of Quaternary Sediments in Xiangqu Drainage Area of the Yarlung Tsangpo River Basin

Yalige Bai[1], Jingen Dai[1*], Zhongpeng Han[1], Zhipeng Lin[1], Chengshan Wang[1]
1. School of Earth Sciences and Resources, China university of Geosciences, Beijing, Beijing, CHINA
E-mail: djgtibet@163.com

Keywords: Quaternary, Sediment Accumulation, Yarlung Tsangpo River, Remote Sensing, Kriging Interpolation

The Quaternary sediments are synchronic records of tectonic and climatic activity. The sedimentary characteristics and total sediment accumulation can effectively reveal the climatic and tectonic information of the study area. However, it is difficult to obtain the total Quaternary sediment accumulation by traditional stratum profile measurement. This paper takes the Quaternary sediments of Xiangqu drainage area, a tributary of Yarlung Tsangpo River, as an example, and proposes a kriging interpolation-pixel integration method based on the remote sensing interpretation maps of Quaternary sediments. According to the method, the total sediment accumulation in Xiangqu drainage area is about 84 cubic kilometers, of which the alluvial and diluvial sediments are 2.7 cubic kilometers and 8 cubic kilometers respectively, with an average of 0.0629 cubic kilometers deposited per kilometer. It is equivalent to 0.066 cubic kilometers per kilometer of sediment accumulation in the wide valley section of the middle reaches of the Yarlung Tsangpo River calculated by previous authors, indicating that the Xiangqu drainage area is in a relatively slow uplift stage. The main lithology of alluvium sediments are coarse gravel, medium gravel, gravel, pebble, medium-coarse sand and sandy loam. The particle size becomes finer from bottom to top. The early deposition of coarse gravel may correspond to the period of reduced snowmelt in the glacial stage. However, due to the uncertainty of depositional age, the relationship between sediment distribution characteristics and total sediment accumulation and climate remains to be further studied.

Keywords: Geologic time scale, Knowledge graph, Open data, Data-driven discovery

With the accumulation of the large amounts of deep-time Earth data, data-driven discovery is ready to apply. These data depend on three basic information: time, space and matter. Geological time scale is a high degree of condensation of deep time data. Nevertheless, valuable hidden knowledge based on different geologic time scales and distributed in various publications. There is a lack of extracting deep time standard in current sedimentological literature. Knowledge graph (KG), as a new type of efficient organization and knowledge representation, has received increasing attention in data-intensive research. To lower the barrier of understanding time concepts in intellectual processes of geologic data, we adopted the KG technique to international geologic time concepts (geologic time scale) in 60 Phanerozoic time scales from 1893 to 2022. A unified description framework is built for the versions through the existing geological time ontology, and graph database is used to store and visualize the timescale. We realized the functions of rapid retrieval, version alignment and version recognition.

Discriminating Qiangtang, Lhasa, and Himalayan sediment sources in the Tibetan Plateau by detrital-zircon U-Pb age facies

Weiwei Xue[1], Xiumian Hu[1*], Eduardo Garzanti[2], Anlin Ma[1], Wen Lai[1]
1. School of Earth Sciences and Engineering, Nanjing University, Nanjing, Jiangsu, CHINA
2. Department of Earth and Environmental Sciences, Università di Milano-Bicocca, Milano, Regione Lombardia, ITALY
E-mail: huxm@nju.edu.cn

Keywords: Tibetan Plateau, Provenance analysis, Multidimensional scaling, Detrital zircon age facies

In the last decades, a great progress in sedimentary provenance research has been made after the advent of detrital geochronology. Because of high closure temperature and excellent durability of zircon, the detrital-zircon U-Pb isotopic system has been most widely used, and a bounty of detrital zircon ages have thus been produced. In this study, 49,111 U-Pb ages of detrital zircons from 533 samples from the six major geological domains across the Tibetan Plateau were compiled. Multidimensional scaling (MDS) statistical analysis allowed a rigorous discrimination among detrital-zircon age spectra in numerous pre-collisional units from South Qiangtang, North Lhasa, South Lhasa and the Tethys Himalaya, and to establish the detrital-zircon age facies (DZF) characteristic of each of these domains. A test based on detrital-zircon data from stratigraphic units in the Bangong-Nujiang and Indus-Yarlung Zangbo sutures demonstrates that the identified DZF represent a reliable useful tool to effectively determine the provenance of sedimentary units contained in these two suture zones. Through this extensive compilation of zircon-age data from across the Tibetan Plateau we highlight the importance of this new approach to sedimentary provenance analysis.

Keywords: Knowledge graph,Semantic technology,Calcareous nannofossil

Knowledge graph is a key technology for semantic translation and data integration, which is essential for geoscience coming to the fourth paradigm of data-intensive scientific discovery. Researchers have shown an increased interest in building knowledge graph of geoscience recently. The specific method, however, is still relatively obscure. We review the concepts of the semantic web and knowledge graph, propose a workflow for building semantic knowledge graph of calcareous nannofossil in the "top-down" approach based on UC Zone, NC Zone, CC Zone data. We give three examples, which are the construction of SPARQL endpoints to support online queries, the import to Protégé for checking logic structure, and the import to Neo4j for visualization, to illustrate the machine readability, compatibility and interoperability of the semantic knowledge graph. We hope this paper will be helpful to geoscientists who are interested in paleontology with few backgrounds of knowledge graph.

The study of the Earth's evolution helps to better understand our mother-Earth and locate resources needed, thus promoting the harmonious coexistence between man and nature. The Ocean Drilling Project (DSDP, ODP, IODP) has more than 50 years of history and has accumulated a large amount of data, which is an ideal material for studying the Earth's evolution from Jurassic to Neogene. The centralized and unified sediment time frame is a key to drawing a clear picture of the evolutionary history. The Neptune Sandbox Berlin database has collected a large amount of age-related data (biostratigraphy, magnetostratigraphy, cyclostratigraphy), however, it accounts for only about one-seventh of all sediment-related holes. There is still a large amount of data that exists in literature, voyage reports, and other databases such as Pangaea.de and LIMS, to be discovered and harmonized. Therefore, we established a semi-automatic data extraction and mining method to process age-related data from various sources and integrate it into a database, which ensures rapid growth of data and benefits the study of Earth material from Jurassic to Neogene ocean sediments.

In situ multiple techniques uncovering the occurrence of a mini oxygen oasis in near-shore microbialites

Yangfan Li[1], Fei Li[1*]
1. School of Geoscience and Technology, Southwest Petroleum University, , , CHINA
E-mail: lifei@swpu.edu.cn

Keywords: Cambrian, LA-ICP-MS,LA-(TOF)-ICP-MS, Fe oxides

With the development of emerging in-situ analytical techniques in sedimentology, more and more details of element/isotopic spatial variation at microscale levels of rocks are being discovered. In the present study, We used multiple in-situ techniques (EPMA, SEM-Raman, and LA-(TOF)-ICP-MS) to depict the redox characteristics preserved in middle Cambrian oolites and microbialites. Firstly, we acquired redox-sensitive element concentration data of different components using the LA-ICP-MS technique. Then, we drew oxygen gradient maps in ooids, microbial carbonates, and their cements taking advantage of a novel semi-quantitative 2D element imaging technique (LA-TOF-ICP-MS). After carefully examining these data, we noticed that large quantities of clay-sized authigenic minerals were distributed in the microbial components. Further SEM-Raman study confirmed that these are mostly Fe oxides and concentrated in calcified microbial microfossils. Lines of element geochemical evidence support a weakly oxic surface ocean condition in the clean, stirring surface ocean condition at that time, and the authigenic Fe oxides widely-distributed in microbial microfossils may provide compelling evidence on a key source of O_2 producing engine in the surface ocean, i.e., oxygenic photosynthesis. This study also implies that the surface ocean might not be sufficiently oxygenated (like modern level), even in the middle Cambrian time.

Apparent rock fabric number calculation technology and its application in carbonate lithofacies logging identification

Chang Li[1*]
1. Institute of Marine Petroleum Geology, PetroChina Hangzhou Research Institute of Geology, Hangzhou, zhejiang, CHINA
E-mail: lic_hz@petrochina.com.cn

Keywords: carbonate lithofacies, Logging identification, apparent rock fabric Number, KNN algorithm,Longwangmiao formation

The development of carbonate reservoirs is closely related to sedimentary facies. The identification of carbonate rock fabric components by logging data is of great practical significance for the study of carbonate sedimentary facies. However, due to the strong diagenesis and the development of fractures and vugs in the carbonate strata, it has always been a difficult problem to use conventional logging data to identify lithofacies based on rock structure and composition classification with high accuracy. At present, the combination of effective logging parameters and machine learning methods has become an effective means to improve the identification accuracy. As an effective logging parameter, the apparent fabric number (ARFN), it has achieved good application results in carbonate formations. However, this technology is not suitable for deep ancient low-porosity carbonate. Although scholars have improved this, it is still limited to no transition zone and no waterflood effects. For this, in this paper, taking the Longwangmiao Formation in the GM area of the Sichuan Basin as an example, based on the Lucia rock type classification scheme, the lithofacies are divided into three categories: granular dolomite (including dolarenite and fine grannular dolomite), crystal powder dolomite and micrite dolomite (including micrite dolomite and argillaceous micrite dolomite). Based on rock-electricity relationship analysis and formation test data, through core calibration, the rock fabric number calculation formula of Lucia is improved to make it suitable for the low-porosity reservoirs and water layers. The improved apparent rock fabric number parameter is taken as one of the input logging parameters of the K-neighbor classification algorithm (KNN) to carry out lithofacies logging identification. According to verification of the core data, the average identification coincidence rate increased from 74% to 80%. This technology meets the production needs and effectively promotes the fine study of carbonate sedimentary microfacies of the Longwangmiao Formation in the GM area.

E-mail: liukeyu@upc.edu.cn

Keywords: fluid flow, in-situ calcite U-Pb dating, fluid inclusions, isotope geochemistry, carbonate reservoir, Tarim Basin

Reconstructing fluid evolution history in old sedimentary basins is extremely challenging due to the prolonged evolution, lack of exact age constraints and absence of preserved fluids. By integrating in-situ calcite U-Pb dating, fluid inclusion analysis, measurements of major and trace elements and carbon-oxygen-strontium isotopes, and molecular composition analysis of petroleum, we have reconstructed the fluid evolution history during the Carboniferous in an Ordovician deeply buried carbonate reservoir in the Tarim Basin, NW China, with unprecedented temporal resolution. The bituminous calcite vein records at least five generations of calcite precipitation from basinal fluids that compositionally evolved from ~353 Ma to ~316 Ma, spanning over 37 m.y. The initial calcite cement was associated with an intrusion of hyper-saline brine, enriched in REEs. This was followed by influx of meteoric water to precipitate the second and third generations of cement, which are characterized by reduced salinity, anomalously high 87Sr/86Sr ratios and extremely low concentration of REEs. The fourth generation of calcite cement was formed in a deep-fluid system accompanied by oil charge as indicated by the presence of bitumen, oil inclusions and low δ13C and 87Sr/86Sr ratios. The fifth generation of cement was precipitated from equilibrated connate water, and has the lowest salinity and a comparable REE signature to the host rock. Oil charge event occurred around 326 Ma, which is much earlier than previously thought (~250 Ma) based on conventional fluid inclusion analysis coupled with basin modeling results, and may help optimize petroleum exploration strategy. While more work is needed to shed light on the fluid evolution of the entire Tarim Basin, this study demonstrates the effectiveness of combining in-situ calcite U-Pb geochronology, fluid inclusion analysis, elemental and isotopic geochemistry to elucidate high-resolution temporal fluid evolution in old sedimentary basins with a complex tectonic history, providing a new paradigm for studying geofluid evolution.

Keywords: Sedimentary pyrite, Ediacaran, NanoSIMS, Sulfur isotope, Nanhua Basin of China

Conventional geochemical indexes have explored different models of the relationship between profound evolution of eukaryotes and deep-ocean oxygenation in the Neoproterozoic Era. To further address this causality, new traced methods integrating with detailed petrological and in situ geochemical analysis by using scanning electron microscope and nanoscale secondary ion mass spectrometry on Ediacaran sedimentary pyrite, were developed in the fossiliferous Lantian drill core, South China. Samples from the core (Member II and Member III) cover depositional intervals immediately after Marinoan Glaciation (~635 Ma) and host macrofossil 'Lantian biota' (~ 600 Ma). Our results show that pyrite in Lantian black shales is mainly syngenetic, occurring as spherical framboidal, euhedral/subhedral crystals, zoned pyrite aggregates with overgrowth surrounding framboidal or euhedral pyrite cores, and fossil-shape pyrite aggregates. Atomic S/Fe ratios for all forms of pyrite range from 1.9 ± 0.037 to 2.1 ± 0.175, approaching pure-pyrite standard values (2:1). Framboid has consistently negative δ34Spy values with an average of –25.6 ± 7.9‰. Euhedral/subhedral and fossil-shape pyrite have generally positive and variable δ34Spy values with an average of 13.5 ± 14.4‰ and 16.5 ± 4.4‰, respectively. Zoned pyrite has negative and highly variable values (–20.4 ± 10.7‰). Measurement of ratios of framboidal area to total pyrite area indicates that the framboid formation is roughly subject to the high TOC%, and intervals with high content of framboid usually have low bulk δ34Spy values. Euhedral/subhedral pyrite shows distinctive δ34Spy values across the drill-core: they have degrees of overlapped δ34Spy values with framboid in the lower Member II samples, but their δ34Spy values become clearly positive in the upper Member II and lower Member III. Panel distributing patterns of δ34Spy values in zoned pyrite cystals are distinctive in different sampling intervals: δ34Spy values have no significant difference cross the pyrite crystals in the lowest Member II sample, but show increasing value trend from core to overgrowth edge in sample from middle Member II. The δ34Spy values changes of euhedral/subhedral pyrite and zoned pyrite crystals could be attributed to changes of their HS– origins that was caused by gradually deepening chemocline with the increasing sulfate concentration in the early Ediacaran Nanhua ocean. Increasing seawater sulfate in bottom water impels the occurrence of sulfate reduction within sediment, and provided enriched 34S signal to support crystal growth. Sulfate can also penetrate marine sediments to support sulfate reaction with methane beneath the sediment, fosters the formation of the sulfate-methane transition zone, and then promote enriched δ34Spy pyrite formation in comparatively restricted environment. Out research supports the hypothesis that environmental oxygenation acts as a pre-requisite for the complex multicellular life's evolution. The early-Ediacaran deepening chemocline helps to transit sulfidic deep-water to be oxic-suboxic, allowing for the occurrence of "Lantian Biota" that consist of morphologically complex benthic macroalgae and putative animals.

E-mail: geohcui@gmail.com

Keywords: Shuram excursion, secondary ion mass spectrometry, microbial sulfate reduction, anaerobic oxidation of methane, carbon isotopes, authigenic carbonate

The Ediacaran Shuram excursion (SE) records a global decrease in carbonate carbon isotope ($\delta^{13}C_{carb}$) values from +6‰ down to ca. –10‰, representing the largest $\delta^{13}C_{carb}$ negative anomaly in Earth history. While the SE is also widely recorded in the upper Doushantuo Formation of South China, it shows highly variable $\delta^{13}C_{carb}$ profiles among correlative sections. This inconsistent expression of the SE challenges the conventional view of a homogeneous marine dissolved inorganic carbon (DIC) reservoir. A potential process that could explain $\delta^{13}C_{carb}$ variability is local mineralization of isotopically distinct authigenic carbonates near the sediment-water interface during early diagenesis. However, a direct test of such authigenic carbonates is still limited. Here, following a recent study on the SE in intra-shelf environment, we revisited an outer shelf section, identified and analyzed μm-scale, syn-depositional authigenic calcite cements via integrated cathodoluminescence (CL), micro-X-ray fluorescence (μXRF), scanning electron microscope (SEM), energy-dispersive spectroscopy (EDS), and secondary ion mass spectrometry (SIMS). Our new SIMS results reveal remarkable micron-scale heterogeneity of $\delta^{13}C_{carb}$ in authigenic calcite cements, including extremely negative values down to –37.5‰ (VPDB). We interpret these calcite cements as methane-derived authigenic calcite (MDAC) resulting from microbial sulfate reduction (MSR) and anaerobic oxidation of methane (AOM) during early diagenesis. Based on the new results, we propose that the heterogeneous SE in South China — manifest on micrometer, centimeter, and basinal scales — was modulated by methane oxidation under variable local redox and water depth conditions. The SE, therefore, was coupled with different degrees of authigenesis of ^{13}C-depleted carbonates that were locally modulated by methane oxidation in individual basins, and globally triggered by enhanced seawater sulfate during an atmospheric oxygenation event. In light of this study, the potential role of redox variability in methane oxidation during the SE may have been underestimated. Our study demonstrates that integrated SIMS-SEM analysis can distinguish different generations of isotopically distinct carbonates otherwise undetected by conventional analysis, and is thus an effective approach to assess the origin and diagenetic history of $\delta^{13}C_{carb}$ anomalies in the sedimentary record.

Multi-element imaging reveals the environmental context of Precambrian carbonaceous compressions

Fenglian Zhang[1], Huajian Wang[2*], Shenghui Deng[2], Shuichang Zhang[2]
1. School of Ocean Sciences, China University of Geosciences (Beijing), Beijing, CHINA
2. Key Laboratory of Petroleum Geochemistry, Research Institute of Petroleum Exploration & Development, Beijing, CHINA
E-mail: wanghuajian@petrochina.com.cn

Keywords: Xiamaling Formation, Lantian Formation, μ-XRF, Multi-element imaging, Fossil preservation

Fossil life in the Precambrian is commonly preserved as carbonaceous compressions, where Pre-Cryogenian carbonaceous compressions mainly occur in organic-poor rocks. Black-shale-preserved carbonaceous compressions have become more common since the Ediacaran Period. To explore the depositional context of carbonaceous compressions, micro X-ray fluorescence spectroscopy (μ-XRF) was used to image elemental distributions in carbonaceous compressions and surrounding rocks in Mesoproterozoic and Ediacaran-aged rocks. The carbonaceous compressions preserved in the Xiamaling green silty mudstones (1.40 Ga) and Lantian black shales (0.63 Ga) were selected and scanned, respectively. The behavior of redox-sensitive elements (Mo, U, V, Zn, Cu) in the Xiamaling and Lantian rocks and carbonaceous compressions suggest that the overlying water conditions during their sedimentation were not sulfidic. However, the co-enrichments of Fe and S in Xiamaling and Lantian carbonaceous compressions indicate pyrite permineralization. The Lantian carbonaceous compressions have a higher pyrite permineralization degree and a lower organism decomposition degree than those of the Xiamaling carbonaceous compressions. We speculate that these differences are related to a higher sulfate reduction rate and a lower dissimilatory iron reduction rate in the sediments hosting the Lantian carbonaceous compressions. Such conditions might be achieved through rapid burial and encircling by clay minerals. Overall, our results shed new light on understanding the preservation processes of the Precambrian life and the influence o environmental factors.

Keywords: Precambrian, Stable isotope Geochemistry, SIMS

Secondary Ion Mass Spectrometry (SIMS) or ion microprobe is capable of revealing high precision isotopic and elemental heterogeneity at the microscale in various mineral phases. Recent analytical improvements either on the detection part or on the source with the new generation of oxygen primary ion sources have opened new avenues for targeting very small mineral phases, which can be then used for either reconstructing ancient environmental conditions or as potential biosignatures. We will review here recent applications of SIMS analyses in sedimentary rocks from the Precambrian. We will show that micropyrites in microbialites can be used as a biosignatures for microbial Fe and S cycling. Moreover, we will show how combining bulk and SIMS isotopes can be used to decipher diagenetic from deposition conditions. High precision geochemistry at high spatial resolution is thus a powerful approach for reconstructing ancient surface conditions from the sedimentary record through time

Brachiopods from the Latham Shale Lagerstätte (Cambrian Series 2, Stage 4) and Cadiz Formation (Miaolingian, Wuliuan), California

Yue Liang[1], Zhifei Zhang[1*]
1. Department of Geology, Northwest Univeristy, Xi'an, Shaanxi, CHINA
E-mail: elizf@nwu.edu.cn

Keywords: Cambrian, brachiopods, Latham Shale, Cadiz Formation

A moderately diverse assemblage of brachiopods from the Latham Shale Lagerstätte (Cambrian Series 2, upper Stage 4) and the upper Cadiz Formation (Miaolingian, Wuliuan), California, is described in detail for the first time. The fauna includes both linguliform (*Hadrotreta primaea*, *Paterina prospectensis*, *Dictyonina pannula* and *Mickwitzia occidens*) and rhynchonelliform (*Nisusia fulleri* and *Wimanella highlandensis*) brachiopods, together with olenellid trilobites and hyolithids. The fauna differs from other Cambrian Konservat-Lagerstätten (notably Cambrian Series 2 Chengjiang and Guanshan Lagerstätten, eastern Yunnan) in that the brachiopod shell valves in many cases are still preserved with their original mineralization. Moreover, the excellently preserved shale-hosted valves even include cases with exquisite epithelial cell moulds, otherwise only seen in acid-etched material from carbonate rocks. The pitted ornamentation in the *Dictyonina pannula* closely resembles those described from Ordovician linguliforms. The unusual preservation of *Nisusia fulleri* provides important clues for ancestral composition of the brachiopod shell. The two articulated rhynchonelliform species probably represent the oldest records of this group from the west Laurentia. The fauna may also represent the earliest onset of the transition from the Cambrian Evolutionary Fauna (CEF) to the Paleozoic Evolutionary Fauna (PEF).

The utility of NaOCl-etching before the in-situ analysis of pyrite

Li Liu[1,2*], John Mavrogenes[2]
1. Department of Earth Sciences, The University of Toronto, Toronto, Ontario, CANADA
2. Research School of Earth Sciences, The Australian National University, Canberra, ACT, AUSTRALIA
E-mail: emmaliu1016@gmail.com

Keywords: Etching, NaOCl, pyrite, in-situ analysis

Pyrite is widespread in a variety of rocks and ores. It is not uncommon that one pyrite grain is multi-generation indicated by compositional zoning (concentric). Significant information regarding the evolution of sedimentary environments or metamorphic/hydrothermal fluids can be obtained through systematic in-situ analysis (e.g., sulfur/iron isotopic composition, trace element concentration, etc.) of the pyrite growth zones (e.g., Peterson and Mavrogenes, 2014; Liu et al., 2021). It is critical to reveal internal zoning prior to in-situ analysis, otherwise spot sampling can mix multiple growth zones. Hypochlorite etching is a conventional chemical method immersing pyrite grains cast in epoxy mounts or thin sections in NaOCl solution (8–12.5 % NaOCl) for several minutes. The rinsed pyrite grains display colorful surfaces under the reflected light microscopy, and zoning can be revealed by distinct colors (due to trace element variations). The stained color is attributed to the optical interference by a thin layer of elemental sulfur on pyrite surface (Fleet et al., 1993). The spot size of in-situ analysis should then be adjusted to the various thicknesses of the growth zones. This method is fast, effective, efficient, and economical.

Hydraulic Fractures Evaluation and the Effects of Gravel Heterogeneity Based on Cores

Xiangyang Li[1*]
1. college of geosciences, China university of petroleum (Beijing), Beijing, CHINA
E-mail: 15094040073@163.com

Keywords: Hydraulic fractures, Core, Gravel heterogeneity, Propagation mode, Fractures evaluation

The method of experimental and numerical investigation on hydraulic fracture (HF) propagation mode and geometry is indirect, the insight wasn't be verified by the direct information underground, which hit a bottleneck for improving hydraulic fracturing treatment. This study establishes an evaluation of the glutenite HF by integrating cores, imaging logging, and CT scans based on a slant well recovering core. A total of 335 HF are identified from 323.19 m cores, and are divided into two types according to the HF surface feature and propagation mode: (i) shear fracture: the HF partially or completely penetrate the gravel, the fracture propagation mode is straight and the fracture surface is a plane or nearly plane; (ii) tensional fracture: the HF deflects around the gravel, the fracture propagation mode is tortuous and the fracture surface is rough and irregular. The result showed that the HF is dominated by shear fracture. The density of shear fracture is higher than that of tensional fracture. 109 HF occurrence is identified by imaging logging. The dip of the fractures is dominated by high angles, and the strike is 90°~120°, which is consistent with the direction of maximum principal stress. The impact of gravel size, supporting types, and orientation on HF propagation is investigated. It is indicated that in the case of larger gravel size, the HF tends to penetrate gravel and consequently, result in the development of shear fracture; the HF is prone to penetrate sandstone-supported conglomerate than gravel-supported conglomerate; the greater the acute angle between the gravel long axis direction and the HF propagation direction, the easier the HF penetrates gravel. The factors of the abundant shear fractures development in the study area are analyzed, which is mainly controlled by the growth of cobble and the distance of the HF from fracturing wells. The research in this work provides some references for the glutenite hydraulic fracturing treatment and experimental and numerical investigation in future.

A pilot study using LA-TOF-ICP-MS in imaging microscale carbonate diagenesis

Fei Li[1*]
1. School of Geoscience and Technology, Southwest Petroleum University, Chengdu, Sichuan, CHINA
E-mail: lifei@swpu.edu.cn

Keywords: Oolite, microbialite, in-situ element analytical technique, trace element mapping

Numerous sedimentary and diagenetic characteristics are typically controlled by mineral precipitation and alteration at the microscale level. High-resolution spatial mapping of element concentrations may provide clues on specific processes, e.g., cementation, recrystallization, and dolomitization, and would be helpful for studies of carbonate sedimentation and diagenesis. Recently, numerous in-situ element analytical techniques have been carried out in the field of carbonate sedimentology (e.g., SEM-EDS, EPMA, and μXRF), and the results show well-illustrated maps of major elements and some trace elements with relatively high contents (>100 ppm). Here, we reported an up-to-date laser ablation (LA)-based element imaging technique to determine the characteristics of major, trace, and rare-earth element spatial distribution (with concentrations ranging from >1 % to ppm levels) in several samples of microbialites and oolites. This element mapping analysis was performed using an imageGEO 193 nm LA system (Elemental Scientific Lasers) and a coupled time-of-flight (TOF) ICP-MS instrument (TOFWERK, icpTOF R). The rectangular area for LA imaging was set using a series of aligned and combined lines with a width of 7/10 μm. For calibrating carbonate samples that generally contain extremely low trace-element contents, the reference material of this study involved carbonate pellet MACS-3 (USGS) and OOID (unpublished laboratory internal standard, made from pure Bahamian ooid sands). All isotopes that can be measured by TOF-ICP-MS (n >100) were performed in the present study, and ^{25}Mg, ^{34}S, ^{43}Ca, ^{51}V, ^{52}Cr, ^{55}Mn, ^{57}Fe, ^{58}Ni, ^{59}Co, ^{63}Cu, ^{88}Sr, ^{138}La, ^{140}Ce, ^{208}Pb, ^{232}Th, and ^{238}U were focused and shown with good imaging performance to indicate specific diagenetic characteristics.

This study is supported by NSFC (no. 42172136).

Silica effect on dolomite crystal sizes during formation and burial

Yihang Fang[1*], Huifang Xu[1]
1. Geoscience, University of Wisconsin-Madison, Madison, Wisconsin, UNITED STATES
E-mail: fang9@wisc.edu

Keywords: Recrystallization, adsorbed silica, dolomite, Synchrotron high-resolution XRD, EPMA

The formation mechanism of dolomite ($CaMg(CO_3)_2$), especially primary dolomite, has been a long-lasting problem. Although carbonate is prone to recrystallization during diagenesis, micritic dolomite is commonly observed in the rock record. Our recent work demonstrated that an increase in dissolved silica could inhibit precipitation of aragonite, which is the dominant product in modern seawater, and enhance Mg incorporation in high magnesium calcite (HMC) and disordered dolomite. Crystal sizes observed during synthesis experiments showed that dolomite is precipitated as nanometer-size crystals with silica adsorbed on the surface. Therefore, we propose that silica adsorption will affect crystal sizes during growth and possibly during early diagenesis. This work examines crystal size changes through annealing experiments with different silica concentrations and applies to the micritic dolomite in the Byron Formation, the Lower Silurian Burnt Bluff Group, northeastern Wisconsin.

Analyzed with synchrotron-based high-resolution X-ray diffraction, our annealing experiments at 180 °C of dolomite nanocrystals in dissolved silica-bearing solutions show that adsorbed silica can substantially inhibit crystal growth in calcite, dolomite, and HMC during diagenesis. As we think the thick and homogenous dolostones in Byron Formation were precipitated in evaporative tidal flats to semi-closed lagoonal environments with a high dissolved silica concentration, a similar inhibition effect from adsorbed silica is responsible for explaining the micritic nature of these dolomite. EPMA results show that Silurian dolomite contains up to 400 ppm of SiO_2. Annealing experiments and EPMA results indicate that the adsorbed silica is the reason restricting dolomite crystal recrystallization during burial. Some of the Byron dolomite demonstrate micritic dolomite layers with oscillating grain sizes, likely due to different silica concentrations and adsorption amounts during deposition. This inhibition effect would provide a new explanation for the well-preserved Paleozoic and Precambrian micritic dolomite.

Multiple analytical techniques uncovering fluid evolution of hydrothermal flows in the fold-thrust system

Ziye Lu[1*], Chaojin Lu[2], Fei Li[1], Yongmei Zhang[1], Shaonan Zhang[1]
1. School of Geoscience and Technology, Southwest Petroleum University, Chengdu, Sichuan, CHINA
2. Department of Marine Geosciences, University of Miami, Miami, Florida, UNITED STATES
E-mail: luziyei88@163.com

Keywords: LA-ICP-MS, trace elements, hydrothermal fluid, fold-thrust system

Tracing the source and evolution of hydrothermal fluids in the fold-thrust system is still challenging due to the complicated tectonic activities and the frequent mixing of different flows. Although previous work established a two-stage model of hydrothermal flows (overpressure-driven and topography-driven) (Qing and Mountjoy, 1992; Machel, 2004), few of studies could provide compelling petrological and geochemical evidence to verify the source and evolution of hydrothermal fluids especially at a microscopic scale. In this study, we used a promising tool, i.e., in-situ LA-ICP-MS, coupled with other petrological and bulk-rock analytical methods, to elucidate the stages and characteristics of hydrothermal fluids recorded in luminescence-zoned dolomite of the Upper Ediacaran Dengying Formation in the eastern part of the Upper Yangtze Platform. The samples of hydrothermal dolostone were collected from three different areas (spaced approximately 3–5 km apart). From the wall rock to center, identical generations (D1–D3), especially D2 generation that includes seven luminescence zones, were identified in dolomite cements in different areas/occurrences. High-resolution in-situ measurements of trace element contents on different components further support the wide range of hydrothermal flow activities recorded in these dolomite cements. In addition, the features of REE compositions from D2 to D3, and the two-endmember mixing trends in bulk samples (strontium, carbon and oxygen isotopic compositions) provide solid evidence on the evolutionary processes of hydrothermal fluids from the overpressure- to topography-driven stages. Based on the combination of petrological, bulk-rock and in-situ methods, this study provides a template for understanding the evolution of hydrothermal flows in the fold-thrust system.

Soft part preservation in hyolithids from the lower Cambrian (Stage 4) Guanshan Biota of South China and its implications

Fan Liu[1], Christian B Skovsted[1,2], Timothy P Topper[1,2], ZhiFei Zhang[1*]
1. Geology, Northwest University, Xi'an, Shaanxi, CHINA
2. Palaeobiology, Swedish Museum of Natural History, Stockholm, SWEDEN
E-mail: elizf@nwu.edu.cn

Keywords: Hyolitha, Digestive tracts, Taphonomy, Konservat-Lagerstätten, Cambrian Series 2

Hyoliths, known globally from the Cambrian to the Permian are generally recognized as early lophotrochozoan animals of uncertain phylogenetic position. The calcareous exoskeleton of hyolithids, one of the two subgroups of hyoliths, consist of four elements including a conical conch, an external operculum, and a pair of curved enigmatic helens, but their ecology and internal morphology have long been considered controversial. Here we present for the first time, remarkably preserved hyolithids with helens and interior soft tissues from the Guanshan Biota (Cambrian, Stage 4) of Shijiangjun section, Wuding County in eastern Yunnan Province of South China. Preserved soft tissues and organs encompass the digestive tract, muscle scars and connective tissues between the operculum and conch. Three modes of soft part preservation in hyolithids from the Guanshan Biota are described: (1) preservation through pyritization, (2) sediment-infilling of guts, and (3) bacterial biofilm pseudomorphs (expressed as large internal hollow cavities), resulting from endogenous bacterial decay of soft parts. Such differential preservation of hyolith guts indicates different taphonomic modes for the soft parts of Cambrian animals in the Guanshan Biota. The newly collected material yields the oldest preserved guts in hyolithids from Konservat-biotas, and reveals new evidence for reconstructing hyolithid anatomy, such as the articulation mechanism of the opercula and the internal structures in the conch. Comparisons with younger well-preserved hyolithid specimens indicate that the gut anatomy of hyolithids was evolutionarily conservative from the early Cambrian through to at least the Ordovician.

Provenance characteristics and sedimentary-tectonic evolution of Triassic Yanchang Formation in Jiyuan area, Ordos Basin—The evidence from U-Pb age in zircons

Ke Wu[1*]
1. Department of Geology, Northwest University, Xi'an, Shaanxi, CHINA
E-mail: wuke_xbdx@163.com

Keywords: Detrital zircons, LA-ICP-MS, Provenance analysis, Sedimentary-tectonic evolution, Yanchang Formation, Ordos Basin

The Yanchang Formation of the Upper Triassic in the Jiyuan area in the central and western parts of the Ordos Basin is one of the main oil and gas enrichment areas in the basin. However, the tight sandstones of the Yanchang Formation have long been controversial on mineral genesis, formation age, tectonic setting and sediment source. The distribution and variation characteristics of detrital zircon ages were studied using LA-ICP-MS dating and geochemistry testing of the detrital zircons from sandstones in this study. The source of detrital zircons of different age components is identified, and difference of tectono-paleogeographic environments is analyzed. The main conclusions can be drawn as follows. Cathodoluminescence images show that most detrital zircon have a zonal structure. Rare Earth Element distribution models show that the sandstone is rich in HREE and is short of LREE, and all of models are left-dipping patterns. The Th/U values of detrital zircon show that most of the values are greater than 0.4, and a few are less than 0.1.The above geochemical testing results show that the source of detrital zircon is mainly magmatic rocks, followed by metamorphic rocks, and the ages of detrital zircons are reliable.The age results show that there exist three age stages of the Yanchang Formation detrital zircons, i.e., 228- 379 Ma, 1650- 1915 Ma, 2400- 2560 Ma, corresponding to the tectonic movements of indosinian, Hercynin, middle- late Lüliang movement and early-middle Wutai movement.By comparing the isotopic ages for the plutons in and around research areas, the tight sandstone of the Yanchang Formation in the central and western parts of the Ordos Basin derive from the Daqing Mountains-Wula Mountains, Yinshan Mountains and Jining areas in the north-northeast of the Ordos Basin.The sedimentary rocks source from gneissic granite in the late Neoarchean, ancient TTG gneiss and granulite in the early Paleoproterozoic, the khondalite belt in the Lüliang Movement, and the magmatic rock in the Indosinian and Hercynian.

Intelligent identification and characterization of complex lithofacies in fluvial tight sandstone reservoir

Panke Sun[1*], Shiyi Jiang[1], Sicheng Zhu[1], Yuhao Shen[1]
1. College of Geoscience, China University of Petroleum-Beijing, Beijing, CHINA
E-mail: sunpk@cup.edu.cn

Keywords: Tight sandstone reservoir, Lithofacies type, Radial basis-multilayer perceptron neural network, Intelligence

The 8th member of Shihezi Formation in East II Block of Sulige Gasfield, Ordos Basin, is a typical fluvial facies deposit, which has experienced the sedimentary evolution from braided river (lower submember of the 8th of Xiashihezi Formation) to meandering river (upper submember of the 8th of Xiashihezi Formation) from bottom to top. However, the fluvial tight sandstone reservoirs are highly heterogeneous, and the sedimentary and reservoir characteristics of different river types are of great differences. This leads to the key technical problems such as the annual reduction of single well productivity and the difficulty of reservoir optimization in the later stage of development. In order to solve these neck problems, it is urgent to conduct fine anatomical research on reservoir structure (lithofacies units and their combinations) and heterogeneity characteristics constrained by lithofacies. Through the observation and description of core lithology and bedding, this study identified eight lithofacies types: massive bedding gravelly facies, trough cross bedding coarse sandstone facies, plate cross bedding coarse sandstone facies, plate cross bedding medium sandstone facies, parallel bedding medium sandstone facies, cross bedding fine sandstone facies, wavy bedding silty sandstone facies and massive bedding mudstone facies. Through core calibration logging and sensitivity analysis of logging curves, an intelligent lithofacies identification sample database is established, and a radial basis function multilayer perceptron neural network (RBF-MLPNN) joint model suitable for different river lithofacies characteristics is established based on data-driven method. The coincidence rate of this model for the intelligent identification of single well lithofacies in the 8th member of Shihezi Formation reservoir has reached 89.06%, which is significantly higher than that of other methods. This method considers the influence of different river-type lithofacies characteristics on the distribution of logging data, overcomes the shortcomings of existing lithofacies identification methods that are low in accuracy and difficult to popularize, and solves the problem of difficult identification of complex lithofacies. This method provides an effective way for the fine anatomical study of reservoir structure and heterogeneity characteristics of tight sandstone reservoirs in Sulige area.

Research of multi-temporal-spatial-scale variation of suspended sediment in the Bohai Sea: Based on machine learning method

Zhaoying Li[1], Houjie Wang[2*]
1. Deep-Sea Multidisciplinary Research Center, Pilot National Laboratory for Marine Science and Technology (Qingdao), Qingdao , Shandong, CHINA
2. Collage of Marine Geoscience, Ocean University of China, Qingdao, Shandong , CHINA
E-mail: hjwang@ouc.edu.en

Keywords: Suspended sediment, Bohai Sea, Machine Learning;

Based on comparison of multiple machine learning algorithms, a new data-driven method, named as SatelliteFixer, is established herein to predict missing value of satellite data, which could be helpful in long-term continuous data generation with relative high resolution for temporal and spatial analysis. Compared with K-Nearest Neighbor, Support Vector Machine and Deep Neural Network, Random Forest is ultimately selected on account of its sufficiently prediction on the fluctuations in observed data. After application on 2002-2019 MODIS data of Bohai Sea and part North Yellow Sea, a reasonable reproduction of suspended sediment concentration with daily precision in 18 years is obtained by trained SatelliteFixer though constraint relationship of in-situ observational cruise data. Model result indicated a well preformation on retrieving suspended sediment concentration, showing an obvious variation among study area. Using the more comprehensive and accurate data of suspended sediment distribution, it could be calculated that average concentration varies from 0.81 mg/L to 38.95 mg/L in 18 years influencing by environment factors including wind, wave, current and tide. Controlled by East Asian Monsoon, the seasonal fluctuation of suspended sediment concentration and distribution with high concentration center located near Yellow River estuary is corresponded with hydrodynamic movement trend, while the average value is higher in Spring than in Autumn all as transition periods. Benefit from meticulous depiction by daily suspended sediment value, typical area analysis indicates regional imbalance of suspended sediment concentration dominated by varied environment factors, such as staggering peak of maximum value in winter. The subtle signal of river sediment load is captured with unstable value in summer and early entry of turbid period, while the concentration comparison of stations in Laizhou Bay demonstrates the human activity influence on river including dam construction, artificial avulsion and water-soil conservation program. Under the influence of multiple factors, the suspended sediment concentration in study area has a downward trend over the entirety reflected by Mann-Kendall test.

Transfer zones developed within fold-and-thrust belts under differential compression based on 3D numerical simulation results

Zhuoyi Shen[1*], Fusheng Yu[1]
1. Department of Earth Sciences, China University of Petroleum (Beijing), Beijing, CHINA
E-mail: 2020210048@student.cup.edu.cn

Keywords: 3D numerical simulation, Discrete element method, Fold-and-thrust belt, Transfer zone, Junggar Basin

The tectonic evolution and kinematic mechanism of fold-and-thrust belts have been studied in the field by using both physical analog experiments and numerical simulations. In this work, we study the growth and origin of the structural patterns in fold-and-thrust belts that develop under differential compression. The experiments are based on particle-flow simulations. Two simulations are configured to use four velocity modules, which can result in different shortening at the same time: (i) the homogenous module filled with brittle simulating sediment is used to investigate the structural response with a velocity difference and (ii) the module with ductile detachment at the front of each module is used to test how the weak layer affects deformation.

Two differential compression simulations were conducted in this work to investigate the structural styles and kinematic evolution of the differential shortening fold-and-thrust belts, which raises the following major points: (1) Resistance from the slower adjacent module can lead to back-thrusts prevailing in the faster module. Conversely, weak nucleation in the slower module is influenced by drag from the other side. The development of the piedmont thrust belt, gentle syncline, and pop-up structure is characteristic of the simulated ductile detachment. (2) Two strike-slip fault systems are recognized in the differential-compression simulation, Riedel shears at the foot of the backstop have a “flower structure,” which is composed of steep faults in the cross section, and the transfer faults in front appear flat thrusts with back-thrusts on the hanging wall. The different shortening distances concentrated near the backstops create Riedel shear (Naylor et al., 1986), following which the thrusts formed in front soon accommodate the compressive stress, which explains why the shear is limited to the toes of the backstops. Transfer faults that are oblique in front of the wedges transport material laterally. The uplifting of the hanging wall in the detachment simulation is characteristic of the ramp-flat fold sliding above the ductile detachment in the slower module. Material transportation in the shortening and lateral directions are the major kinematic mechanisms creating transfer faults in differential compression simulations. (3) The results of these simulations identify two factors that control the structural patterns of the south margin of the Junggar Basin. Oblique and curved fold-and-thrust belts are generated from the differential compression, and multiple rows of anticline, such as the Huoerguosi and the Anjihai anticlines, are related to the ductile detachment.

A novel evaluation method of tight conglomerate reservoir based on petrophysical facies：A case study of Triassic Baikouquan Formation, northern Mahu Sag, Junggar Basin, China.

ZHICHAO YU[1], ZHIZHANG WANG[1*]
1. College of Geoscience, China University of Petroleum Beijing, Beijing, CHINA
E-mail: wang_zhizhang@126.com

Keywords: Keywords: Reservoir evaluation,Tight conglomerate, Petrophysical facies, Mahu Sag.

The determination of high-quality regions with highly porous and permeable areas in tight oil reservoirs has always been a challenging work due to ultralow petrophysics attributes. To date, extensive reservoir evaluation studies have been undertaken to locate the favorable zones for oil exploration and exploitation. However, the selected evaluation parameters depend heavily on experience or pure mathematical methods, lacking the geological controlling factors which determine the reservoir quality, and it is hard to carry out horizontal comparison. Hence, we propose a novel reservoir evaluation method based on petrophysical facies to undertake the reservoir quality assessment for the tight conglomerate-dominated reservoir of the Triassic Baikouquan formation in the northern Mahu sag, Junggar Basin. The lithological type and diagenetic features were firstly identified based on laboratory data. Subsequently, petrophysical facies types were recognized by the combination of lithofacies and diagenesis facies. Afterwards, capillary pressure curves of different petrophysical facies were clustered to clarify the reservoir quality variation in distinct geological origin. Consequently, the evaluation standard was established and the reservoir quality distribution was analysed and drawn out. These results indicate that the distributional status of the optimal reservoir (RT1) and the worst reservoir (RT4) are primarily determined by grain size, while RT2 and RT3 are predominantly controlled by dissolution and compaction. Moreover, an evident positive association exists between the reservoir property classification and the single well production capacity, which reveals that the utilization of petrophysical facies to assess reservoir property is reliable. It is concluded that reservoir evaluation based on petrophysical facies harbors the potential to be a pivotal tool for reservoir property assessment and prediction of favorable porosity and permeability zones.

Advances of Optically Simulated Luminescence dating on marine sediments

Tao Jiang[1,2*], Yipan Hu[2], Maqsood Ur Rahman[2], Congyan Zhou[2], Kanglin Chen[2], Chen Liang[2]
1. -, Southern Marine Science and Engineering Guangdong Laboratory (Guangzhou), Guangzhou, CHINA
2. College of Marine Science and Technology, China University of Geoscieces, Wuhan, Hubei, CHINA
E-mail: taojiang@cug.edu.cn

Keywords: OSL Dating, Marine Sediment, Coast, Deep Sea

Marine sediments record the history of the earth since they are generally subjected to rare disturbance by human activities in marine environment. In order to illustrate the geological stories recorded in marine sediments, the applicability and precision of geochronological methods must be taken into account. The luminescence dating has been applied to marine sediments since 1970s' due to its long time range and reporting the ages in calendar years. Many different types of coastal sediments have been dated, including beaches, beach ridges, raised beaches, beachrocks, marine terraces, aeolianites, foredunes, back-barrier dunes or dune cordons, palaeosols, tsunami deposits, storm deposits and estuarine and tidal-flat sediments. However, due to the absence of terrigenous quartz and feldspar in deep sea, the applications of luminescence dating are few reported.

In this presentation, some case studies of Optically Simulated Luminescence (OSL) dating on marine sediments from coast to deep sea will be reviewed as follows. 1)The samples acquired from marine terraces in offshore Hainan Island, southern China were detected to illustrate the relative sea level changes, and the late Holocene coastal sediments of Hainan Island might have been reformed by tropical cyclones with a highstand sea level. 2) The ages of gas hydrate reservoirs have been detected in northern South China Sea for better understanding the accumulation processes of gas hydrates. 3) Samples collected from Hole U1431A of International Ocean Discovery Program (IODP) Expedition349 have been detected to illustrate the palaeoenviromental changes in the central South China Sea over the past 115 kyr. 4) The OSL samples from IODP Exp. 316 in Nankai Trough have been applied for great earthquake recurrences and the results show that the Philippine sea plate subduction is faster than its current rate of ~4.5 cm/yr, resulting in more frequent great earthquake events than 180-200 yr recurrence interval during the past 1,300 year. 5) A new OSL dating material called siliceous sponge spicules for deep sea sediments recovered by IODP Exp. 369 will be established. The more applications of OSL dating on marine sediments can be expected in the future to provide high precision geochronological constrains for our geoscience community.

Keywords: Pore structure, Pore-scale fluid flow simulation, CFD

The understanding and management of oil and gas recovery depend critically on quantifying microscopic pore structure features and how fluid flow through tortuous pore systems. Here an integrated approach based primarily on image processing combined with MICP tests was served to investigate the geometrical and topological features of pore spaces and single-phase flow behavior in porous media. The pore spaces were extracted by segmenting 3D images (X-CT) and 2D images (thin sections and SEM) based on grayscale threshold or color threshold, and watershed algorithms was implemented to explicitly identify pores and throats. In addition, the connected and isolated pore spaces were distinguished according to whether connected paths can be generated in Y-axis direction, and single-phase flow simulation was performed using pore network models and traditional CFD methods respectively. Results show that the isolated pore spaces occur extensively scattered within the fine-grained sandstones, conversely the connected pore spaces are spatially concentrated. In 3D representation of pore spaces, 82.64% of isolated pore spaces are dead end pores, while 73.95% of the connected pore spaces are connected by at least two throats. Smaller shape factors and network tortuosity of connected pore spaces can be obtained, which indicate more irregular shapes and less curved paths for connected pore spaces. Pore and throat size distribution has been shown to determine pore structures and reservoir quality. The 3D images can provide broadly information about pore and throat size, but the limitation is that not all pores are captured in one single imaging experiments, due to finite resolution and sample volume of the experiments. The 2D images of different resolutions allow to capture geometrical features of pore spaces in different scales, but they cannot effectively reflect the realistic topology characters of pore spaces, i.e. the connectivity of pore spaces (2D) is significantly poorer than their real connectivity and it is substantially difficult to find connected paths in 2D images. Solving single-phase transport properties using pore network models is numerically efficient, which attempt to simply the pore geometries while retain pore topology features. Good positive correlation between coordination number and pore radius could be found in pore network model, which means that larger pores are more likely to be connected by throats and emerge better pore connectivity. The throat radius records a good positive correlation with fluid flow rate, which is consistent with the results of MICP tests, that is, a small number of large throats in low-permeability sandstones contribute the vast majority of permeability. The simulation results of CFD methods also show that the large pore throats in the sandstone constitute the dominant seepage paths.

A comprehensive method for investigating 3D pore structures and its influence on fluid flow capacity of low-permeability sandstones

Ya Wang[1*], Lizhen Ge[1], Jiatao Wen[1], Chao Liu[1], Yongping Wang[1]
1. Bohai Oilfield Research Institute, CNOOC China Limited, Tianjin Branch, Tianjin, CHINA
E-mail: wangyayifan@163.com

Keywords: Pore structures, fluid flow, low-permeability sandstones

Pore structures determine the reservoir petrophysical properties and thus control fluid flow in sandstones. Detailed investigation of pore structures is vital for evaluating reservoir quality and improving the efficiency of oil/gas development. Poroperm analysis, mercury injection capillary pressure (MICP), and X-ray CT imaging were performed to probe the pore structures of the low-permeability sandstones. We then combined with numerical simulation to quantify the fluid flow behavior. Four types of pore systems were identified: residual intergranular pores, secondary dissolution pores, micropores and a minor amount of micro-fractures. The large pore throats are well developed in the pore system dominated by residual intergranular pores. The pore systems composed mainly of secondary dissolution pores exhibit a highly variable pore size distribution, and there coexists micro-scale pore throats and nano-scale pore throats. X-ray CT scanning experiments with different resolutions were conducted, and the resolution effects on pore structure characterization were revealed. The selection of imaging resolution must address the dilema between sample representativeness and scanning accuracy at the same time. For low-permeability sandstones with small grain sizes, the X-ray CT data with an imaging resolution of 1.0 μm is appropriate. Due to the limitation of image resolution and image processing technology, the image-based porosity and permeability is larger than the helium porosity and air permeability detected by laboratory experimental measurement. Finally, the controls of pore throat size, pore connectivity, and spatial combination of pore-throats on fluid flow capacity were clarified. The dominant flow channels are generally well developed in the sandstones with strong microscopic heterogeneity and good pore connectivity. Furthermore, the results are of great significance in predicting reservoir quality and fluid flow properties in low-permeability sandstone reservoirs.

Sedimentary evolution of alluvial fan and fluvial facies under the sequence architecture of the Guantao Formation, Binxian uplift and surrounding areas, Jiyang Depression, China

Yu He[1], Qing Li[1*]
1. China University of Petroleum (Beijing), College of Geosciences, Beijing, CHINA
E-mail: liqing@cup.edu.cn

Keywords: Sequence architecture, INPEFA curve, Wavelet change, Guantao Formation, Binxian uplift

To the problems of the strong heterogeneity and the multi-solution of lateral comparison of alluvial fan and fluvial facies of the Neogene Guantao Formation in the Binxian uplift and the surrounding areas of the Jiyang Depression, a new stratigraphic division method combining high-resolution sequence stratigraphy with cyclic stratigraphy is established, revealing the sequence architecture and the sedimentary filling characteristics of the parasequence group within the third-order sequence in the study area. Using the INPEFA curve obtained by the maximum entropy spectral attribute analysis technique and the time-frequency features extracted by the wavelet transform method, combined with the well-seismic method, the identification of the high-resolution sequence stratigraphic interface and isochronous stratigraphic correlation of the Guantao Formation have been completed. Compared with the conventional logging division method, the trend inflection point of the processed curve can improve the accuracy of the identification of cycles at all levels, and the coupling between cycles and sedimentary facies sequence is better. The results reveal that the Guantao Formation corresponds to a third-order sequence, which can be divided into one long-term cycle (LNG), four medium-term cycles (from bottom to top, MNG1-MNG4), and 11 short-term cycles (from bottom to top, SNG1-SNG11). During the depositional period of the Guantao Formation, alluvial fans, braided rivers and meandering rivers were mainly developed. The sequence plays an important role in controlling sedimentary facies. With an increase in the ratio of accommodating space to sediment supply, alluvial fans have gradually evolved into braided rivers and meandering rivers. Alluvial fans and braided river deposits are mainly developed in the rising period of the LNG, while meandering river deposits are mainly developed in the falling period of the LNG. The transition between rising and falling periods was located in the middle and upper part of the Guantao Formation. As the base level rises, the sand bodies gradually decrease, and the Binxian uplift is gradually filled up. The integration of multi-scale methods has certain reference significance for the construction of sequence stratigraphic framework and sedimentary filling model in areas with strong heterogeneity and provides a reference for the subsequent sand body prediction and exploration and development of the Guantao Formation.

Digital Processing and Recognition of Core Fluorescence Response Image

Jian Fu[1*], Longwei Qiu[1], Xin Li[1]
1. School of Geosciences, China University of Petroleum, Qingdao, Shandong, CHINA
E-mail: fujian@93learn.com

Keywords: core fluorescence image,computer automatic identification,core

As important data for observing the structure of underground rock formations, the core fluorescence image is of great significance to the analysis of the meaning of its different color responses. Computer automatic identification can remove errors in human observation and improve the efficiency of related research and analysis.

The method I have used is

1. Based on the reflection color of the core box, the difference between the corresponding color of the core fluorescence and the core fluorescence is used to exclude the influence of light reflection on the results. The output fluorescence image is an RGB image. The pure reflection value without fluorescence response is (0, 0, 255), and the ideal and best organic matter fluorescence response value is (255, 255, 0), so the difference will not affect the fluorescence response of organic matter.

2. Convert the RGB image output by the computer into an HSV image, and obtain the one-dimensional feature vectors of three cut cores HSV=H*QH*QS+S*QV+V (H: Hue (0~360) S: Saturation (0~1) V: Brightness (0~1) QH, QV, QS are the quantification levels of H, S, V, respectively), and a fluorescence corresponding curve is obtained after averaging.

3. Coarse quantization of various corresponding colors, that is, the H component is quantized to 16 levels, the S component is non-uniformly quantized to 4 levels, and the brightness has a small distinction between colors, which is not considered, for the time being, to obtain 64 representative colors. Assign values to get the corresponding curve.

4. Use conventional methods to analyze the abnormality of the fluorescence response curve to obtain a standard plate of fluorescence response.

V. Application of fluorescence response standard plate for core fluorescence image recognition.

The core fluorescence response color is not only affected by the content of organic matter, but also by the comprehensive effect of many factors such as the content, size, and microstructure of bright crystal particles.

Technical method for analysis of provenance system characteristics of Laiyang Group in Lingshan Island and its surrounding areas

Ya chao Wang[1*]
1. , , , , CHINA
E-mail: 2862584055@qq.com

Keywords: Source system characteristics, Laiyang group, Lingshan Island, Tracer method of heavy mineral analysis source

Lingshan Island is located in the middle of Jiaonan uplift and Qianliyan uplift, on the suture line of Sulu orogenic belt, and is controlled by the collision between North China plate and Yangtze plate. Lingshan Island formation mainly develops turbidite of Laiyang Group of Lower Cretaceous, terrigenous clastic rocks, volcanic rocks and pyroclastic rocks of Qingshan Group. The strata of Laiyang Group mainly show the interbedding of gravity flow sedimentary rocks, siliceous rocks and siltstones. Its distribution is not limited to Lingshan Island, but extends parallel to the orogenic belt in the northeast and reaches Wulian fault in the south. The provenance system characteristics of Laiyang Group in Lingshan Island and its surrounding areas can be comprehensively analyzed by the following methods: (1) Paleocurrent direction analysis, which indicates the direction of restoring paleocurrent through many indicators of paleocurrent direction preserved in the strata, such as corrugation, oblique bedding, trough pattern, directional arrangement of gravel, etc. (2) The analysis of debris composition and the change of gravel detritus composition can indicate the evolution of provenance composition and tectonic setting of orogenic belt, and can also reflect the crustal uplift and subsidence in provenance area; (3) Trace method of provenance of heavy mineral analysis, which can be divided into heavy mineral combination analysis, heavy mineral corresponding index analysis, single mineral analysis, etc. Single mineral analysis, such as zircon U-Pb isotope dating and apatite trace element analysis, establishes the sedimentological relationship between sediments and provenance, effectively traces the background and properties of provenance, and can obtain the internal relationship between basin subsidence and important thermal tectonic events. Through these technical means and methods, the provenance system characteristics of Lingshan Island and its surrounding outcrop areas are analyzed, and the structural pattern change characteristics of basin and mountain ranges in the study area of Laiyang Group during the sedimentary period are discussed, which will provide some guidance for further understanding the relationship between Riqingwei Basin and Jiaolai Basin.

Logs predication for high-quality shale based on support-vector-regression and Particle swarm optimization: A study case of Shahejie formation, Boxing Depression, Bohai Basin

Qian Feng[1], Wanzhong Shi[1*], Xiaofeng Xu[1]
1. School of Resources, China University of Geosciences, Wuhan, Hubei Province, CHINA
E-mail: 1973453157@qq.com

Keywords: shale, logs, lithofacies predication, SVR, PSO

The continental shale is characterized by strong vertical heterogeneity, usually with a laminated structure, which is composed of carbonate or siliciclastic rocks and organic-rich clay laminas. There are significantly different in the mineral composition, hydrocarbon generation potential, and pore structure. Thus, the division of lacustrine shale lithofacies needs to be based on the mineral composition (carbonate, quartz and feldspar, clay), rock structure, and the total organic carbon (TOC) and it is the foundation of reservoir evaluation and prediction.

The laminated structures are areally developed within the fourth member of Shahejie formation of Boxing depression. The laminated shale almost is carbonate laminas interbedded with organic-rich clays and little siliciclastic laminas. Logs data provide abundant and high precision geological information which is always used for prediction. Many methodologies have been applicated to predict the shale lithofacies including multiple linear regression (MLR), Kohonen neural network (KNN), and Bayes classifier. But these methods cannot work for the prediction of shale lithofacies in the study area due to the lack of measured data and the poor correlation between the minerals content and the logs.

In this research, we used X-Ray diffraction (XRD), TOC, and logging of well A to divide the shale lithofacies, and rock pyrolysis was used to identify the high-quality shale lithofacies. We selected AC (acoustic log), RT (true formation resistivity), GR (gamma-ray), and CNL (neutron log) as the feature parameters to fit the mineral content using the support-vector-regression (SVR) model. It was trained by particle swarm optimization (PSO). We used the model to predict the vertical shale lithofacies by the calculated mineral contents.

The measured data show that eight lithofacies are present in the study area: (1) organic-rich laminated sandy limestone; (2) organic-rich laminated limestone; (3) organic-rich laminated calcareous sandstone; (4) organic-rich laminated argillaceous sandstone; (5) organic-rich bedded sandy limestone; (6) organic laminated sandy limestone; (7) organic bedded sandy limestone; (8) organic massive calcareous sandstone. The organic-rich laminated sandy limestone is high-quality lithofacies. We identified several organic-rich laminated sandy limestones in well A. The results show that the mean absolute deviation (MAE) between predictive and measured values of mineral contents is 5% in the SVR model. This study shows that the SVR method is a powerful tool for shale lithofacies prediction in the background of measured data is small and the correlation between logs and mineral content is very poor.

Virtual Digital Outcrop Under DDE

Yulong Liu[1], TingShan Zhang[1*], Shixin Li[1]
1. , , , SICHUAN, CHINA
E-mail: zts_3@126.com

Keywords: Digital Outcrop,UAV,DDE,UE4

The outcrop is the basic part of geological research, geologists usually visit the site to study its characteristics and infer the underground rock. The study of outcrops is not limited to the basic field, it is often used in the oil industry for reservoir modeling and to fill the gap between the seismic scale. The outcrop is often far away from the urban area and is located in difficult landforms. Scholars often face difficulties such as data collection, dangerous working environment, long working cycle and so on. In view of the importance of outcrop research in geology and its branches, the emergence of virtual outcrop model (VOM) enables research to be carried out in the laboratory. In the past ten years, LiDAR has been used as the main acquisition method for outcrop modeling, and its acquisition cycle and post-processing cycle are relatively long. In this study, UAV tilt photography is used as the outcrop acquisition method to model a profile with multi-precision blocks. With the support of UE4 engine, the 3D models with different precision are assembled, and the outcrop micro-geological information is fused with the scene roaming function by using UE4 development function. Result shows that: (1) On the basis of flexible and efficient acquisition, the modeling accuracy of UAV tilt photography can also meet the research needs; (2) The outcrop models with different precision and position can be spliced by UE4 engine, and the outcrop model is modularized. (3) The development function of UE4 can integrate the micro-scale information such as sedimentary structure, paleontological fossils and thin slices with the virtual outcrop model, and realize the roaming function, which can be used as the construction scheme of mathematical information database of outcrop profile, which is consistent with the purpose of DDE to "share global geoscience knowledge". (4) In teaching, it provides cognitive assistance for geological field practice.

Fault propagation in pull-apart basin and its implication on depocenter migration: A discontinuum based numerical study

Xin Li[1*], Lei Huang[1]
1. geology, Northwest University, Xi'an, Shaanxi, CHINA
E-mail: 1123372004@qq.com

Keywords: Strike-slip fault, pull-apart basin, depocenter migration, numerical simulation

The development degree and formation process of faults control the subsidence evolution in strike-slip pull-apart basin. In previous studies on the characteristics and evolution process of strike-slip pull-apart basin by physical simulation, there is a lack of correlation analysis between fault development process and basin subsidence process. Based on the discrete element method software PFC2D, this paper simulates the geometric morphology and deformation characteristics of strike-slip pull-apart basin evolution caused by strike-slip faults underlapping and overlapping. According to the curves of stress and displacement, the variation law of stress at different positions is explained. Combined with the characteristics of average stress distribution and contact force distribution in the basin, the influence of fault development on basin depocenter migration is discussed. The simulation results reveal that the fault extension process in the early stage of basin development in both cases is developed from the main fault endpoint to the opposite plate. In the late stage of basin development, underlapping model developed penetrating faults in the basin, and the new faults expanded outward. There was no large penetrating fault in the overlapping model, and the faults only expanded outward. The corresponding depocenter of the basin develops from both ends of the main fault to the interior, with the extension of the fault and then to the exterior. The fault propagation and basin depocenter migration of the KSG basin in North Africa correspond well with the simulation observation conclusion. The relevant research results can provide a theoretical basis for the analysis of similar basins and the judgment of the evolution stage of basin development.

Cyclostratigraphy of xingouzui Formation in Jiangling Sag, Jianghan Basin and its sedimentary response to Paleocene-Eocene Thermal Maximum heat events

Xu enze[1], Wang yaning[1*]
1. School of GeoSciences, Yangtze University, Wuhan, Hubei Province, CHINA
E-mail: wyn-ml@foxmail.com

Keywords: Jiangling Depression, Cyclostratigraphy, Xingouzui Formation, Absolutely Astronomical Time Scale, Deposition rate,

Jiangling depression is located in the west of jianghan basin, southern China is on the Yangtze continental block in the development of Cenozoic continental basin, the deposition of thick more continuous Cenozoic strata, after years of exploration, predecessors to the structure and evolution characteristics of jiangling depression had certain understanding, but for the regional stratigraphic age there is a big controversy, including new groove tip group basic assurance for floor age 56 Ma, However, the age of the top boundary is still uncertain, and the age difference leads to the uncertainty of the duration of the Xingouzui Formation, which affects the understanding of the structural evolution and hydrocarbon accumulation law of jiangling Depression. Based on spectral analysis of logging data from typical Wells in Xingou Zui Formation, Jiangling Depression, Jianghan Basin, the 405 kyr long eccentricality orbital period in the sedimentary record was identified and astronomically tuned. Floating astronomical chronoscales with duration of 8.921 Myr for well E9 and 5.504 Myr for well L8 were established. Based on the Eocene bottom age of the 2020 International paleomagnetic standard polar column of 56 Ma as the time anchor, a high-precision absolute astronomical age scale of 56-47.079 Ma was established for the Xingou Zui Formation. The deposition rates of The Xingou Zui Formation in Well E9 and Well L8 are estimated to be 9.98cm/kyr and 16.85cm/kyr, respectivelyIt is helpful to infer the distribution range of reservoir and source rock through the difference of different deposition rates for subsequent oil and gas exploration. In addition, a preliminary discussion was made on the reason why the long eccentricity signal of 405kyr was obviously weakened during the middle palaeocene extreme heat event in the xingouzui formation.

Application of high frequency 3D sequence stratigraphy technique in prediction of carbonate deposition law

XU Hai[1*]
1. Oversea Department, Exploration & Production Research Institute, Sinopec, Beijing, CHINA
E-mail: xuhai.syky@sinopec.com

Keywords: high frequency sequence, horizon cube, stratigraphic body, carbonate rock, sedimentary evolution

The concept of high-frequency sequence stratigraphic body is put forward for the first time, which is the further development and extension of seismic stratigraphy, sequence stratigraphy and well logging geology. The principle of spatial relative resolution and the concept of stratigraphic body is introduced and utilized; the calibration and application methods of high-frequency sequence stratigraphic body (HFSSB) are described in detail; at the same time, the technical flow, and analysis with application methods emphatically are introduced. Under the framework of this technology, taking S5 and S6 reservoirs in the Middle East oil field as an example, firstly the HFSSB is calibrated by high-frequency sequence stratigraphy of wells. In addition, 10 five-order cycles are further subdivided in the period of a transgressive and regressive sedimentary cycle. According to paleo-geomorphology restoration, based on the theory of relative spatial resolution, according to the reflection interface extracted from reservoir position of the high frequency sequence stratigraphic body, within the limited seismic wave group, following the vertical sedimentary time series, the reservoir properties of HFSSB are deeply decoded in space. Combined with the information of logging and geological calibration, the spatial distribution of s6-2 to S5-1 carbonate deposits is also successively analyzed in vertical direction, the horizontal attributes show that the sedimentary law and changes of tidal channel of shoal deposits are predicted more accurately than conventional method.

Evolution of the hydrocarbon migration system of the Lower Enping Group in the Pearl River Estuary Basin

Shengmin Huang[1*]
1. college of geosciences, China University of PetroleumBeijing, Beijing, CHINA
E-mail: 1316855479@qq.com

Keywords: favorable area, fluid inclusion, hydrocarbon expulsion threshold, hydrocarbon migration, Lufeng sag

The Enping Group of the Paleogene System in the Lufeng south area of the Pearl River Estuary Basin has good potential for hydrocarbon exploration. It is characterized by a vertically large distribution of a crude oil type and a widely horizontal distribution of similar crude oil. With the complex characteristics of hydrocarbon distribution and migration, studying the evolution mode of this migration system on a dynamic scale is necessary. In this study, the key accumulation period was determined using existing logging, seismic, and microscopic data combined with fluid inclusion and burial history. Then, the system's migration path and the direction of migration in the key accumulation period were analyzed, and the migration system and evolution model in the study area were established. The results show two stages of accumulation in the southern Lufeng area: 19–8 Ma and 8–0 Ma. In the first stage, the reservoir mainly followed the transport of a far-source fault–sand–ridge coupling system and the traps on the migration path were favorable for hydrocarbon accumulation. In the second accumulation period, traps that developed near the oil-source faults were favorable for hydrocarbon accumulation. The favorable traps in the first accumulation period were distributed in the whole area. The traps in the southwest wells B921 and C1211 were larger than the first stage, whereas the favorable traps in the northeast and central parts were mainly distributed in B211D and its adjacent well area, with smaller and scattered traps. Favorable traps in the second accumulation period were mainly distributed in the eastern and central regions, around wells B211D and B161, whereas the traps in the southwest were not conducive to hydrocarbon accumulation due to the lack of effective transport system connection. The results of this study have a certain guiding significance for practical exploration.

Modeling method of paleokarst restoration under multivariate constraints based on Digital Outcrop

Xiang Gao[1], jianwei Feng[1*]
1. School of Earth Science and technology, China University of Petroleum (East China), Qingdao, Shandong, CHINA
E-mail: 1823691694@qq.com

Keywords: Paleokarst cave reservoir,Multivariate constraints,Multipoint geostatistics,Digital Outcrop

A large area of deep carbonate reservoirs are developed in the platform basin of Tarim Basin. Different from the conventional clastic reservoirs, carbonate paleokarst cave reservoirs have their unique distribution rules. The traditional sedimentary facies modeling methods can not achieve good modeling results in this kind of reservoirs. Based on the investigation of typical karst outcrop in Yijianfang area, this paper uses modern measurement means such as UAV proximity photography and three-dimensional laser scanning to collect multiple data and construct an integrated digital outcrop model. Based on the fine identification and division of geological parameters of Digital Outcrop, a new method of paleokarst restoration modeling under the constraint of multivariate data is proposed. Taking the typical outcrop karst quantitative development model highly summarized as the training sample, combined with modern karst achievements, the karst development training image database is constructed. At the same time, the virtual well construction technology is used to construct the actual karst cave parameters with the virtual well method as the hard data-driven model. The multi-point geostatistics method under multivariate constraints is mainly adopted. Through the multivariate data fusion theory based on optimal parameter estimation, the three kinds of constraint data of fault parameters, fracture data and stratum attributes are fully integrated as the simulated trend constraint data. Combined with the training images and soft and hard data, the three-dimensional prototype geological model of paleokarst is constructed. The results show that the simulation results are more faithful to the hard data, and the restored paleokarst model is highly consistent with the karst development model of underground river type reservoir in Tabei reservoir.

Dual-Energy CT: a new perspective for non-destructive analysis of sediment cores using stoichiometric calibration method

Margherita Martini[1*], Pierre Francus[1,2], Leonardo Di Schiavi Trotta[3], Philippe Després[3]
1. Earth Science, INRS, Québec, CANADA
2. Research Centre on the Dynamics of the Earth System, GEOTOP, Montréal, Québec, CANADA
3. Department of Physics, Physical Engineering and Optics, Université Laval, Québec, CANADA
E-mail: margherita.martini@inrs.ca

Keywords: X-rays, sedimentology, medical CT, lacustrine sediment, chemical composition and electron density

Dual-energy CT (DECT) consists in imaging objects using two X-ray incident beams with different energies in order to discriminate and identify the different phases within a sample based on their density (specifically electron density, ρ_e) and elemental composition (effective atomic number, Z_{eff}). Here, a stoichiometric calibration method, originally developed for medical purposes and not requiring the previous knowledge of incident X-ray beam is applied to sediment cores, exploring the potential of this non-destructive technique for studying in 3D the inner changes in sedimentary composition, e.g. mineralogy and porosity.

Lacustrine sediment cores from the Canadian Artic containing pronounced sedimentary variations were tested. Cores were scanned using a medical CT instrument at 70 kV and 140 kV and chemical composition and electron density were calculated using the above-mentioned stoichiometric calibration protocol. ρ_e and Z_{eff} profiles were then compared to element profiles obtained from the same cores at the same resolution using a µXRF core scanner. Comparison of these profiles reveals elements having the strongest influence on two properties inferred with the CT-scanner.

Then, the prediction of sediment core chemical composition using DECT was tested, verifying the possibility to make this approach an alternative to current techniques.

In conclusion, dual-energy CT is a versatile method able not only to visualize non-destructively the inner structure of sediments but also shows promising prospect in identifying mineralogical and/or porosity changes in three dimensions.

Characterization of Pore Structure and Connectivity of Sedimentary Rocks by Synchrotron Small-Angle X-ray Scattering (SAXS)

Linhao Zhang[1], Shu Jiang[1*]

1. Key Laboratory of Tectonics and Petroleum Resources, Ministry of Education,, China University of Geoscience, Wuhan, Hubei, CHINA

E-mail: jiangsu@cug.edu.cn

Keywords: Longmaxi shale, small-angle X-ray scattering, closed pores, fractal dimension, absolute scattering intensity

Sedimentary rock pores are the storage space of many fossil energy. As a typical unconventional fine-grained sedimentary reservoir, the pore-throat configuration relationship of shale is more complex than that of sandstone and carbonate, which leads to the problem of low oil recovery in the process of exploitation. However, the complex pore-fracture network system is more conducive to the physical binding of carbon dioxide by rocks and promotes its dissolution and mineralization reaction, and also leads to shale reservoir being target fotmation for carbon dioxide geological sequestration. Therefore, revealing the pore structure and connectivity of shale is of great significance for the transformation of pore-fracture system in the process of oil and gas exploitation, and can be further used to guide the geological sequestration of carbon dioxide.

Small-angle X-ray scattering (SAXS) is a non-injection and non-destructive method that can be used to quickly and comprehensively characterize various parameters in shale pore systems at the nanoscale. In general the relative scattering intensities obtained irectly from SAXS can be used to calculate parameters related to the scatterer morphology such as the radius of gyration and particle/pore size distribution of the material, and therefore have a wide range of applications in nanoscience, structural resolution dependent on biological function, etc. Radlinski et al., (1996) was the first to use SAXS for the characterisation of pore distribution in porous media such as coal rock. When it comes to calculating parameters related to the mass density of a sample such as total porosity, specific surface area, etc., absolute scattering intensity must be used. Many scholars have investigated the process of absolute scattering intensity correction for weak scatterers such as biomolecules, but less research has been done on absolute scattering intensity correction for strong scatterers such as shales. In this study, the absolute SAXS intensities of typical fine-grained sedimentary rock samples, such as shales of the Longmaxi Formation in the Sichuan Basin, China, were calibrated by various methods under the Shanghai Synchrotron Radiation Facility. This study combined with the Debye-Porod theory on how to calculate porosity and specific surface area of porous media by absolute scattering intensity, reveals that the pore structure and connectivity characteristics of mud shale reservoirs are important for studying the diagenetic evolution of shale reservoirs, searching for shale oil and gas sweet spots, and predicting fracturing effects.

SEDIMENTARY FACIES CHARACTERIZATION WITH AN INTEGRATED ANALYSIS OF HIGH-RESOLUTION BOREHOLE IMAGES, NUCLEAR MAGNETIC RESONANCE LOGS, MINERALOGIC LOGS, CORE AND CT DATA IN GLAUCONITIC SANDSTONES OF M2 SANDSTONE, ORIENTE BASIN-ECUADOR

Washington Alarcon[1], Janeth Gaibor[2*], Armando Gomez[2]
1. G&P, Grupo Cobra, Quito, Pichincha, ECUADOR
2. Wireline and Perforating, Halliburton Latinoamerica, Quito, Pichincha, ECUADOR

Keywords: glauconitic sandstones, image logs, nuclear magnetic resonance, CT, cretaceous

The main reservoirs in the Oriente Basin in Ecuador corresponds to the Hollin Formation and the U Sandstone and T Sandstone members of the Napo Formation. However, the last drilling campaign in the Cuyabeno field suggested that the M2 Sandstones Member of Napo Formation can become a potential secondary reservoir. However, secondary reservoirs as the M2 Sandstones Member of the Napo Formation are poorly known due to lack of information and more complex mineralogy. For example, the presence of glauconite could affect to gamma ray, resistive and density logs, which conventional petrophysical analysis can presents many uncertainties in this kind of reservoir. Hence, this sedimentological characterization is the result of the integration of novel technology as high-resolution borehole images, nuclear magnetic resonance, mineralogy, and core data. The core analysis includes porosity/permeability analysis, thin sections description, XRD analysis and computed tomography (CT) data. The core data was used to calibrate the interpretation of the high-resolution borehole, nuclear magnetic resonance and mineralogic well logs.

The core data is the main part of the interpretation for a sedimentological analysis. Nevertheless, on few occasions the core covers all the reservoir, and they are taken in a limited number of wells. In other hand, the well logs acquire information of the entire stratigraphic column. The combination of these data permit to elaborate a detailed sedimentological description of the geological formation.

The presence of glauconite and illite defined in the XRD data, thin section analysis, mineralogic logs and type of bioturbations suggests a shallow marine environment. The textures present in the image logs as cemented beds, and nodules, propose several diagenetic events in these sandstones, which can reduce the reservoir properties. And finally, the changes in the grain size present in the core are correlated with variations in mineralogy and pore size defined by mineralogic and nuclear magnetic resonance logs.

The integrated sedimentological interpretation together with detailed well correlations suggest that different sandbodies of the M2 Sandstone could be represent marine bars.

The result of this integration permitted to elaborate a robust sedimentological model of the M2 Sandstone. This detail analysis enhanced the petrophysical interpretation, and will be a input for the elaboration of a posterior geocellular model in order to develop this mature field.

E-mail: Marie-Eugenie.Jamba@inrs.ca

Keywords: Paleoclimatic reconstructions, Particle-size, Micro-CT, Varves

Particle-size analyses from thin sections of sediment cores extracted from lakes and oceans allowed to obtain robust paleoclimatic reconstructions. These reconstructions consisted of a detailed study of the structure and texture of varved sediments using image analysis of pictures taken at the scanning electron microscope. This method is destructive, laborious and requires long periods of sample preparation. This paper investigates the possibility to use X-ray micro-tomodensitometry (µCT) for such paleoclimatic studies. µCT allows the observation of objects whose sizes are of the order of several micrometres and has the advantage of being a non-destructive technique, facilitating the study of the internal structures of a wide variety of geological objects. A home-made sample holder was designed and built to scan cores that were previously studied by the thin sections method. Then, several instrumental acquisition and images 3D reconstruction settings were tested in order to identify the best possible configuration to 1) determine the limits of varves; 2) perform the varve counting; 3) estimate the annual mass accumulation rate by the estimation of each varve density; 4) access the morphology and size of sediment grains, which are, in favourable settings, revealing indices of the prevailing climatic conditions at the time of their deposition. These µCT results will be compared to the ones obtained by the thin sections method to evaluate the effectiveness of the method for paleoclimatic analyses.

Measurement and sampling of dynamic near-seafloor flows in Kaikōura Submarine Canyon, offshore Aotearoa New Zealand

Katherine Leigh Maier[1*], Scott D Nodder[1], Stacy Deppeler[1], Peter Gerring[1], Oliver Twigge[1], Joshu Mountjoy[1]
1. Wellington, National Institute of Water and Atmospheric Research, Te Whanganui-a-Tara Wellington, NEW ZEALAND
E-mail: katie.maier@niwa.co.nz

Keywords: submarine canyon, sediment, flow, lander, mooring

Linking measurements of process to depositional products has been a long-standing challenge in sedimentology and stratigraphy. This has been particularly difficult in deep-sea submarine canyon and channel environments that experience dynamic and often unpredictable flows with varying sediment flux to the seafloor and along channels. Targeted studies along such systems including paired near-seafloor and seabed samples and measurements are needed to characterise and quantify sediment and organic carbon flux. Here, we present initial results of a pilot study in the Kaikōura Submarine Canyon, offshore northeastern Te Waipounamu South Island, Aotearoa New Zealand. The experiment focused on three locations along the submarine canyon floor from ~900 to ~1500 metres water depth with sediment traps mounted on a mooring (~15-16 metres above the seafloor) and on a benthic lander (~2 metres above the seafloor), with complementary multicores (across the sediment-water interface) collected at each site. Benthic landers deployed for few weeks allowed a detailed view of near-seafloor canyon sedimentary dynamics. Preliminary results suggest that sediment fluxes and organic carbon composition varies with distance down-canyon, distance above the seafloor, and over time. The new measurements were acquired following an earthquake-triggered canyon-flushing event in 2016 that overall caused significant erosion (up to 50 m in the upper canyon) but locally resulted in a complex pattern of erosion and deposition along the canyon system. Our new near-seafloor data provide detailed information on canyon dynamics following canyon-flushing that reveal the processes of canyon infill between such large events at much shorter time-and smaller space-scales.

3. Marine Mineral Resources Evaluation and Exploration Technology Function Laboratory, Pilot National Laboratory for Marine Science and Technology (Qingdao), Qingdao, Shandong, CHINA
E-mail: yanshijuan@fio.org.cn

Keywords: BIM, GIS, Model, Cobalt-rich crusts

Cobalt-rich crusts contain Mn, Co, Pt, Ni, Pb, Ti, Ce and other elements. The content of cobalt is very high. Co can be used to produce heat-resistant alloys, cemented carbide, anti-corrosion alloys, magnetic alloys, etc. It is a scarce strategic resource and the crusts are located in shallow water, so the development and extraction technology and investment costs are lower than those of deep-sea polymetallic nodules, making it a high-quality seabed mineral resource. The cobalt-rich crusts resource exploration contract signed between China and the International Seabed Authority at Caiwei and Jiaxie Guyots in the Magellan Seamount group has been implemented for eight years, during which a large amount of data such as geological sampling, geophysical survey lines, video survey lines, environmental exploration and related analysis have been acquired. Spatial modelling of various data, realizing full-cycle management of data and establishing digital mining area models are very important aspects of the follow-up work. The ME Seamount, which is adjacent to the crust mineral area, is one of the larger seamounts in the Magellan Seamount chain and is the most heavily investigated apart from the mineral area. BIM (Building Information Modeling) technology is a numerical tool applied to engineering design and construction management, which supports dynamic databases through the integration of informative models of data to be shared and transmitted throughout the life cycle process of planning, operation and maintenance. GIS provides an advanced spatial data management and visualisation environment. Based on BIM and GIS, Revit solid model and ArcScene surface model are produced on the basis of product data like DEM, survey stations, survey line data and resource assessment in ME Seamount. Then these two models are integrated into a geometric parametric model. The surface texture of the terrain is extracted from the DEM and the original image with orientation parameters, and the texture is pasted on the geometric model to build the ME Seamount geometric parametric model. The study shows that BIM+GIS-based data modelling of cobalt-rich crusts can help realise the full-cycle digital management of data collection and management, spatial analysis, resource evaluation and strategy support, etc. The technology can realise 3D visualisation of mine data at a lower cost and higher efficiency, and provide a visualisation tool for optimal mining management.

E-mail: machao@cdut.edu.cn

Keywords: Deep time, Spatial interpolation, Sediment distribution, Scientific Ocean Drilling

Resolving the spatial extension information of a stratigraphic column or borehole is an essential step toward understanding the distribution of sediment and its quantitative spatial-temporal evolution. However, due to the non-intuitiveness, non-parametric and irregular distribution of geological spatial information, some current spatial interpolation techniques have limited applicability in deep time geological research. Here, we systematically review the existing related methods and their applications of modern geographical spatial interpolation, each method has its specific assumptions and features. Based on the geological conditions and principles, we propose a “deep-time” spatial interpolation method, which can bridge the gap between deep-time and modern geological space. Finally, using the spatial interpolation method, we map a deep-time sediment distribution and quantitatively calculate the total amount of sediment based on the data from Scientific Ocean Drilling.

The Relationship Between Paleogeography and Sedimentary of Upper Urho Formation in Junggar Basin

Ruijing Guo[1], Youliang Ji[1*]
1. Geoscience, China University of Petroleum Beijing, Beijing, CHINA
E-mail: jiyouliang@cup.edu.cn

Keywords: Junggar Basin, Upper Urho Formation, Paleogeography, Sedimentary, Ancient Gullies

Recently the exploration of oil and gas in the Junggar Basin has gradually moved from conventional traps outside the source to inside, and has significant achievements. With the deeper exploration, several oil reservoirs have been discovered in Upper Urho Formation, and it turns to be the most important layer to increase production. Actually we found that the distribution of the sedimentary system in this area was obviously controlled by the paleogeomorphology. Based on the determination of the sequence stratigraphic framework of the Upper Urho Formation, we analyzed the data of core, slices, seismics, outcrops and logging datas to establish the paleogeology, and clarified the characteristics of sedimentary.

Results show that: (1)Junggar basin was divided into 8 primary tectonic units and 42 secondary tectonic units. We can see a higher-to-lower characteristics when it goes from north to south. The highest part was the western uplift in the northwestern basin, and the lowest part was the thrust belt in the southern basin. (2)The sedimentary systems in Junggar basin contained steep slope-fan delta in the western and gentle slope-waved fan delta. The basin area was smaller in the first period of Urho Formation, and there displayed fan deltas along the edge of Junggar basin. The second period of Urho Formation was transgression with plenty of sources, therefore more sand bodies were deposited on the edge of the lake, and it was also a fan-delta period. There was a widely transgression in the third of the Urho Formation with less sediments in less main rivers, so only few sand bodies were deposited at the edge and mainly deposition was lacustrine mudstone. (3) The main transport channels of sand in this area were ancient gullies, and we found U-type and V-type ancient gullies here, most gullies were V-type. The gullies mainly distributed in northwest and east of basin, with perpendicular and parallel to the source direction. The characteristics of transportation channels were different between northwest basin and east basin, which leaded to different sedimentary models. In the northwest, we found most gullies were perpendicular to sources, and there was a severely altitude difference. The single thickness of the sand body was lager, and distributed widely, showing a continuous superimposition. In the east, we distinguished three groove systems: Shaqiuhe system, Shaqiu system and Shuangquangou system, and it turned that three lobes: Fubei lobe, Shaqiu lobe and Shuangquan lobe were controlled by three systems mentioned.(4)There's significant effect on sedimentary distribution caused by the paleogeology, different geomorphic pattern in different period and continuous sedimentary of sand body. This formed the situation of sand body largely distributed along ancient gullies. And we summarized the patterns of relationship between paleogeography and sedimentary.

Back-arc basin evolution in collision zones: Sedimentary records of early Permian subduction tectonics in Ailaoshan Orogenic Belt

wei feng[1*]
1. sedimentary, China University of Geosciences, Wuhan, Hubei, CHINA
E-mail: fwvent0319@gmail.com

Keywords: ailaoshan,back-arc basin,Volcanic debris

Ailaoshan tectonic belt is located between Indochina-Simao block and South China block, which belongs to both Gondwana and South China continental tectonic units(Metcalfe, 2002; Metcalfe, 2013b; Zhao et al., 2017; Li et al., 2021) There are many related researches have been carrying out in the Paleotethys ocean closure(Fan et al., 2010; Jian et al.,2009a; Jian et al.,2009b; Xu et al., 2019) and the late collisional orogeny(Cao et al.,2012; Wang et al., 2019; Yu et al., 2020; Zheng et al.,2021), however, the trench-arc-basin evolution occurred in the early days of collision orogenic belt is rarely to be noticed. Meanwhile, Ailaoshan tectonic belt can be divided into three evolutionary stages, which have different tectonic attributes in different geological stages(Wang et al.,2000; Liu et al.,2011). The Ailaoshan ocean basin has been considered as a branch of the Paleotethys ocean and is of great significance to the evolution of the Paleotethys Ocean(Wang et al., 2000;Lai et al.,2012;Pan et al., 2012;Xia et al., 2020). In previous studies, the Ailaoshan ocean basin was believed to have been opened in the Late Paleozoic and closed in the Early Triassic(Li et al., 2013;Xia et al.,2016;Xu et al.,2020). However, by summarizing the research results, it is found that the main research object is arc volcanic rocks around the Ailaoshan tectonic belt(Fan et al.,2010; Liu et al.,2011;Li et al.,2013;Sun et al.,2016; Faure et al.,2016). Through the study of volcanic rocks, a series of discussions and explanations have been carried out on the tectonic attributes, suture positions and closure time of Ailaoshan ocean basin, but the opening time of Ailaoshan ocean basin is still controversial(Liu et al.,2018), the unique tectonic background of "early subduction evolution in collision tectonic belt" of Ailaoshan ocean basin has not been thoroughly discussed.

To test the initial subduction of the Ailaoshan ocean basin, we here report high-precision U-Pb dating and Hf isotope method to carry out the early subduction initiation time of the Ailaoshan Ocean, and the subduction direction by comparing with the detrital zircon age of the same period in the surrounding area, and established the early subduction mode of the ocean basin in the background of collisional orogenic belt.

Sedimentation, Structure, and Reservoir Properties in Prospective Offshore Geologic Carbon Sinks, Gulf of Mexico

Jack Pashin[1*], Justin Spears[1], Joshua Ademilola[1]
1. Boone Pickens School of Geology, Oklahoma State University, Stillwater, Oklahoma, UNITED STATES
E-mail: jack.pashin@okstate.edu

Keywords: Deep water, Gulf of Mexico, turbidite, salt tectonics, reservoir properties

Deep-water deposits in the upper continental slope in the Central Gulf of Mexico include many of the largest oil and gas reservoirs in North America and are potentially vast targets for CO_2-enhanced oil recovery and saline formation storage of CO_2. As part of the SECARB Offshore Partnership program, an assessment of the enhanced oil recovery and saline formation storage resource is underway in the Mississippi Canyon, Green Canyon, Viosca Knoll, and Atwater Valley areas of the central Gulf of Mexico. This region has long been a frontier for the development of deep-water drilling and production technology, and long-range planning is required to develop strategies for the implementation of CO_2-enhanced recovery and storage so that technology is ready to apply as reservoirs mature.

Data from more than 7,200 wells and 74 3D seismic surveys indicate that target reservoir strata are dominated by sandstone ranging in age from Miocene to Pleistocene and are distributed through a section that in places is thicker than 10 km. The region contains a spectrum of salt-tectonic structures, including large allochthonous salt sheets. Sedimentation is dominated by turbidite systems, and an intricate relationship exists between salt movement and sedimentation. Numerous minibasins have subsided between salt bodies, compartmentalizing the turbidite systems; minibasin, subsalt, and suprasalt reservoirs are abundant.

Turbidite sandstone occurs between thick mudstone units that are on the order of 100 m thick. Sandstone thickness is highly variable, and values form a distinct statistical population. These values have a log-normal distribution with a geometric mean of 7 m, and values between 3 and 19 m fall within the standard deviation; the maximum is 220 m. Sandstone thinner than 10 m is typical of mid to outer fan deposits, whereas thicker sand is characteristic of fan channels. Channels are deepest at the margins of the minibasins. Fan deposits thin away from the channels and commonly terminate basinward of the edges of the minibasins. This depositional heterogeneity contributes a component of stratigraphic trapping to what is otherwise a salt-structural regime. Porosity of reservoir sandstone typically ranges from 20-35%, and permeability is generally 100–1,100 mD. Porosity decreases with depth, and values indicate high reservoir quality throughout the section.

Reservoir pressure, temperature, and fluid chemistry vary systematically with depth and are primary considerations for CO_2 enhanced recovery and storage. Reservoir pressure is influenced strongly by active hydrocarbon charge, with normal brine-compensated hydrostatic pressure gradients forming the lower limit, and fracture gradient (19.9 kPa/m) forming the upper limit. Temperature gradient varies greatly and depends strongly on the distribution of thermally conducive salt and poorly conductive mudstone and sand. Brine concentration ranges from normal marine at the seabed to ~350,000 mg/L at depths beyond 20,000 ft. The storage resource is >4 Gt in maturing reservoirs and is terratonne-class in saline formations. Results show that there are many technical challenges, but assessment results indicate that the potential for CO_2-enhanced recovery and storage is vast and a strong driver for technology development and implementation.

Early Pleistocene depositional setting at Dachangliang, Nihewan Basin, NE China

Ahmed H. Moghazi[1*], Hailong Zhao[2], Chengjun Zhang[3], Steffen Mischke[1]
1. Institute of Earth Sciences, University of Iceland, Reykjavík, ICELAND
2. College of History Culture, Hebei Normal University, Shijiazhuang, Hebei, CHINA
3. School of Earth Sciences & Key Laboratory of Mineral Resources in Western China, Lanzhou University, Lanzhou, CHINA
E-mail: aha37@hi.is

Keywords: Quaternary, Asia, Ostracoda, Hominins, Paleolithic

The Nihewan Basin preserves the oldest record of hominin occupation in NE Asia, following the earliest locations outside of Africa. The sedimentology and stratigraphy of the early Pleistocene deposits of the Nihewan Formation, exposed in the northeast of the basin, were not adequately investigated so far. Three sediment sections up to 50-m thick were investigated to reconstruct their depositional conditions. The study included analyses of the lithological characteristics of the outcrops, and of grain size, magnetic susceptibility, and ostracod-assemblage data. The exposed sediments predominantly comprise varicoloured silt-sized materials, partially interbedded with calcareous and fine grained sand layers and minor contributions of clay-sized particles. Different sedimentary units typically have specific, homogenous lithological features. Sedimentary structures within the units include various stratification types such as cross-, horizontal and ripple bedding, and burrows, indicating a dynamic depositional setting. Prominent marker beds of white marl enable a lithostratigraphic correlation with the sediment section at the Majuangou site that contains four artefact layers of known age. Sediment accumulation of the studied sections apparently started ca. 1.7 Ma and lasted until ca. 0.9 Ma. The sediments in all sections reveal four sedimentary cycles which are accompanied by cyclical changes in magnetic susceptibility (MS). In each cycle, the grain size fines upwards, while MS values decrease. The ostracod assemblage represents 13 taxa with *Limnocythere flexa*, *Ilyocypris spp*. and *Heterocypris salina* as the most abundant species. In contrast to slightly darker coarser grained sediments, the white marl layers are dominated by *Cytherissa lacustris* and/or *Leucocythere dorsotuberosa.* The investigated sediments and ostracods suggest that the sediments at Dachangliang were mostly deposited in a wetland and/or alluvial plain setting which was at least two times interrupted by the establishment of a relatively deep lake at ca. 1.3 and 0.9 Ma.

Sediment erodibility in the Yangtze Delta: spatial-temporal distribution and their sedimentary significance

Chaoran Xu[1], Jianjun Jia[1*]

1. State Key Laboratory of Estuarine and Coastal Research, East China Normal University, ShangHai, CHINA

E-mail: jjjia@sklec.ecnu.edu.cn

Keywords: sediment erodibility, Yangtze subaqueous delta, cohesive strength meter, critical shear stress, sediment activity

An accretion-erosion conversion is occurring in the mouth bar area of the Yangtze estuary under the decreasing sediment flux due to the construction of dams and soil conservation, this could threaten the development of the Yangtze subaqueous delta. The sediment erodibility is an important indicator of subaqueous delta vulnerability. In this study, shore cores were collected in the Yangtze subaqueous delta using a box-corer, and the critical shear stress of the sediment was measured using a cohesive strength meter (CSM) and an empirical formula; the activity of the sediment was analyzed by comparing the critical shear stress of the sediment with the bed shear stress simulated using a numerical model (FVCOM), thus discussing the present and future erodibility of the subaqueous delta. We found that the results of the empirical formula relied only on grain size differ significantly from the situ sediment, but the results of CSM that do not correlate with the empirical formula are more consistent with the situ sediment. The annual surface sediment activity ranges from 5% to 30% based on the CSM results indicate that the surface erodibility is not high. Meanwhile, the critical shear stress in this region increases with increasing water depth but the bed shear stress is the opposite, so there is a low probability of continued vertical erosion after surface sediment erosion. Therefore, the erodibility of the Yangtze subaqueous delta is lower than the mouth bar area, indicating no accretion-erosion conversion, and will not experience continuous vertical erosion under sediment starvation in the next decades.

Diagenesis and Porosity Evolution of Tight Sandstone Gas Reservoirs in the Western Sulige Area

Xinxu DONG[1*], Qianghan FENG[2], Qiang PANG[2]

1. Northwest University(China), Department of Geology, Xi' an, Shaanxi Province, CHINA

2. The Third Gas Production Plant of PetroChina Changqing Oilfield Company, The Third Gas Production Plant of PetroChina Changqing Oilfield Company, Xi'an, Shannxi, CHINA

E-mail: 1276479878@qq.com

Keywords: tight sandstone gas, pore evolution, diagenetic facies, western Sulige area

The purpose of this work was to explore the genesis of tight reservoirs and porosity evolution in the western Sulige area, Ordos Basin. Based on laboratory tests including observation of casting thin sections, electron microscope analysis and high pressure mercury injection, a theoretical calculation model was established, by which qualitative and quantitative analyses were made to the pore evolution of the gas reservoirs in the Su 48 area. The analysis results show that the reservoir lithology of He 8 member is mainly quartz sandstone and lithic quartz sandstone. The generation of the reservoirs was mostly in the early and middle diagenesis stage, and some reached the late diagenesis stage. The diagenesis sequence was as follows: compaction - siliceous cementation - chlorite cementation - clay mineral cementation - dissolution- carbonate cementation. The quantitative results show that compaction and cementation were the primary factorsleading to the decrease of reservoir porosity. The original porosity was reduced 22% by compaction and cementation dropped 9.81%, while the reservoir space was enhanced 3.88% by dissolution, finally resulting in todays tight sandstone reservoirs with average porosity 7.47%. Comparison shows that the calculated results are basically consistent with the measurements with relative error less than 3%. According to the action intensity of diagenesis, combined with the analysis of rock characteristics, the diagenetic facies of He 8 member reservoir in the study area can be divided into four types, i. e., weak -medium cementation strong dissolution facies, medium cementation medium dissolution facies, medium dissolution strong cementation facies and strong compaction tight facies Gas tests demonstrate that the gas production in the area of weak -medium cementation and strong dissolution facies is relatively considerable, which can be regarded as the main research area for continuous gas production.

Lithofacies and diagenetic evolution implications for reservoir quality: A case study of the Triassic Chang 6 Member, Ordos Basin, China

Fu Yong[1*]

1. Department of Geology, Northwest University, Xi'an , Shaanxi Province , CHINA

E-mail: fuyong1995@foxmail.com

Keywords: Lacustrine shallow-water delta front sediments, Lithofacies, Diagenetic evolution, Reservoir quality, Carbonate cements;Ordos Basin

The Chang 6 tight sandstone reservoirs of the Upper Triassic Yanchang Formation in the southeastern Ordos Basin develop large lacustrine shallow-water delta front sediments, and its lithofacies and diagenetic evolution history are complex. Based on core observations, this research integrates casting thin sections, scanning electron microscope, cathodoluminescence, backscatter imaging, electron probe and fluorescence thin section observations and quantitative statistics, capillary pressure, porosity and permeability, homogenization temperature of fluid inclusions, **in-situ carbon and oxygen isotope analysis results of carbonate cements**, and other techniques to investigate the lithofacies, the characteristics and distributions of various diagenetic alterations, and their implications for reservoir quality.

Three types of lithofacies are identified in lacustrine shallow-water delta front deposits. Lithofacies I is gray white fine and medium sandstones, developed large-scale parallel bedding. Lithofacies II is gray fine sandstones, developed massive trough cross bedding. Lithofacies III is gray black muddy siltstones or siltstones, developed wavy bedding.

The various lithofacies have different initial petrological components, diagenetic alteration characteristics and reservoir qualities, and differ in oil-charging phase and intensity. The lithofacies I sandstones are arkose, and the sandstones experienced medium mechanical compaction, finite cementation, intensive dissolution and two phases of oil charging with high intensity. The lithofacies II sandstones are arkose and lithic arkose, and the sandstones experienced moderate to extensive mechanical compaction, relatively extensive cementation, relatively moderate dissolution and two phases of oil charging that the intensity is weaker than lithofacies I sandstones. The lithofacies III sandstones are lithic arkose, and the sandstones experienced rapid compaction densification, continuous cementation, limited dissolution and only early small-scale oil charging.

Mechanical compaction is the most significant reason for the decrease in primary porosity. The carbonate cementation and authigenic clay minerals further reduce the reservoir quality. The origin of microcrystalline calcite($\delta^{18}O_{PDB}$: -13.3 ‰~-10.0 ‰; $\delta^{13}C_{PDB}$: 0.4‰~2.1‰) formed in the eogenesis A stage is related to meteoric water in a shallow buried environment. The origin of sparry calcite I ($\delta^{18}O_{PDB}$: -19.8 ‰~-13.4 ‰; $\delta^{13}C_{PDB}$: -0.4‰~0.8‰) formed in the eogenesis A stage, sparry calcite II ($\delta^{18}O_{PDB}$: -21.8 ‰~-18.7 ‰; $\delta^{13}C_{PDB}$: -5.1‰~-0.4‰) formed in the eogenesis B stage, and ankerite ($\delta^{18}O_{PDB}$: -21.5‰~-16.8‰; $\delta^{13}C_{PDB}$: -4.6‰~-3.9‰) formed in the mesogenesis A stage is gradually correlated with the negative carbon fluid released during the thermal decarboxylation of organic matter. When the chlorite cement content in the reservoir is less than 4%, the primary intergranular pores can be effectively protected. Flaky and fibrous illite deteriorate the reservoir quality. The acidic diagenetic environment formed during the two phases oil charging process is the key factor for the dissolution of laumontite and feldspar. Laumontite cements effectively resisted the intensity of compaction in eogenetic stage, and its dissolution pores formed in mesogenetic stage greatly improved the reservoir quality.

Ultimately, combining the relationship between sedimentary facies and lithofacies with the distribution of different diagenetic processes, four evolutionary patterns are identified for reservoir quality in the lacustrine shallow-water delta front.

TOC Prediction Using A Joint Unsupervised and Supervised Deep Learning Approach

Huijun Wang[1*], Shuangfang Lu[1]
1. School of Geosciences,, China University of Petroleum (East China), Qingdao, Shandong, CHINA
E-mail: b19010005@s.upc.edu.cn

Keywords: Sweet-spot Prediction, Unsupervised Learning, Contrastive Learning-Convolutional Neural Network, Unlabeled Data

Abstract: Total organic carbon content (TOC) is important for sweet spot prediction and resource calculation. However, the prediction accuracy of traditional physical methods is low, while machine learning methods only use labeled samples (core TOC samples and well logging data) to predict TOC, leading to their performance reaching a bottleneck. Meanwhile, there is considerable unlabeled data (well logging data) in many oilfields. Therefore, based on this unlabeled data, we proposed a joint unsupervised and supervised learning approach, named Contrastive Learning-Convolutional Neural Network (CL-CNN) to predict TOC. In recent years, CL has been a research hotspot in the field of unsupervised learning, whose principle is to reduce the distance between similar samples and increase the distance between different samples as much as possible in the feature space. CNN is characterized by local connectivity and weight sharing, which has strong generalization ability and high prediction accuracy. CL-CNN model first applies CL to pretrain the initial parameters of CNN model on a large number of unlabeled datasets and then finetunes the resultant CNN model using the labeled data. The framework combines the advantages of CL and CNN to further improve the prediction accuracy and generalization ability. The proposed method was applied to predict the TOC of shale gas in the Sichuan Basin, China, including 121 core samples and 1224 well logging data (121 logging data for supervised learning and 1103 logging data for unsupervised learning) from the JY 10 well. Besides, the CL-CNN model was further verified by JY 10-10 well data. Experimental results demonstrated that the CL-CNN model outperformed many machine learning methods, such as Support Vector Machine (SVM), Gaussian Process Regression (GPR), Random Forest (RF), and CNN model because of its better accuracy (R^2=0.8958, RMSE=0.3353), generalization and low over fitting, which indicates the feasibility and effectiveness of the proposed method. The CL-CNN model can also be used as a general prediction tool for reservoir parameters such as porosity and permeability.

Analyses on characteristics and main controlling factors of the tight sandstone reservoirs in the Southeastern Ordos Basin

Chunlan Yu[1], Nana Mu[1*], Wenhui Huang [1]
1. School of Energy Resources, China University of Geosciences (Beijing), Beijing, CHINA
E-mail: munn@cugb.edu.cn

Keywords: Tight sandstone reservoirsReservoir characteristics, Diagenesis, Ordos basin

With the continuous expansion of oil exploration and development, tight sandstone reservoirs have become the main target reservoirs of oil and gas exploration and development in China [1]. By means of thin section, scanning electron microscopy, X-ray diffraction, taking Shan 1 Member of Lower Permian Shanxi Formation in Yanchang Gas Field, southeastern Ordos Basin as an example, this study comprehensively studied the main controlling factors of tight sandstone reservoirs, which is of great scientific significance to guide the exploration and development of tight sandstone gas in the Upper Paleozoic in southeastern Ordos Basin. Shan 1 Member is mainly composed of medium sandstone and fine sandstone. The clastic mineral composition of sandstones in Shan 1 Member is mainly quartz (76.2%) and lithic (22.9%), with little feldspar (0.89%). The average content of interstitial materials in Shan 1 Member is 11.95%, including hydromica 3.5%, siliceous 2.6%, carbonate 3%, chlorite film 2.18% and kaolinite 0.63%. The sorting of sandstone grains is medium preference, and some reservoir sections are well sorted. The grinding circle is mainly subangular to subcircular. There is a positive correlation between porosity and permeability in most stratified sections in the study area, but there are also high permeability sections in some well-developed fractures or pore-throat connections. Pore types mainly dissolution pore accounted for 63% of the total pore types; secondly intergranular pore is mainly manifested in authigenic clay minerals such as kaolinite, illite and chlorite in crystallization in the process of the formation of the intergranular pores, feldspar and sialic acid and mineral dissolution of kaolinite intercrystal pore, accounts for about 16%; primary pores are hard to retain only a small amount of primary intergranular pore, it accounts for about 9% of the total pore types due to strong compaction; microcracks within the particles were observed under the microscope, including cracks that run through multiple particles and contraction joints of tuffaceous matter. Fractures are usually accompanied by dissolution, that is, after the formation of fractures, they become effective channels for fluid flow, thus causing formation solutions to form crack solution fractures on both sides of fractures, accounting for about 1.9% of the total pore types. The statistical analysis of grain size in this area shows that intergranular pore and face ratio are positively correlated with grain size, intergranular pore and face ratio are positively correlated with quartz content, and negatively correlated with cuttings content, indicating that the higher quartz content, the better porosity and permeability of the reservoir. Currently, the reservoir is in the middle diagenetic stage B. Mechanical compaction, late carbonate cementation and siliceous cementation are the destructive diagenesis, which are the main reasons for low porosity and low permeability of reservoir rocks. Kaolinite intercrystalline pore reservoirs provide important reservoir space and dissolution greatly improves reservoir performance.

Microscopic characteristics and classification evaluation of tight sandstone reservoirs: A case study of Chang 9 oil-bearing layer in Nanliang area, Ordos Basin

Yunfei Wu[1], Chenglin Liu[1*], Nuo Xu[1], Dehao Feng[1]
1. Department of Geosciences, China university of petroleum (Beijing), Beijng, CHINA
E-mail: 3205275149@qq.com

Keywords: Tight sandstone reservoir, Classification evaluation of reservoirs, Fractal theory, Ordos basin

The reservoir's storage capacity and seepage capacity are controlled by the microstructure of tight sandstone. As a result, it is critical to clarify the properties of microscopic reservoirs for oil and gas exploration and development. Taking the Chang 9 in the Nanliang area, Ordos Basin as an example, the microstructural characteristics of tight sandstone reservoirs were identified using nuclear magnetic resonance (NMR), high-pressure hg injection, X-ray diffraction, scanning electron microscope (SEM), and cathode luminescence. Then applying the fractal theory to classify the pore radius of tight sandstone reservoirs into three categories. The results indicate that strong compaction is the reason for the general densification of tight sandstone reservoirs. On the basis of strong compaction, cementation aggravates the densification of the reservoir, while dissolution improves the quality of the reservoir. In tight sandstone reservoirs, not only are there great differences between different reservoirs but also the microstructure within the same reservoir is extremely complex. With the increase of pore radius, the heterogeneity of pores increases gradually, in which macro-pores control the physical properties of the reservoir. According to the macro-porosity, tight sandstone reservoirs are categorized into three types, and the results are consistent with testing for oil. It is concluded that the combination of high-pressure hg injection, nuclear magnetic resonance and fractal theory can quantitatively characterize the microscopic property of tight sandstone reservoirs, and then determine the key factors affecting the quality of the reservoir, providing a reliable basis for the classification and evaluation of tight sandstone reservoirs.

Fluid-Rock Interaction Mechanism and Porosity Evolution of the First Stage of Huangliu Formation Reservoirs in Gas Field D with High-temperature and High-pressure, Yinggehai Basin

Jinlai Huan[1,2*], Zhaoqiang Yang[2], Yuanlin Meng[1], Guosong Chen[1], Yu Wang[2], Yongnian Gan[2]
1. Department of Earth Sciences, Northeast Petroleum University, Daqing, Heilongjiang, CHINA
2. Nanhai West Petroleum Research Institute, CNOOC China Limited, Hainan Branch, Zhanjiang, Guangdong, CHINA
E-mail: huanjl@cnooc.com.cn

Keywords: chemical thermodynamics, hydrodynamics, fluid-rock interaction mechanism, porosity evolution, the first stage of Huangliu Formation

Since the 1990s, many achievements have been made in the study of reservoir fluid-rock interaction in Yinggehai Basin. However, just like the research on other oilfields, most of the methods used in the previous research were traditional geological methods, which mainly focused on the petrological characteristics, diagenetic characteristics and reservoir performance of the reservoir. They were mainly static, and could not quantitatively combine the process of fluid-rock interaction with the evolution process of reservoir pores, which was difficult to meet the needs of oil and gas field exploration. The Gas Field D is a lithologic trap buried in middle and deep layers which developed in the northwest of the central mud diapir structural belt in Yinggehai Basin, north of South China Sea. It is a typical high-temperature and high-pressure gas reservoir. The vertical physical properties of the first member of Huangliu Formation of the target layer change greatly. To further explore the favorable reservoir in this gas reservoir has always been the focus of current work. In addition to sedimentation, high-temperature and high-pressure fluid-rock interaction under deep burial conditions is bound to have a significant impact on the first member of Huangliu Formation and control the distribution of favorable reservoir.

This paper discusses fluid-rock interaction mechanism, diagenesis model and porosity evolution of the first stage of Huangliu Formation reservoirs in Gas Field D with high-temperature and high pressure, Yinggehai Basin based on chemical thermodynamics and hydrodynamics. The results show that the minerals participating in reaction were feldspar, kaolinite, illite smectite mixed layer, illite, quartz and a few carbonate cements of diagenesis stage. Organic acid, high temperature thermal fluid and over-pressure from underlying formation supplied acid fluid environment of high temperature and high pressure for mineral reaction. From syngenetic period to early A stage of diagenesis, the system was open, the temperature of stratum was below 70℃, the illitization of kaolinite and smectite impeled largely unstable plagioclase to dissolve and K-feldspar was preserved; while part of quartz was expanded and carbonate was deposited locally. Correspondingly, the porosity evolution trended to reduce before stabilization. From early B stage to middle A stage of diagenesis, the system was semi-closed, the temperature of stratum was 70140℃, K-feldspar was largely dissolved, which impeled smectite sequentially illitizate, while albite was largely preserved and SiO_2 was deposited. In correspondence, the porosity evolution trended to reduce steadily. From middle B stage of diagenesis, the system was closed, the temperature of stratum was 140℃, kaolinite and K-feldspar reacted directly to form illite with K-feldspar basically consumed out, but kaolinite and illite coexisted with many remains of albite while part of quartz secondary outgrowth shows harbor-shape dissolution. Then, the porosity evolution trended to rejuvenize in part of the curve.

Influences of structure and sedimentation on heterogeneity of fluid flow in sandstones: A case study of outcrops in the northwestern Tarim Basin, China

Dongsheng Cao[1*], Lianbo Zeng[1,2]

1. State Key Laboratory of Petroleum Resource and Prospecting, China University of Petroleum, Beijing, Beijing, CHINA
2. College of Geosciences, China University of Petroleum, Beijing, Beijing, CHINA

E-mail: dawsoncpu@gmail.com

Keywords: Red beds,Bleeding phenomena,Heterogeneity of diagenetic fluid,The Tarim Basin

The heterogeneity of fluid flow affects the migration and enrichment of oil and gas, oil recovery, and the distribution of remaining oil in reservoirs. Due to the reduction of underground fluid, the reddish-brown and red strata change to grayish-white, grayish-green even white, which is called the ‘bleeding phenomena’. Typical ‘red beds’ sedimentation developed in the Silurian and Devonian in the northwestern Tarim Basin. In the outcrops of these strata, the reduction of partial red beds to grayish-green reveals the heterogeneity of reducing fluid flow, which becomes a favorable case for the study of fluid migration controlled by structures (faults or fractures) and sedimentation. It is found that fluid preferentially migrates along lamina and lithologic interfaces in high porosity strata. In the profile of low porosity strata, irregularly distributed single-cell shape accumulation is formed first and then gradually migrates upward. Furthermore, it will be connected to cell aggregate and finally form a layered distribution. The fluid preferentially exists in the sandstone with high porosity and permeability, which is the primary manifestation of the heterogeneity of the interlayer. The wettability of micro-mineral particles also affects the migration of reducing fluid, resulting in the micro-heterogeneity of fluid activity. When there are faults and fractures in the formation, the fluid preferentially flows through the fracture network and mainly flows within a certain distance from fracture walls. According to the quantitative statistics, the scale of fracture and the width of the fluid seepage zone controlled by it are positively correlated. Under the influence of structures and sedimentation, fluid migrates through the fracture network system and porphyritic aggregates under buoyancy. On the plane, fluid migrates through high porosity and permeability sandstones, lamina, and lithologic interfaces. In three dimensions, it migrates in the network composed of the above dominant channels. The study reveals the heterogeneous differential migration mode of fluid and analyses dominant flow channels in the formation, which provides a geological model and parameters for reservoir modeling.

Drawdown of marine sulfate levels at the onset of Marinoan glaciation

Kun Zhao[1], Xianguo Lang[1*], Guangyou Zhu[2], Mingshi Feng[1], Ran He[1], Chengguo Guan[3], Songzhuo Li[1], Shengxian Zhu[1], Chuanming Zhou[3]

E-mail: langxianguo19@cdut.edu.cn

Keywords: the Datangpo Formation, the Nantuo Formation, pyrite sulfur isotope, marine sulfate concentration, snowball Earth

Microbial sulfate reduction plays significant roles in regulating marine organic matter degradation and thus the variation of ancient marine sulfate level is closely coupled with the changes of global organic carbon burials as well as Earth's surface redox evolution in geological time. It is widely assumed that seawater sulfate concentration was extremely low during the Cryogenian Marinoan glaciation (ca. 650–635 Ma) which represents the most extreme icehouse condition in Earth's history. However, such a low seawater sulfate level has not been explicitly confirmed to date. To address this, here we carried out pyrite content and sulfur isotope (δ^{34}Spy) analysis of the Cryogenian non-glacial (the Datangpo Formation) and the Marinoan glacial successions (the Nantuo Formation) in the South China. Both the Datangpo and Nantuo Formation show relatively high values of δ^{34}Spy, ranging from +19.9 ‰ to +32.9 ‰, and low values of pyrite content (mean value=0.72 wt.%). Mineralogical analysis suggests these pyrites are dominated by euhedral crystals with rare occurrence of framboids, indicating an early diagenetic origin, i.e. pyrite formed in sediments with sulfate supplied from seawater. By using a one-dimensional diffusion-advection-reaction (DAR) model, we calculate marine sulfate levels during the transition from non-glacial to glacial period. The modeling results show that the seawater sulfate concentration is < 1 mM during the transition from the Datangpo to the Nantuo Formation, suggesting a shink of marine sulfate reservoir at the onset of Marinoan glaciation. We propose the low marine sulfate concentration was resulted from a decrease in chemical weathering prior to the initiation of the global glaciation. This study provides a quantitative constraint on marine sulfate levels during the snowball Earth event and may shed new light on our understanding of the marine biogeochemical changes during the Neoproterozoic global glaciation.

Centennial climate oscillations control pyrite sulfur isotopes via sedimentation rates-related AOM changes: Evidence from multiple sulfur isotopes of pyrite from East China Sea

Xiaoxiao Yu[1*]

1. State Key Laboratory of Isotope Geochemistry, Guangzhou Institute of Geochemistry, Guangzhou, Guangdong, CHINA
E-mail: yuxiaoxiao@gig.ac.cn

Keywords: pyrite, multiple sulfur isotopes, anaerobic oxidation of methane, sedimentation rate, climate change

Marine authigenic pyrite and its sulfur isotope plays a critical role in tracing remarkable Earth's surface environment changes. Determining the mechanism of large variations of pyrite sulfur isotopes in young sediments can help to recognize the fractionation effects of pyrite and understand how to use it in reconstructing of Earth's surface redox conditions. We studied the multiple sulfur isotopic compositions of the pyrite in chronological Holocene sediments from East China Sea inner shelf which show 34S in high (2.09 cm/yr) and medium sedimentation rate (1-1.32 cm/yr) layers are ~40‰ and ~25‰ heavier than that of low sedimentation rate (<0.5 cm/yr) layers. Mass-balance modelling and previous reported multiple sulfur isotopes of pyrite show our 34S-enriched pyrite was over grew by AOM-SR pyrite to OSR pyrite. The AOM-SR pyrite overgrowth is only found in medium and high sedimentation rate layers, we suggest the enhanced of AOM activity is controlled by sedimentation rate. Comparing with Holocene climate record, we found the sedimentation rate is controlled by East Asian Summer Monsoon through river sediment discharge and longshore current. Taken together, the multiple sulfur isotopic compositions of pyrite indicate climate changes via sedimentation rate-related AOM.

Analysis of seismic configuration based on "source sink" system -- Taking Paleogene of Panyu 4 depression in Pearl River Mouth Basin as an example

hao Liu[1*]

1. Research and development department, ROCKSTAR PETROLEUM SCIENCE TECHNOLOGY LIMTED, Beijing, CHINA
E-mail: liuh@chinarockstar.com

Keywords: Seismic configuration, Wheeler domain transformation, Configuration attribute, Three dimensional lithofacies interpretation

In the practice of oil and gas exploration and development in the middle and later stage, aiming at the sea area data with complex continental sedimentation, few wells and low resolution of seismic data, the seismic configuration interpretation technology can effectively identify the distribution, style and superposition relationship of different levels of sedimentary configuration units in the sedimentary paleoenvironment. Taking the Paleogene Wenchang Formation of No. 4 depression in Panyu as an example, based on the analysis of the dynamic sedimentary process of the "source sink" system unit, using the prestack high-resolution seismic processing data, under the constraints of the high-frequency sequence stratigraphic framework, combined with the geological background and well data, the class III "source sink" system of steep slope, gentle slope and long axis type and the corresponding relationship between different seismic lithofacies and seismic configuration under it are established, using Wheeler domain transformation, approximate paleogeomorphic restoration The techniques of configuration attribute and three-dimensional lithofacies body interpretation have carried out fine seismic configuration interpretation for the third member of Wenchang Formation in Panyu 4 WA, Pearl River Mouth Basin, and then qualitatively and semi quantitatively described and described the spatial distribution characteristics, spatial configuration relationship and distribution mode of various sedimentary units under different convergence units.

E-mail: liujs_613@163.com

Keywords: Zhuangxi area, Palaeogeomorphology, Seismic sedimentology, Fan delta, Characterization

Zhuangxi area is located in the northeast of Zhanhua Sag and the north of Gubei Sag of Jiyang depression, which is a negative structural unit of Zhanhua Sag. Exploration shows that the area has a favorable prospect for oil and gas exploration and development. The second member of the Shahejie Formation in the study area is characterized by large burial depth, thin stratigraphy, and rapid changes in sedimentary facies, which restrict the understanding of oil and gas distribution. Based on the theory of sequence stratigraphy and in combination with the INPEFA technique, the second member of the Shahejie Formation in the study area is divided into two sand groups and six sub-layers. The provenance direction is determined by the sandstone percent content statistics, seismic attribute analysis, and paleomorphologic restoration. With a comprehensive utilization of core, logging and 3D seismic data, constrained by the isochronous stratigraphic framework, the seismic sedimentological characterization of six sub-layers in the second member of the Shahejie Formation was carried out using techniques such as seismic stratal slicing, phase conversion, frequency decomposion, and multi-attribute RGB fusion which are guided by seismic sedimentology theory. Research shows that: (1)The provenance of the second member of the Shahejie Formation is mainly from the Changdi buried hill in the east of the study area. (2)Under the control of geomorphology characterized by interphased groove and beams in near-source area, a continuous distribution of fan delta front deposition zone is developed in the second member of the Shahejie Formation along the Changdi Fault. (3)During the sedimentary period of the second member of the Shahejie Formation, the study area experienced the process from the initial fault-subsidence period to the strong fault-subsidence period. Fan delta develops in an inherited way, showing the characteristics of multi-phase progression. Practice indicates that the fine characterization of fan delta sedimentary facies belt can be realized by seismic sedimentology, which is of great significance to clarify the distribution of favorable facies belt and the evolution characteristics of sedimentary system.

Subtle reservoirs and implications for hydrocarbon exploration in terrestrial lacustrine fan delta deposits: Insights from the Triassic Baikouquan Formation, Mahu Sag, Junggar Basin, Western China.

Zhichao Yu[1], ZHIZHANG WANG[1*]
1. College of Geoscience, China University of Petroleum Beijing, Beijing, CHINA
E-mail: wang_zhizhang@126.com

Keywords: Keywords: lacustrine fan delta,sequence stratigraphy, sedimentary evolution, subtle reservoir, hydrocarbon reservoir models.

Large-scale lacustrine fan delta reservoirs containing mixed oil in the Baikouquan Formation (MA131 block, Junggar Basin) have abundant petroleum reserves. However, the reservoirs are subtle and it is challenging to identify such reservoirs in lacustrine foreland basins. High-resolution sequence stratigraphy, the sedimentary setting, and reservoir models are established by integration of wireline log data, cores, thin sections, and seismic data. A fifth-order sequence stratigraphic framework for the Baikouquan Formation is formed, which enables reconstruction of the sedimentary setting and further detailing of the reservoir model, such that the correlation to multistage progradation and retrogradation of the fan delta complex is possible. By core observation, eight microfacies are identified, among which sandy debris flows and distributary channels dominate approximately 80% of the depositional system. Stratal slices enable determining the northern Xiazijie and eastern Madong fan delta systems. The northern Xiazijie fan delta is widely distributed throughout sequences SSQ1–SSQ6, whereas the Xiazijie fan delta underwent, in general, gradual retrogradation during the formation of sequences SSQ6 and SSQ7. The eastern Madong gravity flow fan delta system only developed during the formation of sequences SSQ1–SSQ5 at the location of an abrupt slope break. There are nine categories of reservoir models in the area according to source rocks, faults, and reservoirs. Both geomorphology and climate played a significant role in controlling the sedimentary infill. Deep faults and an unconformity between the Permian and the Triassic of the Mahu Sag played a decisive role in controlling the hydrocarbon migration pathways. The faults, source rock, and microfacies jointly exert a significant control on hydrocarbon accumulation. Within the nearshore fan delta front, variable reservoir quality can be observed; Crucial factors in improving reservoir quality are fine grain size and relatively low clay content. This work may serve as a guide on subtle reservoir characterization in other basins.

Geoarchaeological investigation of occupation deposits at the Upper Paleolithic Fodongdi cave site, Southwest China: Sedimentary process, paleoclimate change, site formation process and past human activities in the Late Pleistocene

Yu-Xiu Zhang[1*], Jin-Xu Wu[1]

1. College of Earth and Planetary Sciences, University of Chinese Academy of Sciences, Beijing, CHINA

E-mail: zhangyuxiou@ucas.edu.cn

Keywords: Fodongdi cave site, Geoarchaeology, Micromorphology, Sedimentary process, Site formation process, Past human activities

The Fodongdi cave site which formed in the Permian carbonate of Baoshan-Shanbang terrane, is located in the northwest wall of Nantinghe sinistral strike fault, Yunnan Province, Southwest China. Recent excavations of the Fodongdi cave site have uncovered a ~4.45 m stratigraphic sequence (18,000-11,000 cal. BP, not to the bottom) containing abundant sedimentary features which experienced extensive post-depositional change and archaeological assemblages such as hearth, various tools and biological fossils. The stratigraphic sequence is well defined but complex, including roofspall deposits, aeolian deposits, alluvial deposits, chemical deposits, biological deposits, and anthropogenic deposits. Sedimentological and geochronological analyses suggest that sedimentary process varied markedly through time, both laterally and vertically. Through micromorphological and other geoarchaeological analyses of the stratigraphic sequence, especially three occupation phases, we identified the information of sedimentary history, paleoclimate change, the site formation process and past human activities in the Late Pleistocene. This study provides a good practice for micromorphological study of the cave site formation and reveals the distinct diachronic trends in the frequency of visits and the modes of occupation in Upper Paleolithic South China.

This research was financially supported by the National Natural Science Foundation of China (grants 41472209 and 40802048), and the University of Chinese Academy of Sciences.

E-mail: michael.strasser@uibk.ac.at

Keywords: IODP, Deep-Sea, Japan Trench, Paleoseismology, Event Stratigraphy, Hadal Zone,

Hadal oceanic trenches - formed by the downward-bending of oceanic crust in plate subduction zones – are the deepest places on our planet and arguable one of Earth´s most challenging environments for sedimentological research. They act as terminal sinks for sedimentary mass and carbon, and form high-resolution archives to unravel the history of subduction zone processes, including the world's largest earthquakes that occur in such subduction plate boundary systems, and to investigate the deep-ocean elemental cycles.

International Ocean Discovery Program (IODP) Expedition 386, Japan Trench Paleoseismology was designed as a Mission Specific Platform Expedition, and, for the first time within IODP, to use Giant Piston Coring (GPC) technology to recover subsurface samples. In 2021, we successfully collected 29 GPCs at 15 sites (1 to 3 holes each; total core recovery 831 meters), recovering 20 to 40-meter-long, continuous, upper Pleistocene to Holocene stratigraphic successions of 11 individual trench-fill basins along an axis-parallel transect from 36°N – 40.4°N, at water depths between 7445-8023 m below sea level. These offshore expedition achievements revealed the first ever high-temporal and high spatial resolution investigation and sampling of a hadal oceanic trench.

The cores are currently being examined by multimethod applications to characterize and date hadal trench sediments and extreme event deposits, for which the detailed sedimentological, physical and (bio-)geochemical features, stratigraphic expressions and spatiotemporal distribution will be analyzed for proxy evidences of giant earthquakes and (bio-)geochemical cycling in deep sea sediments. Initial preliminary results presented in this ISC presentation show event-stratigraphic successions comprising several 10s of potentially giant-earthquake related event beds, revealing a fascinating record that will unravel the earthquake history of the different along-strike segments. Post-Expedition research projects further analyzing these initial IODP data sets will (i) enable statistically robust assessment of the recurrence patterns of giant earthquakes, while advancing our understanding of earthquake-induced geohazards along subduction zones and (ii) provide new constraints on sediment and carbon fluxes of event-triggered sediment mobilization to a deep-sea trench and its influence on the hadal environments.

Distribution and evolution of sedimentary facies in Zhujiang Formation

shiwei xia[1*]
1. Resource Academy, China University of GeosciencesWuhan, Wuhan, Hubei Province, CHINA
E-mail: 1227119799@qq.com

Keywords: Zhusan depression,Zhujiang Formation,drilling,logging,sedimentary facies

As one of the main battlefields of oil and gas exploration in the northern continental margin of the South China Sea, and there are large potentials of oil and gas exploration in the Zhu III depression, the Pearl River Mouth Basin. The sandstone section in the Zhujiang Formation is the main reservoir of oil and gas in the fault depression transition stage. In order to have a good knowledege of the distribution of high-quality sandstone reservoirs in the Zhujiang Formation, this study comprehensively analyzes the sedimentary distribution and evolution of the Zhujiang formation by using drilling, logging and seismic data in Wenchang sag. From bottom to top, there are two segments in the Zhujiang formation, the first member of Zhujiang Formation which can also be divided into two sub-facies and the second member of Zhujiang Formation; The sedimentation of the second member of Zhujiang Formation is characterized by the influence of tide. Tidal flat sedimentary facies mainly composed of uniform massive fine sandstone mudstone are developed at the bottom, and the sand rich sedimentation continued to advance into Wenchang sag; The continuous influence of tide made sand content increase obviously with the decrease of buried depth. The lithology gradually changes into pebbly sandstone and locally containing medium sandstone and mudstone, which entirely belonging to the sedimentary environment of sand flat sub-facies of tidal flat facies; In the lower sub member of the first member of the Zhujiang Formation, the rise of sea level made most of the study area in an underwater sedimentary environment. The grain size of the sediments formed at this stage is finer than that of the fan delta. The underwater distributary channel sand is dominated by medium sandstone and developed small cross bedding. Medium fine sandstone with parallel bedding and cross bedding predominated in river mouth bar deposits; Due to the continuous rise of sea level, the lithology of the upper sub-member of the first member of the Pearl River formation is characterized by deep-water fine-grained sedimentation, the sandbar deposits and neritic mud sedimentation is dominant; The lithologic traps formed by offshore sandbar deposits, which are widely developed in these fine-grained sediments, are the main objects of oil and gas exploration in the next step.

Keywords: Carbon cycling, sea-level change, paleo-drainage system, Pliocene-Pleistocene, Maritime Continent, Sunda Shelf

The Earth has been cooling over the past 5 million years, leading to the development of Northern Hemisphere ice sheets and the followed frequent occurrence of alternating interglacial and glacial stages. Many hypotheses have been proposed to explain this cooling trend, but with no consensus. The emergence of the low-latitude Maritime Continent has been proposed to be a driver for such climate change during the Pliocene-Pleistocene epochs. To test this scientific hypothesis, we have proposed to drill in tectonically stable sedimentary basins on the tropic Sunda Shelf, the western part of the Maritime Continent, to reconstruct Pliocene-Pleistocene sea-level change, drainage system development, and carbon cycling.

The Sunda Shelf provides particularly well-suited conditions for comprehensive high-resolution studies to reconstruct major geomorphic changes on the Maritime Continent and to assess associated interactions with the global climate. As the largest tropical shelf in the world, the Sunda Shelf was completely exposed during sea-level lowstand periods, allowing the development of large paleo-drainage systems and widespread rainforests and marine vegetations. Sampling the paleo-river systems to determine their age and sedimentary environment will allow to reconstruct the eustatic sea-level fluctuations and the development of major drainage systems. The Sunda Shelf and adjacent land regions were covered by rainforests and marine vegetations during sea-level lowstand periods. The retrieved sedimentary sequences will be used to evaluate the contribution of the glacial exposure of this major tropical shelf region functioning as an enormous CO_2 sink and carbon sequestration.

Sedimentary and geochemical records of northwestern Australia during the Mid-Pleistocene and their implications for paleoenvironment

Jian Xu[1*], Jianghua Qiao[1], Peng Zhang[1], Sarim Muhammad[1]
1. State Key Laboratory of Continental Dynamics, Department of Geology, Northwest University, Xi'an, Shaanxi, CHINA
E-mail: jx08@live.cn

Keywords: clay mineral, grain size, sediment source, Mid-Pleistocene Transition, Australian paleo-monsoon

Based on the analyses of clay mineral X-ray diffraction (XRD) and grain size test of sediment core form Site U1483 (13°05.24′S, 121°48.25′E, water depth 1,733 m) that was drilled offshore northwestern Australia during International Ocean Discovery Program (IODP) Expedition 363, evolution characteristics and dynamic environment characteristics of sediments in the Timor Sea area during the Mid-Pleistocene (1600ka~800ka) are reconstructed, and the transport process and dynamic mechanism of continental sediments into the sea on orbital scale are discussed.

The content of clay minerals shows obvious glacial-interglacial cycles. Smectite is the main clay mineral (30~70%, with an average value of 52%), and the content increases during glacial periods; while the contents of kaolinite (14~35%, with an average value of 23%), illite (11~29%, with an average value of 18%) and chlorite (2~16%, with an average value of 7%) show a similar pattern, which shares a mirror relationship with the change of smectite content, i.e. the content in glacial period is lower than that in interglacial period.

The grain size data shows that the sedimental particles are mainly silt and clay, with an average mean grain size of ~9.1μm, and the main distribution range is 4.8~17.6μm. The time series of grain size shows a glacial-interglacial cycle, which is related to the change of sea level. It is worth noting that the grain size has fluctuated severely and decreased during the Mid-Pleistocene Transition, which reflects that the hydrodynamic conditions variations at this period, indicating the fluctuating sedimentary environment as well, which provides an evidence for the environmental variations before the Mid-Pleistocene Transition.

By comparing with the potential source area, it is considered that the clay minerals dominated by smectite are terrestrial clastic origin, and most of them come from the material input of Fitzroy River and Ord River in the continent of northwestern Australia. During the cold and dry glacial periods, smectite content becomes high due to the strengthened physical erosion, delivered by the river to the sea inlet, and then transported to the shelf area by the southward Leuven current. Spectrum analyses also show that the change of clay mineral assemblage shares strong 100ka and 23ka periods, which is in consistent with the eccentricity (100ka) and precession (23ka) periods. The precession period reflects the intensity of weathering on the northwestern Australia, which is influenced by the power of river runoff that controlled by the rainfall distribution under the influence of Australian paleo-monsoon. It is inferred that the variations of clay minerals are controlled by sea-level changes and the Australian paleo-monsoon system regulated by orbital parameters.

Effects Between Grain Size and Slope to Speak the Depositional System

Xinghe Yu[1*]
1. Energy School, China University of Geosciences, Beijing, Beijing, CHINA
E-mail: billyu@cugb.edu.cn

Keywords: Terrain slope, detrital material, sand content (N/G), Uni-directional flow, "Mass-slope" coupling,

The three-dimensional distribution characteristics of the clastic depositional system and its genetic mechanism are the core content of establishing a sedimentary model and predicting the distribution of its sand bodies, which is also a critical scientific issue in sedimentology research. Most of the depositional systems from the source area to the catchment area, the topographic slope (height difference) is a normal transition process from steep to gentle, this process (Catastrophism and Gradualism) determines the response of fluid transport energy changes and sediment transport mode, resulting in changes in their flow patterns and deposition processes, resulting in the formation of different depositional systems or different phase zones of the same depositional system. Most of the scholars who have studied the clastic depositional system at home and abroad believe that its planar morphology and profile filling structure are closely related to the slope and slope shape of its deposition as well as the quality of clastic particles, but there is no unified and clear understanding of this quantitative law so far. Based on this point, the topography of the clastic sediment body is classified into three basic slopes: linear, up-convex, and down-concave, from the perspective of sediment dynamics in this paper. Moreover, according to the composition of the proportion of different debris particles, the composition of debris material is divided into five types from coarse to fine: gravel-rich, sand-gravel, sand-rich, sand-mud, and mud-rich. In this way, we analyze the response between clastic particle size and deposition pattern under different topographic slope changes and then reveal the mechanism controlling the sedimentary system's three-dimensional spatial distribution of sand content (N/G) under additional slope shapes/slope drops. The "mass-slope" coupling effect of the clastic sediment is proposed: a large number of flume experiments and field investigations have proved that the sediment formed in the context of linear and concave slopes has a negative geomorphic unit with a positive grain sequence; while the sediment formed in the context of convex slopes forms positive geomorphic units with inverse grain order; topographic features and slope descent mainly control the planar morphology of the sediment, and the rate of change of slope controls its essence, and the grain size is exponentially related to the slope. However, the superposition pattern of debris material under different slope drops is more the result of the mutual coupling of different debris material compositions and topographic slope. This theoretical understanding explains the phenomenon that the natural clastic depositional system is "small and numerous on steep slopes, large and few on gentle slopes, few fan-shaped waterways on steep slopes, and many rivers bend on gentle slopes, gravel on steep slopes, sand on gentle slopes, and more mud on the bay.

Seismic response and distribution of Lianggaoshan shale, Sichuan Basin, China

Hua Bai[1*], Xu Guan[1], YuChao Qiu[1]
1. Exploration and Development Research Institute, CNPC Southwest Oilfeld Company, Chengdu, Sichuan, CHINA
E-mail: baihua1282@163.com

Keywords: Shale oil, Seismic response, Lianggaoshan Formation, Sichuan Basin

Recently, well PA1 achieved a major breakthrough of shale oil in the Lower Jurassic Lianggaoshan Formation in Sichuan Basin, showing the huge exploration prospect of shale oil in the Basin. The exploration of shale oil in the Lianggaoshan Formation is still in its infancy, and systematic research has not been carried out. The distribution of favorable and high-quality shale is unclear, and the favorable exploration zone is uncertain. It is necessary to carry out comprehensive geological-seismic research to guide future shale oil exploration. On the basis of seismic sedimentology research, the seismic response characteristics of shale in Lianggaoshan Formation and its distribution at the basin scale are clarified for the first time. The results show that: (1) the seismic response of the shale-rich section is characterized by strong trough reflection; (2) the Lianggaoshan Formation developed two large-scale lake flooding, and high-quality shale developed in deep lake and semi-deep lake; (3) from lower section to upper section of Lianggaoshan Formation, the lake center migrated from east to northwest; (4) the shale in the lower section is mainly distributed in the central and eastern Sichuan Basin, with a favorable area of 37,000 km^2; the shale in the middle section is mainly distributed in the Guang'an-Longgang area and eastern Sichuan Basin, with a favorable area of 34,000 km^2.

Paleogene giant sand injectites: a case study from the Eastern Russian Platform

Svetlana Zorina[1*], Nadezhda Afanasieva[1], Konstantin Nikashin[1], Nadia Hamada[1], Bulat Gareev[1]
1. Institute of Geology and Petroleum Technologies, Kazan Federal University, Kazan, Tatarstan Republic, RUSSIA
E-mail: svzorina@yandex.ru

Keywords: Sand injectites, Paleogene, Russian Platform

The Paleogene quartz sands and sandstones of the Sosnov formation occurred in the Ulyanovsk-Syzran Volga region of the Eastern Russian Platform have been actively developing for a long time as they are known as a valuable source of industrial minerals, of which glass raw materials are of particular value. Predicting new deposits based on ideas on the coastal-marine origin of the Sosnov sands exhausted possibilities due to the lack of marine bedding in sands and extraordinary variability in their thickness. Thus, the current research aims to consider the Sosnov Formation is formed not in the coastal-marine environment but by injecting of deep-layered sands into the Paleocene opokas and diatomites.

We offer a new origin of the Sosnov formation which is based on the widely occurring geological phenomenon of sand injectites. Those are defined as a result of injection of loose fluidised sands into overlaying strata under the impact of pressure excess (e.g. Hurst et al., 2011).

The sand sill investigated in the Kuchury Quarry (the Ulyanovsk Region, Russia) reveals the considerable (over 33 m) thickness of the Sosnov pure quartz sands and sandstones. Probably, the loose quartz sands of the Bathonian (Middle Jurassic) Lukoyanov formation are supposed to be a source of the injected sand material. Complex of analytical methods is used to compaire both the Sosnov and Lukoyanov sands. It includes the sieve grain size, petrography, mineralogy, XRD, scanning electron microscope, electron microprobe, Raman spectroscopy, ICP-MS and X-ray fluorescence element geochemical analyses of rocks and minerals, U-Pb and Zircon Fission Track dating of detrital zircons, etc. The results obtained make it possible to provide provenance analysis of the Paleogene Sosnov sands (injected sands) and the Bathonian Lukoyanov sands (parent unit), reconstruct the Paleogene paleoenvironments in the Russian Platform (RP), and solve a problem of origin of the Sosnov rocks.

Study of the spatial distribution of the Sosnov sands according to drilling data and geological reports, reveals the sandy sills occur at different stratigraphic levels having the variable thickness (up to 150 m) and dimensions (over 20,000 km^2). Those mentioned can rank the sand body as gigantic injectite (Davies et al., 2006; Hurst et al., 2011; Løseth et al., 2012).

Considering the Sosnov sands intrude the Danian-Thanetian opoka and diatomite succession occuring throughout the study area, the age of sand injectites can be proposed post-Thanetian. Interestingly, it coincides with the Late Paleocene activity of the Main Zhiguli Fault extended sublatitudinally 90 km south of the Kuchurov quarry, which led to the uplift of the southern flank by 350-450 m (Davletshin et al., 2017). This tectonic event most likely triggered the formation of giant injectites in the adjacent territories.

Effect of lamina structure on reservoir quality in fine-grained sedimentary rocks: The Lucaogou Formation in Jimusar Sag, Junggar Basin, China

Xiaojiao Pang[1], Guiwen Wang[1*], Jin Lai[1]
1. Department of Geology, College of Geosciences, China University of Petroleum Beijing, Beijing, CHINA
E-mail: wanggw@cup.edu.cn

Keywords: lamina structure, reservoir quality, well logs, fine-grained sedimentary rocks

Fine-grained sedimentary rocks, as important reservoirs and source rocks for tight and shale oil and gas, have become a research focus. The development of laminae determines the accumulation and production of tight and shale oil and gas in fine-grained rocks. However, due to the limitation of resolution of conventional logs, it is difficult to recognize the features of centimeter-scale laminae. To close this gap, complementary studies including core observation, thin section, X-ray diffraction (XRD), conventional log analysis, and slabs of image logs were conducted to unravel the centimeter-scale laminae. Then the recognition models for laminae were built using well logs. The fine-grained rocks can be divided into laminated rock (thickness of lamina < 0.01 m), layered rock (0.01 m–0.1 m), and massive rock (no layer or layer spacing > 0.1 m) according to the scale of laminae from core observation. Then the laminated rocks can be further divided into binary, ternary, and multiple structure according to the mineral superposition assemblages from thin section observation. The typical mineral components, image logs, and NMR T_2 distributions of various lamina types are unraveled. The core can identify the centimeter to millimeter-scale laminae, and thin section can identify the millimeter scale to micrometer scale laminae, and additionally, they can detect mineral types and their superposition sequence. Conventional logs can identify the meter scale layers, while image logs and related slab images can identify the millimeter to centimeter scale laminae variations. Therefore, the slab of image logs combined with thin sections can identify laminae assemblage characteristics, including the thickness and vertical assemblage of laminae. Therefore the identification and classification of lamina structure of various scales on a single well can be predicted using conventional logs, image logs, slabs combined with thin sections. The layered rocks have better reservoir quality and oil-bearing potential than the massive and laminated rocks. In the laminated rocks, the binary lamina is better than the ternary and multiple layers due to high content of felsic minerals. The results above built the predictable model for multi-scale lamina structure using well logs. The results will provide insights into the lamina structure-controlled reservoir quality and oil mobility, and help sweet spots prediction in fine-grained sedimentary rocks worldwide.

Stratigraphic and sedimentologic review of the alluvial units deposited during the initial stages of development of the Montalbán subbasin (latest Cretaceous, Iberian Basin)

Diego Torromé Sanz[1*], Marcos Aurell Cardona[1]
1. Department of Stratigraphy, University of Zaragoza, Zaragoza, SPAIN
E-mail: dtorrome@gmail.com

Keywords: Cretaceous, Montalbán subbasin, Alluvial system, chronostratigraphy

During the Alpine compression, the rift system that conformed the Iberian basin was inverted, giving rise to the Iberian Ranges and many Cenozoic subbasins in the Northeastern part of the system. One of these Cenozoic subbasins, the Montalbán subbasin, presents more than 50 km in length with a triangle shape geometry that opens to the west. This subbasin forms a syncline structure, with Cenozoic deposits in the nucleus bounded by Mesozoic units from the Utrillas thrust (SSW) and the Montalbán anticline (NNE). The uppermost Cretaceous-Cenozoic units consist of 2 km-thick alluvial deposits varying from conglomerates and sandstones at the margins, decreasing its grain size to central areas of the system where lacustrine limestones appear. This succession was previously divided in 5 tecto-sedimentary units (T1-T5) that were correlated to other nearby subbasins found around the Montlabán anticline.

This study is focused in the Northwestern area of the Montalbán subbasin, adjacent to the Mesozoic flanks of the Montalbán anticline. Before this study, the uppermost Cretaceous units consisted of two lithostratigraphic units: (1) La Cañadilla Fm, Coastal limestones with rudists and foraminifera from the Middle Santonian-Early Campanian and (2) Fortanete Fm, lacustrine carbonates with charophytes, terrestrial gastropods and black pebbles. However, new dinosaur fossil sites recently discovered in the first units previously assigned to the late Paleocene-Eocene (T1-T2), opened the possibility to a general review of the chronostratigraphy of the subbasin. More than 26 new fossil sites have been discovered, of particular interest are the well-preserved caudal vertebra from titanosauridae. Moreover, eggshells, crocodrile? teeth and charophytes also represents the paleontologic potential of the area. In order to stablish the most possible precise chronostratigraphy, a detailed magnetostratigraphy study has been done along the 700 m-thick composite section of the newly defined Allueva Fm.

A detailed analysis of the sedimentology and paleoenvironment of the alluvial system that conforms the Allueva Fm has been developed. Based on 5 stratigraphic logs, dominant lithologies, grain size, sedimentary structures and roundness/sphericity a total of 6 lithofacies have been differentiated. Furthermore, analysis of relations between lithofacies resulted in the differentiation of 5 facies associations, each one representing different sub-environments of the alluvial system. The most proximal associations (FA1, FA2) are dominated by tabular conglomeratic levels with rounded intraclasts and both massive and laminated sandstones, related to the intermediate areas of the alluvial system. Lutite dominate associations (FA3, FA4) with intercalations of thin and isolated levels of conglomerates, sandstones and limestones are interpreted as intermediate-distal flood plains with high decantation of fine-grained lutite and sporadic lakes. Finally, limestone dominated association (FA5) is composed by continuous m-thick levels of limestones with large oncoids (up to 15 cm in diameter), and are related to the most distal areas where big and stable lake systems are stablished. The absence of viscosity fluxes such as debris flow deposits or extremely bad sorted and angulous intraclasts suggests that the study area only represents the intermediate and distal areas of the alluvial system.

Control of Mineral Composition on Reservoir Physical Properties in Deep-buried Clastic Rocks——A Case Study in Surrounding Area of Bozhong Sag

Li Xin Qi[1*], Wang Qing Bin[1], Feng Chong[1], Cui Yuan[1], Li Rui[1]
1. Bohai petroleum research institude, Tianjin branch of China National Offshore Oil Corporation , Tianjin, CHINA
E-mail: lixq16@cnooc.com.cn

Keywords: Bohai Sea, Paleogene, deep clastic rock, mineral composition, reservoir physical properties

Compared with other depressions in Bohai Bay Basin, the exploration degree and commercial success rate of Paleogene deep clastic rocks in Bohai Sea are the lowest. Many deep wells (> 3500 m) in the surrounding area of Bozhong Sag reveal the giant thick clastic reservoirs. Due to the large overall burial depth, the reservoir is obviously densified, only a few wells have high productivity. The differential evolution mechanism of reservoirs is a key issue that restricts exploration. Aiming at the differential evolution mechanism of the reservoir, this paper carried out experiments such as thin slice, scanning electron microscope, x-ray diffraction, compaction and dissolution Simulation. Studies have shown that the differential evolution of the reservoir is significantly affected by the provenance. The parent rock coming from granite, clastic rocks with low miscellaneous base content have good reservoir physical properties. While the clastic rocks with high miscellaneous base content have poor physical properties. If the clastic rock is mixed with some carbonate particles, its reservoir physical properties increase first and then decrease with the increase of carbonate particle content. The clastic rock with small amount of carbonate particles, developed strong dissolution, and good reservoir physical properties.The existence of a large number of carbonate particles will cause strong cementation and tightness in the early stage of the reservoir, and the productivity is still poor after fracturing. Appropriate amount of volcanic cuttings will improve reservoir physical properties. The dissolution of the rhyolite cuttings promote the development of secondary pores. With the content of volcanic materials increases, tuffaceous components will fill inter grain in the form of heterobase, which makes physical properties worse. It can be seen that different provenance systems control different mineral composition combinations, thereby controlling the physical property evolution of reservoirs. Through statistics and fitting calculation of a large number of measured physical properties and X-ray diffraction mineral composition, it is found that the upper limit of impurity content in deep high-quality clastic reservoir is about 13 %. The upper limits of carbonate and volcanic particles are 20 % and 39 %, respectively. On this basis, a reservoir physical property evaluation template of deep clastic rock in surrounding area of Bozhong Sag is established based on mineral composition ratio, which has a good prediction on the physical property of clastic rock reservoir in the area without well and the area with less well.

Eocene mammal tracks in southeastern Tibetan Plateau

Tingyuan Yuan[1,2], Huan Xu[1*], Gaozheng Liu[1], Bihui Zhang[1]
1. Yunnan Key Laboratory of Earth System Science, Yunnan University, Kunming, Yunnan, CHINA
2. School of Ecology and Environmental Science, Yunnan University, Kunming, Yunnan, CHINA
E-mail: xh0816@ynu.edu.cn

Keywords: Southeastern Tibetan Plateau, Eocene, Artiodactyl tracks, Anoplotheriipus zeuctus

The uplift of the Tibetan Plateau has a significant impact on some groups of mammals in the aspects of their origin, radiation and evolution. Compared with intensive studies of Neogene mammals, the research of Paleogene mammals in the Tibetan Plateau is extraordinarily poor due to the scarcity of the Paleogene mammal fossils, which has restrained our recognition of the biota and paleoecology during the early uplift of the Tibetan Plateau. Fortunately, we have recently discovered some mammal tracks from the upper Baoxiangsi Formation of the Jianchuan Basin in southeastern Tibetan Plateau, including six artiodactyl tracks and two carnivore tracks. Previous chronological studies constrained the age of the tracks to the late Eocene. All tracks are preserved in purple red medium to thick-bedded fine-grained sandstones with ripple marks and rain prints, which represents shore lake facies. Based on the morphological analysis, the artiodactyl tracks documented here are referred to as *Anoplotheriipus zeuctus*. Moreover, combined with artiodactyl fossils that had been reported in the Baoxiangsi Formation, artiodactyl tracks are attributed to eoentelodonts. In contrast, mesonychids are the probable trackmaker of carnivore tracks. All mammal tracks reported here not only make up for the scarcity of mammal fossils during the Paleogene in Tibetan Plateau, but also provide new materials to discuss the biodiversity, paleoclimate and paleoenvironment of southeastern Tibetan Plateau during the late Eocene.

Characteristics and origin of chlorite coats in the Oligocene gas sandstone reservoirs of the Upper Huagang Formation, Xihu Depression, East China Sea Shelf Basin

Jianli Lin[1*], Chunmei Dong[1], Binbin Liu[2], Xin Huang[2], Xiaohan Zhao[3]
1. School of Geosciences, China University of Petroleum (East China), Qingdao, Shandong, CHINA
2. Shanghai Branch of CNOOC Ltd, Shanghai Branch of CNOOC Ltd, Shanghai, CHINA

E-mail: diagenesis_lin@163.com

Keywords: Clay coats, Chlorite coats, Crystal nucleation and growth, Braided channel sandstones, Xihu Depression, East China Sea Shelf Basin

Chlorite coats appear extensively in the braided river sandstones in the Xihu Depression on the East China Sea Shelf Basin. The origins of chlorite coats with different morphologies and chemical compositions were studied based on detailed analyses of sedimentary features and sandstone petrography. The present chlorite coats can be identified by two layers. The inner coats are mainly composed of chlorite and illite components transformed from detrital clay precursors. Illite components are generally recognized in the dentations or embayments of detrital grains and have a dense, parallel texture. These components are transformed from smectitic clay precursors and are distributed in both low-energy and high-energy braided channels. The chlorite components display as small, euhedral crystals and pile up to exhibit a chaotic texture, dispersing on detrital grain surfaces or as pore-filling aggregates, and are observed mainly in high-energy braided channels with abundant mud rip-up clasts. These components may originate from the thermally driven recrystallization of Fe-rich clay precursors, which are likely derived from the intense cut-bank erosion of adjacent floodplain mudstones that are more readily enriched in flocculated fluvial Fe oxides and hydroxides. The outer coats occur as well-developed chlorite crystals on the surface of detrital grains or inner coats but differ in their crystal sizes among different types of channels. These coats likely originate from direct precipitation from pore waters. Iron and magnesium are mainly supplied by the alteration and dissolution of volcanic material and smectite illitization within clay matrices or mud rip-up clasts. During the growth of chlorite coats, different types of braided channels significantly control their morphologies and chemical compositions. Transport abrasion and variations in hydrodynamic energy determine the clay precursors, which subsequently control the thickness and completeness of the chlorite coats. Moreover, the crystal sizes of the outer coats vary due to distinct material supply processes in different channels; in this study, two growth models were investigated: 1) The continuous growth model is suitable for a relatively closed diagenetic system with continuous supplementation of iron and magnesium. A sustained and relatively high chlorite supersaturation ensures continuous crystallization for the outer coats to reach large sizes; 2) the intermittent growth model is suitable for a more open diagenetic system that has difficulty maintaining a relatively high supersaturation state for chlorite precipitation, resulting in multiple crystallization processes on one or more layers of the finer chlorite crystals.

Sequence stratigraphic framework and sedimentary evolution of the first member of the Zhujiang Formation, Qionghai uplift, Zhu III Depression, Pearl River Mouth Basin

Taifei Wu[1*]
1. Resource Academy, China University of Geoscience (Wuhan), Wuhan, Hubei Province, CHINA
E-mail: 1240332650@qq.com

Keywords: sequence stratigraphy,sedimentary evolution,Zhujiang Formation,Qionghai uplift,Pearl River Mouth Basin

The zhujiang Formation in Zhu III depression of Pearl River Mouth Basin is widely developed in shallow sea delta sedimentary system. Qionghai uplift is located in the west of Zhu III depression, and its upper shallow sea shelf sand body is an important oil and gas reservoir. This paper makes full use of the core, well-logging and high-resolution 3D seismic data, and the unit is quaternary sequence to study the sedimentary characteristics of shallow sea delta of the first member of Zhujiang Formation in Qionghai uplift area of Zhu-3 depression, and its evolution law and main controlling factors were analyzed. The results show that the first member of Zhujiang Formation in Qionghai uplift area of Zhu IIIdepression can be divided into four quaternary sequences: PS1, PS2, PS3 and PS4.During PS3 and PS4, delta deposits were mainly developed, and fan bodies were NW-SE distributed, with underwater distributary channel, mouth bar and far sand bar. The PS1 and PS2 periods are characterized by the large-scale development of shallow sea sedimentary systems, with tidal sand ridges in the west and offshore sand bars in the east. The sedimentary system and sand body distribution of Qionghai uplift in Zhusan depression are controlled by the dual hydrodynamic action of river and tide. Sandstone and mudstone develop mutually, forming good reservoir and cap assemblage. The deltaic sand body is covered by transgressive mudstone, forming stratigraphic trap, and tidal sand ridge and offshore sand bar are favorable areas for lithologic trap development. In this paper, the study of shallow sea delta depositional system plays a positive geological significance for trap exploration.

New perspectives on Opalinus Clay facies descriptions based on new drill cores in eastern Switzerland

Géraldine Nicole Zimmerli[1*], Bruno Lauper[1], Gaudenz Deplazes[2], David Jaeggi[3], Stephan Wohlwend[4], Anneleen Foubert[1]
1. Department of Geosciences, University of Fribourg, Fribourg, SWITZERLAND

4. Geological Institute, ETH Zurich, Zurich, SWITZERLAND
E-mail: geraldine.zimmerli@unifr.ch

Keywords: Opalinus Clay, radioactive waste disposal, subfacies, depositional model

The Opalinus Clay, an argillaceous to silty claystone formation, is known in Switzerland as being the selected host rock for deep geological disposal of high-, intermediate- and low-level radioactive waste. Since the 1990s, various properties of the Opalinus Clay have been studied within the framework of the Nagra (National Cooperative for the Disposal of Radioactive Waste) deep drilling campaigns and the Mont Terri Project (international research program dedicated to the investigation of claystone). The Opalinus Clay succession was deposited during the Late Toarcian to Early Aalenian in an epicontinental sea covering central Europe.

The Opalinus Clay is relatively homogeneous at formation-scale compared to other Mesozoic formations in northern Switzerland. At higher spatial resolution however, sedimentological variations do occur. Besides m-scale lithofacies variations, high, intra-facies lithological variability occur at dm- to cm-scale. The facies diversity is primary attributed to regional differences in depositional, environmental and diagenetic conditions. In order to harmonize petrographic descriptions in an objective and quantitative way within all fields of research related to the Opalinus Clay, a subfacies classification scheme has been developed ((Lauper et al., 2018, 2021). The subfacies are distinguished by parameters such as texture (grain size, bedding, fabric and colour) and composition (nature and mineralogy of components). The five subfacies types can be further refined by additional attributes and sedimentary characteristics (biogenic, diagenetic, structural).

Subfacies descriptions are crucial to understand the lateral and vertical facies variability at regional scale. Moreover, accurate petrographic descriptions are a crucial prerequisite to many geotechnical studies and the predictive modelling of petrophysical properties.

The main goal of the present study is to define a subfacies classification model covering the entire Opalinus Clay succession of the Mont Terri rock laboratory and successions deposited further to the east where Nagra is currently investigating three potential sites for radioactive waste storage within the Opalinus Clay. Nine new drill cores are used to apply the subfacies classification scheme. The current subfacies classification scheme will be adapted considering regional facies heterogeneities. Based on the revised subfacies classification, facies and intra-facies variability will be captured. This will form the base for the revision of depositional models for the Opalinus Clay using a basin-wide approach.

Evaluation method of gas hydrate and free gas system and its application in Shenhu Area, South China Sea

Tingwei Li[1*]

1. Gas Hydrate Engineering Technology Center, Guangzhou Marine Geological Survey, Guangzhou, Guangdong, CHINA
E-mail: litingwei_@126.com

Keywords: Shenhu area, Gas hydrate, Free gas, Well-to-seismic calibration method

As a new alternative energy source, gas hydrate has attracted wide attention all over the world. Since gas hydrate is always associated with free gas, the evaluation of gas hydrate and free gas system is an important aspect of hydrate reservoir exploration and development. In this study, based on identifying gas hydrate and free gas by well logging, the seismic reflection characteristics of gas hydrate and free gas are determined by accurate well-to-seismic calibration method. On account of seismic reflection characteristics, AVO attributes are used to identify gas hydrate and free gas qualitatively. Using pre-stack and post-stack inversion to get the ratio of P-wave impedance and P-wave-to-S-wave velocities, we determine the three-dimensional space distribution of gas hydrate and free gas, predict their effective porosity and saturation, and eventually achieve the meticulous depiction of gas hydrate and free gas in the body, which is necessary in subsequent estimation of gas hydrate and free gas resources. Results show that according to logging interpretation, gas hydrate of B-well is located in the depth range of 1460 – 1510 mbsl, and free gas is in 1510 – 1542 mbsl. Moreover, gas hydrate of A-well is located in the depth range of 1425 – 1512 mbsl, and no obvious free gas is identified. Gas hydrate is located above free gas and distributed continuously. In plane form, gas hydrate and free gas both present sub-elliptical distribution in NW-SE direction. Gas hydrate has an effective porosity of 0.30 – 0.40, an average saturation of 0.33 – 0.40 and an effective thickness of 3.0 – 10.5 m, whereas free gas possesses an effective porosity of 0.35 – 0.40, a saturation of 0.24 – 0.32 and an effective thickness of 2.0 – 5.0 m.

Combining indicators analysis and chemometrics to trace the geographical origin of crude oil

Tong Li[1*]
1. School of Earth Resources, China University of Geosciences(Wuhan), Wuhan city, Hubei Province, CHINA
E-mail: absinthe@cug.edu.cn

Keywords: Crude oil, Origin traceability, Chemometrics

Geographic traceability is crucial to global oil trade security. This study discusses the possibility of using multivariate statistical methods combined with multi-indicator analysis to identify samples from five major source countries of crude oil imports to China. The physicochemical properties and trace elements of crude oil were detected by Petroleum product standards and inductively coupled plasma atomic emission spectrometry (ICP-AES). Eight indexes (moisture, density, sulfur content, acid value, organochlorine, carbon residual, V, and Ni) were analyzed. Principal component analysis (PCA), hierarchical clustering analysis (HCA), Orthogonal projections to lateen structures- discriminant analysis (OPLS-DA), and other multivariate data analysis methods were used to determine the geographical origin of crude oil samples. Satisfying results have been obtained by using PCA to reduce the dimensions of the indicators of crude oil from different sources. It allows the reduction of 8 variables to 3 principal components and accounts for 80.06% of the total variance. The HCA shows five clusters corresponding to five sources of crude oil. This will help improve the utilization rate of crude oil with different characteristics, improve the quality of crude oil trade, and ensure the high quality of crude oil trade. For the sample set used for modeling, the model's accuracy was 97.19% after OPLS-DA optimization. These results show that multi-index analysis and stoichiometry are practical tools for identifying crude oil origin, filling the technical gap in rapidly identifying crude oil origin.

Method of geological parameters cutoffs of determination based on the single well EUR of tight reservoirs

Yuru Xiao[1*]

1. STrategically % Planning department, Petroleum Exploration and Production Research Institute, SINOPEC, Beijing, China, Beijing , Beijing, CHINA

E-mail: xiaoyr.syky@sinopec.com

Keywords: Heterogeneity,Uncertainty,Single well EURMinimum quantities of EUR, economic limit, cutoffs of geological parameters

Tight oil resources are abundant in China, the amount of recoverable resources is 1.94 billion tons and has become an important replacement field of crude oil production in China. Due to the heterogeneity and uncertainties of reservoirs, fracture, oil-bearing and adaptability of engineering technology, the method using static data of the conventional reservoir to determine the cutoffs of reservoir geological paramerters cannot meet for the needs of the profitable development evaluation of tight reservoirs. Highlighted single well information, the key parameter of the single well EUR affecting economic of tight reservoir was carried out, and combined with the analysis of main control factors of reserve uncertainty. A series of determination methods and process based on the single well EUR for the cutoffs of geological reservoir parameters of tight reservoirs was established. Considering the particularity of tight reservoir, the fracture development degree was added in the study of cutoffs of the geological parameters.Five paramerters, including single well EUR, net pay, effective porosity, initial oil saturation and fracture development degree, were selected for classification and subdivided into six types.By compiling the intersection diagram of single well EUR and net pay, the cutoffs of geological parameters were determined comprehensively by comparing the economic limit and the classification of reservoir geological parameters under the two scenarios. The method was applied to Chang 8 reservoir in Honghe oilfield of Ordos Basin, and its feasibility was verified.The practical application shows that this method can provide effective technical support to screen sweet spots and development deployment optimizing in tight reservoirs.

The control of low sequence faults on reservoir quality and its practical production significance

Qing Song[1], Panke Sun[1*]
1. Faculty of Earth Sciences, China University of Petroleum, Beijing, China, Beijing, Changping District, CHINA
E-mail: sunpk@cup.edu.cn

Keywords: Low sequence secondary fault ,Reservoir quality ,Production significance

Faults are of great significance to the basin and its internal structural evolution, sedimentation and oil and gas reservoir exploration and development. High sequence faults usually control the distribution of sedimentary sand bodies under the influence of regional structural background, which requires additional attention in the early exploration stage. However, with the continuous advancement of oil and gas field development process, low sequence faults are the focus of our attention, including the impact on reservoir quality and residual oil and gas distribution. Based on the data of seismic, drilling and logging, production performance and so on, this paper quantitatively analyzes the differences of reservoir physical properties under different stress segments along the fault strike in the second East Sulige area, and discusses the control effect of the fault on the distribution of remaining oil and gas. The results show that the physical property data of tension torsion section is obviously better than that of compression torsion section, which is considered to be caused by the change of rock composition structure of sand body caused by local tectonic stress and the formation of micro cracks in the sand body of reservoir; However, the fault sealing ability of the tension torsion section is poor, which often can not prevent fluid migration. From the actual drilling situation of well points, it can be seen that more oil and gas reservoirs are distributed in the compression torsion section, and only some dessert reservoirs can form small oil and gas reservoirs; The production dynamic data also show that under the same production measures, the high yield and rapid drop of tension torsion section is not conducive to long-term development. Based on the above understanding, it is considered that the tension torsion section is easier to form the early dessert reservoir section, and the compression torsion section can not be ignored in the process of residual oil development in the later stage.

The application of waveform indicator inversion based on Fisher discriminant reconstruction curve in low permeability reservoir prediction — taking EP-A oilfield as an example

bin xie[1], xun tai liu[1*]

1. School of Geosciences, China University of Petroleum (East China), Qing Dao City, Shan Dong Province, CHINA

E-mail: liutx@upc.edu.cn

Keywords: Waveform indicator inversion,low permeability reservoir,curve reconstruction,The Zhu jiang Formation,Fisher discriminant method

The prediction of low-permeability thin reservoirs has always been a difficult point in oil and gas exploration and development. The Zhu jiang Formation of EP-A Oilfield in Yang jiang Depression is a typical low-permeability thin reservoir. This kind of reservoir has the characteristics of rapid lateral change of sand body, poor continuity, small size of single sand body, low porosity and low permeability. The traditional seismic inversion method has low inversion accuracy for such reservoirs. In order to obtain high-precision inversion results and predict reservoir, seismic waveform indicator inversion method is used. High resolution reservoir prediction is carried out by using lateral variation of seismic waveform instead of variation function and well seismic combination. Firstly, based on the sensitive curve analysis, the elastic parameters and electrical parameters are reconstructed by Fisher discriminant method. The reconstructed curve can better identify conventional sandstone, low permeability sandstone and mudstone; Then, the optimal cutoff frequency is determined according to the main frequency and frequency width of seismic data; Finally, the waveform indicator inversion is carried out by using the reconstructed curve to obtain the inversion results and calculate the thickness of each main layer. The results show that the seismic waveform indication inversion improves the lateral and vertical prediction accuracy of the reservoir. It can successfully predict the sand body boundary and sand body thickness, The results are in line with the sedimentary geological law of the study area and provide a basis for guiding further oil and gas exploration and development.

Origin and source of deep oils in the Dongying depression, Bohai Bay Basin: Insights from geochemical and geological analyses

Xiaoxiao Zhou[1*]
1. Dongxin oil production plant, Shengli oil field, Dongying city, Shandong province, CHINA
E-mail: 1061249534@qq.com

Keywords: Petroleum potential, Biomarkers, Oil-source correlation, Minfeng sag

The origin and source of oils from the Mbr 4 of the Shahejie Fm in the Minfeng sag, Dongying depression, Bohai Bay Basin are researched based on geochemical experiments, including TOC, Rock-Eval pyrolysis, gas chromatography-mass spectrometry (GC-MS) of saturated and aromatic hydrocarbon, the saturated hydrocarbon GC, whole oil GC and diamondoids quantitative analysis. Based on hierarchical cluster analysis of selected biomarker parameters, the crude oils from the Mbr 4 of the Shahejie Fm in the Minfeng sag are identified into 3 groups. According to the biomarker characteristics and depositional environment, the source rocks of the lower sub-member of Mbr 4 of the Shahejie Fm are further divided into the lower and upper part.

Group I oils from the lower sub-member of Mbr 4 of the Shahejie Fm in the Fengshen area are mature and high mature with low-medium thermal cracking degrees. These oils are characterized by low β-carotene/nC25 and C30 4-methylsterane index (4MI), and high oleane index (oleane/C30-Hopane, O/H), C27 diasterane/C27 regular sterane (C27Dia/C27), Regular sterane/17 α Hopane (S/H), and Gammacerane/C30 hopane (G/H), and medium Pr/Ph. This suggests that Group I oils contain important contributions from the mudstones between gypsum salt rocks in the upper part of the lower sub-member of the Mbr 4 of the Shahejie Fm. Group II oils are mature oils from the upper sub-member of the Mbr 4 of the Shahejie Fm in the Yanjia area with high 4MI and Pr/Ph, and low O/H, S/H, C27Dia/C27, and medium β-carotene/nC25 and G/H. These features are similar to the lacustrine mudstones in the upper sub-member of the Mbr 4 of the Shahejie Fm, indicating their genetic correlation. Group III oils from the upper sub-member of the Mbr 4 of the Shahejie Fm in the Yong'an area show the lowest maturity. Typical features of Group III oils include high β-carotene/nC25 and S/H, and the low O/H, Pr/Ph and 4MI, which are different from the source rocks in the Mbr 4 of the Shahejie Fm in the Fengshen area. Literature research suggests the mudstones in the upper sub-member of the Mbr 4 of the Shahejie Fm in the local Yong'an area are potential source rocks for Group III oils.

Characteristics of hydrocarbon accumulation and exploration potential of passive continental margin basins around Indian Ocean

HUO Hong[1*], Liu Yanli[1]

1. Overseas exploration and project evaluation department, SINOPEC Petroleum Exploration and Development Institute, BEIJING, CHINA

E-mail: huohong.syky@sinopec.com

Keywords: Passive continental margin basin, hyfrocarbon accumulation model, exploration potential

In order to enrich the theory of oil and gas accumulation in global passive continental margin basin, the tectonic evolution periods of the passive continental margin basin around the Indian Ocean are divided, and the characteristics of regional hydrocarbon accumulation and enrichment are analyzed. Two hydrocarbon accumulation models in two types of passive continental basin in East Africa are summarized. The models help to point out the exploration direction of frontier exploration basins. The study shows that the passive continental margin basins around Indian Ocean have experienced four tectonic evolution stages, pre-rift craton, rift, transition and drift, forming four sets of sedimentary, pre rift, rift, sag and continental marginal strata. Regional research shows that the long term rift-sag and restricted to semi restricted environment control the high quality source rocks in pre rift and rift stage respectively. Large provenance controls the high quality reservoir distribution of drift stage. Kerogen type and thermal evolution of source rock result in Indian Ocean is dominated by natural gas. The hydrocarbon accumulation models of transformed basin and extensional basin are established. Through the models, the exploration potential of frontier exploration basins in East Africa is definited.

Constraint of interstitial materials on the Paleogene Huangliu Formation reservoirs with low to medium permeability in the Dongfang 13 block, Yinggehai Basin

Xuebao Liu[1], Longwei Qiu[1*], Danish Khan[1], Xin Li[1]
1. China University of Petroleum (East China), School of Geosciences, Qingdao City, Shandong Province, CHINA
E-mail: 690035485@qq.com

Keywords: submarine-fan,low permeability reservoir,calcareous material ,argillaceous material

The submarine-fan reservoirs in Dongfang 13 block of Yinggehai Basin is characterized by medium porosity and low permeability, and the reservoir rock type is mainly feldspathic lithic sandstone. Interstitial materials have an important influence on the development of reservoir physical properties.The earlier understanding shows that sedimentation is one of the main controlling factors of the low permeability eservoirs in the study area, and the influence mechanism of the interstitial materials such as calcareous and argillaceous material on the low permeability reservoirs in dongfang 13 block is more obvious.

Based on thin section petrographic analysis, combined with core, physical property test data, logging interpretation results and seismic attribute slices, the main controlling factors of low permeability reservoir in the study area are studied in detail. The results show that:(1) The reservoir interstitial materials in the study area are mainly composed of calcareous and argillaceous materials. Take a certain depth section of the study formation as an examplethe content of calcareous material and argillaceous materials in the reservoir is 7% and 38% respectively, and the content of calcareous material is mainly iron calcite, which is more than 70%, followed by dolomite and micrite. The argillaceous components are mainly clay and a small amount of felsic clastic grains of corresponding grain size.(2) Calcareous material is distributed unevenly in the form of silty iron calcite, cementing metasomatic particles and affecting the original physical properties of the reservoir.(3) From the perspective of thin section scale, the distribution of illite and chlorite plays a decisive role in reservoir permeability, which is banded along the layer and has poor vertical connectivity. The pore type is mainly cast hole, and the reservoir permeability is generally less than 20mD. If the llite and chlorite is randomly distributed, the overall connectivity of the reservoir is poor,and the permeability is often less than 1mD.

Based on the influence of calcareous material and argillaceous material base on low permeability reservoir, this research work tries to explain their origin and formation mode, which has guiding significance for the future favorable reservoir development.

Sedimentological record of alternate bar in embanked river: case study of the lower reaches of Natori River, northeastern Japan

Takako UTSUGAWA[1*], Hiroshi SHIMAZU[2]
1. Department of Geography, Hosei Univ., Chiyoda-ku, Tokyo, JAPAN
2. Department of Geography, Rissho Univ., Kumagaya, Saitama, JAPAN
E-mail: takako.utsugawa.73@hosei.ac.jp

Keywords: Alternate point bar, Transport-depositional processes, Suspension, Typhoon Hagibis, Natori River

To examine the transport–depositional processes of fluvial clastic sediment in the embanked river, we investigated the sedimentological record based on the eroded outcrop exposing along the high-water level riverbed in the lower reaches of Natori River flowing down in the Sendai Plain, Miyagi Prefecture, northeastern Japan. The sedimentological record observed in embanked river (Utsugawa and Shirai, 2020; Shirai and Utsugawa, 2021) of which the water flow and clastic transportation are restricted has not been reported enough.

The Sendai Plain is an alluvial plain surrounded by the Neogene volcanic rock hill, and the east side of this plain faces the Sendai Bay and the Pacific Ocean (Shimazu, 2016). After the World War II, by construction of the continuous embankments the floodplain was separated from the embanked floodplain (Shimazu and Utsugawa, 2020). Nowadays there are alternate point bars which the elevation from water level are approximately 2 to 5 m. Typhoon Hagibis caused flooding of the river and the flood stage was above approximately 2 m on the high riverbed on October 2019. After that, in the lower reaches of Natori River, the exposed outcrops of high-water level riverbed were surveyed on December 2019 and February 2020.

The sedimentological characteristics were almost similar at the sites as described below; (i) at the bottom, subrounded–rounded gravel layer was covered by silty sand layer. The gravel size is similar to the clast deposited near the current riverbed. (ii) The silty (slightly soiled) very fine–fine sand layer was almost massive due to bioturbation. Man-made materials (e.g., plastic bag, can, glass bottle) were often included. (iii) The surface was capped by sand layer derived from suspension of flooding on October 2019. The thickness was only several to ten centimeters. At the flood, although the large amount of detritus containing wood debris was delivered from upstream, the deposited wood debris was few in number on the surface. It means that the wood debris was caught on the forest developed at the upper side of the point bars.

E-mail: hassane.oubaassine@edu.uca.ma

Keywords: Morocco, Anti-Atlas Belt, Igherm Inlier, Proterozoic, lower Anti-Atlas Supergroup, lithostratigraphy.

In the western part of the Moroccan Anti-Atlas, the lower Anti-Atlas Supergroup contains a sedimentary succession deposited along the northern margin of the West African craton. It is composed of sedimentary units and associated, mafic intrusive and extrusive rocks. Similarly, it is developed in the Igherm inlier where the Ourty Series includes pelite-carbonate and thick quartzite sequences, and mafic intrusive rocks. Based on sedimentological and lithostratigraphic studies, we have subdivided the Ourty Series into several units with the total thickness ranging between 2 to 3 km. Lithostratigraphic correlation of the sections in separate parts of the Ighrem Inlier and correlation with the lower Anti-Atlas Supergroup in the Anti-Atlas Inliers identified from the base to the top the following, five higher-rank units. 1) The ca. 2030-1706 Ma Tasserda-Taghatine Group of the Tagadirt Igzouln area that corresponds to interbedded coarse quartzites, shales, sandstones, and limestones cut by dolerite sills. This unit was deposited in fluvial to shoreface sedimentary environments. 2) the ca. 1745-1650 Ma Oumoula (Mimount) Formation of the Labaste-Taghout area that consists of quartzites and pelites also cut by a set of doleritic sills; the sedimentary structures indicate fluvial to littoral, backshore, depositional environments. 3) The ca. 1650 Ma to >883 Ma Tizi n'Taghatine Group, recognized in the Tizi N'Tilin area, is composed of limestones alternating with mud-rich horizons grading to shales interlayered with quartz sandstones. It was deposited in shoreface to offshore depositional environments. 4) The ca. 883 Ma Tachdamt Formation consists of mafic volcanic rocks exposed in the Ourti Boyarf area. 5) The ca. 700 Ma Bleida Formation, developed in the Tizgui N'Oufla-Assaka area, consists of shales and quartz sandstones interbedded with aleurolites of laminated, volcanic layers and limestones alternating with shaly horizons. The facies analysis of the latter unit indicates shoreface to offshore depositional environments. The compilation of published and our own field data have led to a revised lithostratigraphy for the lower Anti-Atlas Supergroup in the Ighrem Inlier.

Influence of inherited paleorelief (palimpsests) during the late Permian marine transgression on distribution of evaporitic sediments - an example from SW Poland

Tomasz Selerowicz[1,2*], Jurand Wojewoda[2]
1. Department of Geology, KGHM CUPRUM Sp. z.o.o. – R&D Centre, Wroclaw, Lower Silesia, POLAND
2. Faculty of Earth Sciences and Environmental Management, University of Wroclaw, Wroclaw, Lower Silesia, POLAND
E-mail: tomaszselerowicz@gmail.com

Keywords: Zechstein, evaporates, carbonates, sediment distribution, differential compaction

Basing on over 500 boreholes the maps of the top-surfaces of several sedimentary/stratigraphic units were created - lower Permian sandstone, upper Permian (Zechstein): dolomite (Ca1), anhydrites (lower and upper), salt (Na1). Then, for 218 of boreholes, located within or in vicinity of the copper mines area, in which the above mentioned sedimentary units were recognized, an agglomerative hierarchical clustering was performed based on one minus the Pearson correlation coefficient, using different methods. The Pearson correlation coefficient was calculated for the groups obtained. In case of Ca1 and lower anhydrite, additional maps of thicknesses were created due to the additional information from hundreds of shorter boreholes made from mine drifts.

The Zechstein Sea overflooded the area of aeolian accumulation. Due to the water invasion onto the palaeorelief of ancient dunes, less-more parallel seifs, the oversaturated sandy material was partly fluidized and replaced down the dune slopes, what significantly reduced their primary highs. Nevertheless, the reworked topography continued to be an important factor influencing distribution of early transgressive marine sediments, e.g. between flooded dune crests, on the interdune areas, a significantly higher amount of fine grained mud was deposited what is documented by its larger thickness. Later deposited carbonates of the Ca1 horizon had been formed as rigid plate which covered still uncompacted muds. Those pre-lithification deformation is documented by occurrence of numerous intrusive sand dikes which cut the both horizons and are variously deformed due to later differential compaction.

An analysis of the Ca1 thickness variation map identify a fragment of the east-west oriented carbonate platform, a structure recognizable regionally within the Zechstein Basin. Along the edge of this carbonate platform, a barrier developed with thickness above 100 m. High resolution map present at least partly, the correlation of Ca1 horizon thickness with recognized sandstone elevation. Northwards from the barrier edge, the top surface of carbonate unit successively slopes down what reduces the thickness to c.a. 15 m on a distance of few km. Further northwards thickness is reduced slowly to few meters. Further, due to water depth decreasing, sulfate sedimentation began. On the carbonate platform top surface the sulfates thicknesses vary between few and c.a. 40 m. On the barrier's slope of Ca1 a sulfate platform developed with regular thicknesses c.a. 60-80 m. On the high resolution map of the lower A1 thicknesses, correlation between growing values of anhydrite thicknesses and sandstone elevations positions is observed. That may suggest the presence of (slight?) palaeo-relief undulations, which may have been influenced the distribution of the sulphates during its deposition. Correlation is observed in the zones with relatively low Ca1 thicknesses. That might suggest it was probably a result of syndepositional mud compaction. In the region where the salt is now present, a negative correlation with the lower anhydrite is observed, probably as chlorides were deposited in salt pans surrounded by elevations built of sulphates. In general, the thickness of the evaporites increases towards the depocenter of the Zechstein Sea Basin. A part of the visual observations are supported by statistical correlations.
